## Abstract

In Parkinson's disease (PD), intracellular neuronal inclusions containing amyloid-like aggregates of the protein  $\alpha$ -synuclein ( $\alpha$ S) are deposited in the pigmented nuclei of the brainstem. The mechanisms underlying the structural transition of innocuous, presumably natively unfolded  $\alpha$ S to oligomeric neurotoxic forms of the protein are largely unknown.

The major aim of this thesis has been the characterization of the ensemble of conformers that  $\alpha$ S populates in its monomeric native state and the early transitions that lead to protein oligomerization, by the use of nuclear magnetic resonance (NMR) spectroscopy. The conformational flexibility inherent to this kind of proteins places them beyond the reach of classical structural biology, and a special set of NMR-based experiments had to be implemented in order to study the native soluble state of  $\alpha$ S, namely paramagnetic relaxation enhancement (PRE) from nitroxide spin labels and residual dipolar couplings (RDCs).

Our results show evidence that monomeric  $\alpha$ S assumes conformations that are stabilized by long-range interactions and act to inhibit aggregation. As probed by RDCs, these auto-inhibitory conformations are formed on a ns to  $\mu$ s timescale that is precisely that in which secondary structure elements form during folding. In addition, PRE-derived distance restraints have been employed to derive a low resolution model for the ensemble of structures of  $\alpha$ S compatible with the experimental findings.

The conformations populated by  $\alpha$ S under disease-state circumstances were further investigated. Missense mutations linked to early onset PD, and environmental conditions that promote  $\alpha$ S aggregation were found to release the inherent tertiary structure of the protein. Thus mutant or ligand bound  $\alpha$ S overcomes more easily the energetic barrier for self-association, leading to an increased tendency to oligomerize.

The homologous protein  $\beta$ S, which is proposed to inhibit the toxicity of  $\alpha$ S, has been also characterized by means of high resolution NMR. It was found that the conformations populated by this protein do not account for long range interactions as  $\alpha$ S does, but a higher degree of residual structure is attained, likely polyproline II extended conformations.

Finally, the binding of divalent transition metal cations to  $\alpha$ S was studied by a set of spectroscopic techniques. It was found that among several transition metals, Cu(II) is strongly bound by the N-terminus of the protein with an affinity of  $\sim 100$  nM, and the complex is more prone to aggregate than the free protein. Other metals as Fe(II), Mn (II), Ni(II) and Co(II) do not influence protein aggregation since they bind to the C-terminus of the protein

with  $10^4$  lower affinities. Our results suggest that impairment of Cu(II) homeostasis links the three major amyloid neurodegenerative disorders Alzheimer's, Prion and Parkinson's disease.

From the therapeutic point of view, it is foreseen that the reinforcement of these native, auto-inhibitory, long-range interactions in  $\alpha$ S may be a (the) key target of new pharmacological agents designed to impede or even reverse aggregate formation in Parkinson's disease. Conformationally altered  $\alpha$ S may also constitute a general molecular mechanism underlying the induction of PD by both environmental and genetic conditions. Thus, agents specifically designed to stabilize the native state of  $\alpha$ S may also prove useful in impeding or reversing its pathologic aggregation in familial forms of PD.

UCH-L1	Ubiquitin Carboxy-Terminal Hydrolase-L1
UPS	Ubiquitin-proteasomal system
wt	Wild type

## *Introduction*

---

## 1. Introduction

### 1.1. Protein folding

Organisms have evolved such as the native states of proteins are required to perform diverse biochemical functions, ranging from mere pillars of the overall cellular architecture, like actins and tubulin, up to exquisitely complex molecular machines, as the DNA and RNA polymerases. In all cases adopting a proper structure is essential if the proteins are to carry out their biological function. Failing to do so has often critical consequences for cellular homeostasis (Dobson, 2003).

The mechanism by which a polypeptide chain attains its unique native three dimensional structure is known as protein folding. Inside a cell proteins fold during, or immediately after, their synthesis in response to the crowding nature of the media and the concerted action of chaperones (Young et al., 2004). Nevertheless the fold of a protein appears to be solely encoded in the primary amino acid sequence, inasmuch as polypeptide chains fold *in vitro* in the absence of any auxiliary factors (Anfinsen, 1973; Dobson and Karplus, 1999). Indeed, the self assembly capability of proteins has allowed the occurrence of the early biologically-driven chemical processes, and the stability of such catalytically-competent polypeptide-based systems is believed to have been crucial for evolution to have taken place.

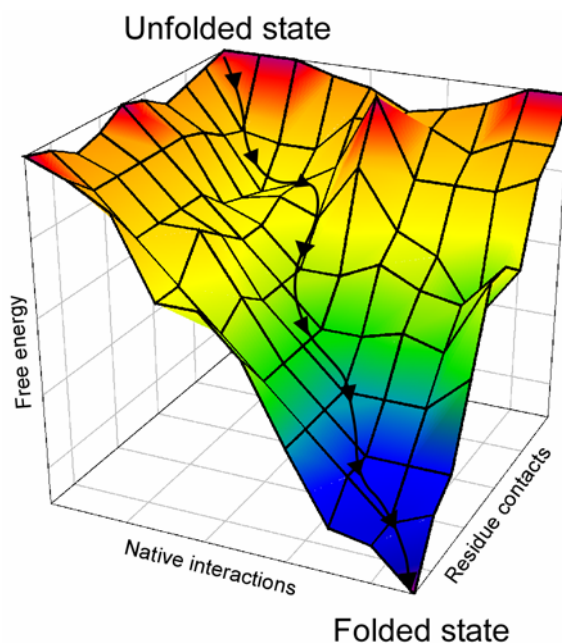

#### 1.1.1. The energy landscape of protein folding

An unbiased search for the most stable structure of a protein would demand the population of all possible conformations that the polypeptide chain could adopt, until the state with the lowest energy is attained. As the average size of naturally occurring proteins is about 300 amino acids, it would take an astronomical amount of time for a polypeptide to fold via a random search of the conformations (Fersht, 1999). However, most proteins fold in the order of  $\mu\text{s}$  to  $\text{ms}$ , suggesting a preferential population of conformational states, as already proposed by Levinthal in the late '60s (Dill and Chan, 1997).

Several models have emerged to explain the existence of folding pathways, from the framework model according to which secondary structure forms locally followed by collision of the folded segments, to the nucleation model in which folding is initiated locally and propagated through the chain. A third model, the hydrophobic collapse model, hypothesizes that the polypeptide would collapse rapidly around its hydrophobic side chains and then rearrange from the restricted conformational space that is then sampled (Fersht, 1999). All

three models are reasonable and fit experimental data, such that a single generic mechanism for protein folding may not exist in nature.

A conceptual mechanism for understanding how a protein folds while avoiding the Levinthal paradox is a folding funnel, described by the most probable pathways leading to the adoption of the unique native structure of a protein (Wolynes et al., 1995; Dill and Chan, 1997; Dinner et al., 2000). In a folding funnel, as schematized on figure 1.1, the unfolded state possesses the highest free energy and comprises an ensemble of multiple conformations constituting the starting point of the folding pathway. The fast dynamics and low conformational restriction that characterize this state allow the occurrence of interactions between different parts of the chain, and, among them, native-like contacts involving key residues are energetically favored. This causes a fast collapse of the polypeptide chain, often driven by the formation of hydrophobic clusters decreasing the free energy of the system. Thus proteins may fold from the random state by collapsing and reconfiguring (Fersht, 1999). A loosely collapsed state with fluctuating tertiary interactions and very weak secondary structure, known as the “molten globule”, may be observed, and some times isolated.

**Figure 1.1. Landscape for protein folding.** Theoretical folding surface for a polypeptide chain. One folding pathway is indicated by the continuous arrowed line, where the rapid collapse of the chain is represented by the population of the first valley, which makes that only few particular conformations overtake the higher free energy of the transition state. After the saddle point is reached folding readily occurs downhill. Adapted from Dinner et al. (Dinner et al., 2000).

Neighboring residues start then to populate conformations with increasing amount of stable secondary structure, with turns and helices forming more rapidly than beta sheets (Eaton et al., 1998; Plaxco et al., 1998; Mayor et al., 2003). The population of a defined secondary structure requires that many residues concomitantly adopt concerted backbone conformations capable of forming hydrogen bonds between amide and carbonyl groups of the main chain, which further reduce the degree of freedom of the system. In many cases, depending on the mechanism by which the protein folds, a relatively stable transition state is populated, which adopts an overall three-dimensional shape that closely resembles the one of the native state of the protein (Vendruscolo et al., 2003). After the transition state the protein folds downhill until it attains the single unique state with the lowest energy.

In summary, the native state of a protein is achieved through a precise interplay of both short- and long-range interactions, determining that only a small number of conformations need to be sampled, thereby speeding up the process.

### **1.1.2. Protein folding in the cell**

In a cellular environment protein folding occurs co-translationally in the cytoplasm, mainly due to the slow synthesis rate by the ribosome, of  $\sim 8$  amino acid residues per second. The concerted effect of chaperones prevents hydrophobic stretches from newly synthesized polypeptides to be exposed and to self-interact, avoiding protein aggregation (Hartl and Hayer-Hartl, 2002). Major cytosolic chaperones belong to the class of small heat shock proteins (HSPs), like the HSP60s (GroEL-GroES, CCT/TRiC), HSP70s, HSP90s and HSP100s, and another important class is represented by foldases, like the peptidyl-prolyl *cis-trans* isomerases, which isomerases peptidyl-prolyl bonds in proteins (Bukau and Horwich, 1998).

Insights into the mechanism of protein folding *in vivo* were recently provided by high resolution structural studies of bacterial chaperones, but mammalian systems are homologous and very likely to proceed similarly (Bukau and Horwich, 1998). In bacteria protein synthesis occurs at a speed of 20 residues per second, and the nascent polypeptide leaves the ribosome through a 10 nm exit tunnel placed in the large subunit. This hollow cage may accommodate up to 35 residues, but its narrow diameter (about 15 Å) impedes folding. To the end of this tunnel is recruited the ribosome-associated chaperone trigger factor (TF), a 48 kDa protein which provides a cage where hydrophobic residues of the nascent polypeptide are able to fold. TF possess high affinity for emerging exposed hydrophobic stretches but the interaction weakens as the protein folds and such residues are buried, leading to detachment from the

complex (Maier et al., 2005). Two other systems provide folding assistance either co- or post-translationally, the DnaK-DnaJ chaperone complex (HSP70 family) and the GroEL-GroES chaperonin (HSP60 family). In contrast to TF, these two mechanisms require ATP and co-chaperone systems. DnaK preferentially associates with elongating polypeptides larger than 20 to 30 kDa and thus acts on nascent chains subsequent to TF. It does not possess a cage, and rather facilitates the posttranslational folding of multidomain proteins through cycles of binding and release (Teter et al., 1999). The GroEL-GroES system forms a hydrophobic cage (also termed “Anfinsen cage”) in which non-native proteins up to 60 kDa can be encapsulated and are free to fold. Folding is allowed to proceed for 10 s, as timed by the hydrolysis of ATP (Hartl and Hayer-Hartl, 2002).

The concerted action of the three chaperone-based system ensures proper folding in the cell; however it remains to be determined which fraction of proteins does entirely rely on chaperones to fold. For example a recent quantitative assessment of the GroES-GroEL chaperone function *in vivo* suggests that it may only be involved in the folding of ~ 100 proteins in *E. coli*. (Kerner et al., 2005).

Proteins that are directed to the secretory pathway or to mitochondria do not fold in the cytoplasm since they have to traverse the phospholipidic bilayers, remaining thus unfolded until they reach their final destination. Protein folding in the endoplasmic reticulum (ER) is also assisted by chaperones of the HSP70 and HSP90 class, GrpE-like and DnaJ-like, among others, and foldases, lectines and N-linked oligosaccharide-modifying enzymes are also present to ensure that polypeptides adopt their proper structure. Importantly, prior to vesicular release, folded proteins suffer a tight quality check based on glycosylations and de-glycosylations by the proteins UGGT and BiP (Schroder and Kaufman, 2005).

*In vitro*, re-folding after denaturation seems to be successful only for small to medium-size proteins, and very often large multidomains proteins fail to re-fold, mainly due to intra- and inter-molecular interactions (Kiefhaber et al., 1991). The picture *in vivo* is very similar, where off-pathway conformations are more likely to be populated if chaperones would not protect hydrophobic patches and force nascent polypeptide domains to fold independently and in a subsequent manner. Thus, in kinetic terms, chaperones do not themselves increase the rate of folding, rather they foster the overall efficiency of the process by reducing the probability of competing reactions, in particular aggregation (Schmid et al., 1994). In addition, confinement in the chaperone cage may smooth the energy landscape of folding for some larger proteins, either by preventing the formation of certain kinetically

trapped intermediates or by facilitating their progression toward the compact, native state (Hartl and Hayer-Hartl, 2002). As a conclusion, the evidence points that *in vivo* the folding of a protein is also exclusively dictated by the amino acid code of the polypeptide chain, and thus the generic applicability of the principles of protein folding (Dobson, 2003).

### **1.1.3. Quality control mechanisms of protein folding**

Cells possess quality control mechanisms that ensure a proper folding of proteins and facilitate removal of misfolded species, mainly based on the concerted action of chaperones and the ubiquitin-proteasomal system (UPS). Although the buffering capacity of chaperones may be sufficient for counterbalancing small changes in the amount of non-native proteins, it is often required to clear species that do not properly re-fold and may aggregate (Buchner, 1996). To achieve such a task, cells couple the chaperone system to proteasome-based pathways of protein degradation, like the chaperone BiP (HSP70 class), which binds to a mutant Prion protein and mediates its degradation by the proteasome (Jin et al., 2000). The proteasome is a multisubunit complex that manages protein turnover, either by direct interaction with the protein substrate or by recognition of ubiquitinated substrates. Three different proteasomes are found in mammalian cells, two which are ubiquitin-independent, the 20S and 26S, and one ubiquitin-dependent, the 26S, the latter being the main degradation pathway of the cell (Ciechanover, 2005).

Chaperones are not only able to protect proteins as they fold, but they also rescue misfolded and aggregated proteins, providing them a new chance to get properly folded (Hartl and Hayer-Hartl, 2002). In particular, the chaperone HSP100 is thought to participate in ATP-dependant disaggregation of proteins, and polyglutamine-expanded ataxin 1 misfolding and aggregation is suppressed by chaperones of the HSP70 family (Cummings et al., 1998).

Extracellular protein-rich depositions are also in part derived from the misfolding of polypeptides, and in the light of few molecular chaperones present outside the cell, extracellular membrane or secreted proteins undergo a tight quality check in the ER. The concerted action of glycosylases and deglycosylases determines the fate of proteins that cannot fold correctly (Schroder and Kaufman, 2005). Indeed, it was observed that a large fraction of newly synthesized proteins fail to pass the stringent checks at the ER, and are thus degraded by the proteasome (Schubert et al., 2000).

## 1.2. Protein misfolding and disease

The quality control mechanisms of protein folding discussed above are often overpowered in a disease state of the cell, increasing the chances for a polypeptide chain to adopt conformations that are not conducive to the native structure of proteins. Furthermore, feedback to such impairment of cell homeostasis will come from proteins that do not fold correctly, or do not remain correctly folded, since they are often prone to aggregate and to form toxic oligomers, which sustain proteasomal impairment (Dobson, 2003).

For example, a primary trigger for proteasomal failure is a massive overloading of unfolded substrates, but UPS malfunction may also arise from deficiencies in ubiquitinating enzymes responsible for determining the fate of misfolded proteins (Ciechanover and Brundin, 2003). Ubiquitin-independent degradation via the proteasome is also heavily challenged upon stress situations or when chaperones are incapable of refolding proteins, and accumulated misfolded proteins, which are not able to be cleared under these conditions, are progressively deposited in protein-rich aggregates called aggresomes (Johnston et al., 1998). Moreover, recent studies suggest that such protein aggregates cause cytotoxicity by inhibiting proteasomal and/or UPS function, which may be causative of neurodegenerative disorders such as Alzheimer's, Parkinson's, Huntington's and Prion diseases (Bence et al., 2001; Ciechanover and Brundin, 2003). Indeed, impairment of proteasomal function in the *substantia nigra* has been described for Alzheimer's and Parkinson's patients (McNaught and Jenner, 2001; Keck et al., 2003). The mechanism by which this inhibitory effect takes place is largely unknown, but supports the idea of a generic toxic property of protein aggregates (Dobson, 2003).

In addition, the function of the ER is perturbed when the influx of unfolded polypeptides exceeds its folding capacity, which is often the case upon over-expression of proteins such as antithrombin III or blood coagulation factor VIII, which sequester chaperones and form protein aggregates. The ER normally responds by a complex signaling cascade known as the unfolded protein response, increasing the expression of chaperones and generally repressing transcription and translation (Schroder and Kaufman, 2005). Misfolded proteins in the ER are retro-translocated to the cytoplasm and degraded by the 26S proteasome (Mayer et al., 1998). Nevertheless, long-term abnormal accumulation of folding-incompetent proteins may produce oligomers resistant to proteasomal degradation, which completely disrupts the ER and activates apoptotic signaling pathways, leading to a disease-state of the cell (Davis et al., 1999; Nakagawa et al., 2000).

It is therefore not surprising that aberrations in the folding and abnormal deposition of certain proteins are now associated with a wide range of human diseases, collectively known as misfolding diseases (table 1.1). Such disorders may arise from the presence of mutations that impede a proper folding of the polypeptide chain or from stress factors that specifically trigger the misfolding of the protein, escaping control mechanisms and forming toxic species to cells (Dobson, 2004).

Disease	Protein	Site of folding
Hypercholesterolaemia	Low-density lipoprotein receptor	ER
Cystic fibrosis	Cystic fibrosis transmembr. regulator	ER
Phenylketonuria	Phenylalanine hydroxylase	Cytosol
Amyot. lateral sclerosis	Cu, Zn, superoxide dismutase	Cytosol
Huntington's disease	Huntingtin	Cytosol
Sickle cell anemia	Haemoglobin	Cytosol
Alzheimer's disease	<b>Amyloid <math>\beta</math>-peptide / Tau</b>	ER
Parkinson's disease	<b><math>\alpha</math>-synuclein</b>	Cytosol
Creutzfeld-Jakob disease	<b>Prion protein</b>	ER
Familial amyloidoses	<b>Transthyretin / Lysozyme</b>	ER
Cataracts	Crystallins	Cytosol
Cancer	P53	Cytosol

**Table 1.1. Representative protein folding diseases.** Selected disorders that are linked to the misfolding and aberrant deposition of proteins are listed. Proteins responsible of such deposits and the respective cellular compartment of folding are also depicted. Proteins displaying amyloid deposition in disease are highlighted in bold. Adapted from Dobson, 2004 (Dobson, 2004).

A common denominator of many if not all of these diseases is the modern-man intervention. For example, spanning our life-term permits accumulating damage to cells reducing the stringency of quality control mechanisms, in particular for protein folding, facilitating the occurrence of Alzheimer's (AD) and Parkinson's disease (PD). Exposure to environmental toxins, like MTTP or Rotenone is another major cause of PD, and medical treatments as long-term dialysis unexpectedly cause deposition of proteins in liver or

osteoarticular tissue. The outburst of mad-cow disease during the last decade have also been a consequence of man's intervention in the feeding of animals, allowing misfolded proteins to cross natural barriers. The current idea behind these afflictions is that the actions of modern man have radically altered the evolutionary pressure on proteins. Thus the challenge to science strategists is to devise the means for circumventing interventions with deleterious effects while promoting those offering ecologically responsible benefits to the human race.

### **1.2.1. Amyloid diseases**

A sub-set of these pathologies, including AD, PD, Prion diseases and late-onset diabetes, among others, are associated with the deposition of structurally defined protein aggregates in the tissue known as amyloid fibrils (Koo et al., 1999; Serpell, 2000). Amyloid in disease is generally defined to be extracellular, although intracellular structures sharing the same core structures are described in PD (Serpell et al., 2000).

Amyloid is defined in terms of empirical observations from X-ray fiber diffraction, electron microscopy, FTIR and specific chemical staining with dyes such as Congo Red and Thioflavine T. Thus to be classified as an amyloid protein, its deposits should be straight, unbranched, of about 10 nm in diameter, reach a  $\mu\text{m}$  in length, present a cross- $\beta$  diffraction with two sharp reflections at 4.7 Å and 10 Å, and display green birefringence after staining with Congo Red.

The pathological hallmark of these conformational diseases is not constrained to the formation of amyloid-like fibrils. In several disorders, protein deposits are composed of amorphous aggregates, without micro- or macroscopical order. Similarly, stable soluble oligomers derived from the self-association of soluble misfolded species, could be the final product of the aggregation process, and the culprit of many of these disorders (Caughey and Lansbury, 2003).

### **1.2.2. Molecular basis of amyloid formation**

In order to deposit in the form of ordered filamentous protein-rich aggregates, a dramatic change in the structure of a protein has to occur. A conformational change triggered on the polypeptide chain cause a transition from its natural soluble conformation towards a more insoluble state. Although more than 20 proteins are known to be involved with such pathological depositions, they do not share any sequence homology, and may be either rich in  $\beta$ -sheets,  $\alpha$ -helix, or lack significant secondary structure in their native states (Uversky and Fink, 2004). However, independently of the originating protein, they all form a common

cross- $\beta$  structure in which continuous  $\beta$ -sheets are formed with  $\beta$ -strands running perpendicular to the fibril axis (Makin and Serpell, 2005).

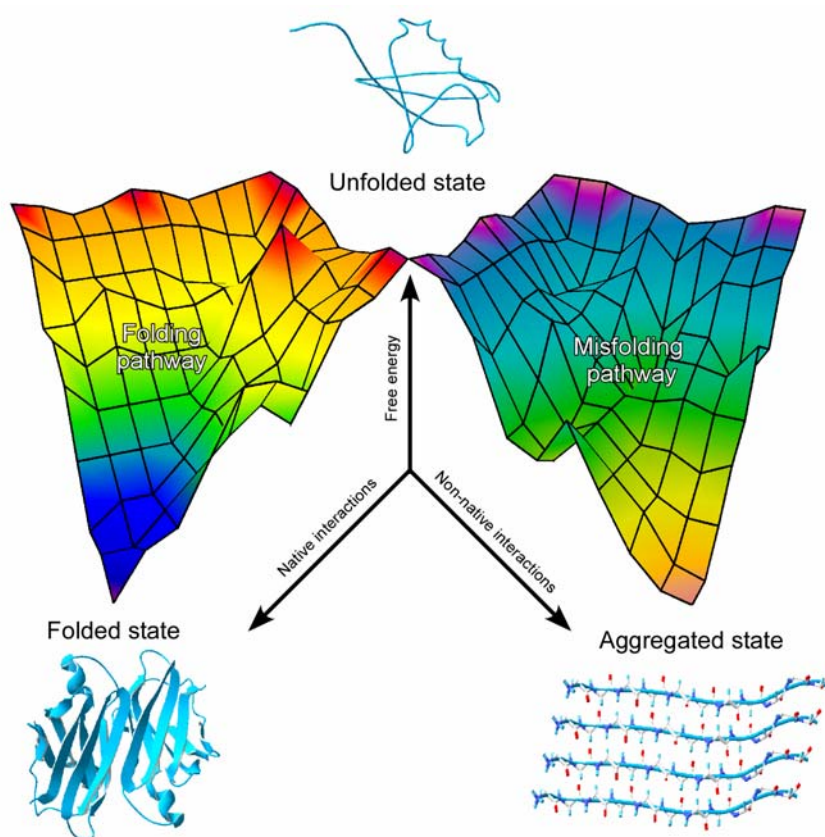

To reconcile this observation, it has been proposed that fibrillation may occur when the rigid native structure of a protein is destabilized, favoring a partial unfolding. Such partially or completely unstructured conformations of the polypeptide chains are particularly high aggregation-prone, presumably via specific non-native intermolecular interactions conducive for oligomerization (Uversky and Fink, 2004). Indeed, many of the pathogenic mutations that are associated with familial deposition diseases increase the population of partially unfolded states by decreasing the stability of the native state or reducing its global cooperativity, as observed for lysozyme (Booth et al., 1997; Dumoulin et al., 2005). For Transthyretine it has also been postulated that pathogenic mutants destabilize the native tetramer of the protein, favoring a kinetic partition towards the monomeric state which easily destabilizes and aggregates (Hammarstrom et al., 2002).

Conformations that lead to misfolded states of a protein are not dictated by the polypeptide sequence, and thus are not generally part of the folding funnel, which is sequence-specific, giving rise to a second energetic landscape known as misfolding pathway (Figure 2.1). Although misfolded structures possess a low free energy, and could even be more stable than the native state of the protein, the energetic barrier dictates that the unfolded state has to be attained earlier than such conformations are populated (Uversky and Fink, 2004).

*In vitro* assembly of recombinantly expressed amyloid proteins has given sustained to such findings, demonstrating that fibrils readily form when the native state is destabilized by addition of denaturant or organic solvents, low pH, high temperature, pressure, or amino-acids substitutions. In most of these conditions, the population of a partially unfolded conformation has been documented (Uversky and Fink, 2004).

However, exceptions to this empirically-derived rule have been described. For example  $\beta$ 2-microglobulin has been found to fibrillate through a native-like folding intermediate. This amyloidogenic conformation involves the formation of a non-native trans-prolyl isomer which is part of the folding pathway of the protein, but is just rarely populated in native conditions. This suggests that the folding and aggregation landscapes of this protein are, at least, partially overlapping (Jahn et al., 2006). Similarly, an acylphosphatase variant was found to aggregate via the population of a conformation that retains its enzymatic

activity and native-like structure. Afterwards, this intermediate species interconverts slowly into enzymatically inactive amyloid-like protofibrils (Plakoutsi et al., 2005).

**Figure 1.2. Landscape for protein misfolding.** Analogous to the folding funnel determined for the folding of a protein, a similar landscape for the adoption of stable misfolded conformations of a protein is devised. The misfolding pathway is linked to the folding pathway through the unfolded state, and necessarily involves self-oligomerization of the polypeptide chain. In contrast to the folding situation where a single native structure is attained, several misfolded species may be populated in a stable manner, and are kinetically related. Depicted are the native and misfolded states of the amyloidogenic protein Transthyretine (native state based on 1bmz and fibril state based on 1rvs). Adapted from Jahn, 2005 (Jahn and Radford, 2005).

Limited proteolysis may also give rise to the exposure of highly aggregation prone regions, which readily self-associate, as in the process of the amyloid precursor protein APP, or in some cases with  $\alpha$ S, giving rise to a C-terminal truncated species (Li et al., 2005). This may be explained in terms of cooperativity, another crucial factor in enabling proteins to remain soluble, ensuring that the equilibrium population of unfolded regions is minimal.

The tendency of proteins to form amyloidogenic conformations has been the subject of intense speculation by theoreticians. Electrostatic repulsion, hydrophobicity and secondary

structure propensity have all been shown to have a major influence on the tendency of fully or partially unfolded conformations to aggregate (Chiti et al., 2003). Interactions between solvent exposed, hydrophobic and flexible regions that lack stable hydrogen bonded elements of secondary structure are also suggested as factors initiating fibrillation (Uversky and Fink, 2004). Nevertheless, a specific conformational state seems not to be required for ordered aggregates to form, provided that the solution conditions permit relatively stable intermolecular interactions (Calamai et al., 2005).

### **1.2.3. Conformational plasticity in amyloid formation**

Kinetic studies of *in vitro* protein aggregation have revealed a conserved fibrillation pathway for amyloid proteins, characterized by the intermediacy of ordered prefibrillar aggregates of distinct morphology (Figure 1.3) (Caughey and Lansbury, 2003). After partially unfolded states are reached, conformations rich in  $\beta$ -sheet secondary structure content are populated, concomitantly with oligomerization (Uversky and Fink, 2004).

Soluble oligomers rapidly convert to fibrillation intermediates, designated protofibrils, which were first described for A $\beta$  but now seem to be a general feature of amyloid formation (Harper et al., 1997; Walsh et al., 1997; El-Agnaf et al., 2001; Haass and Steiner, 2001; Bucciantini et al., 2002; Poirier et al., 2002). Early formed metastable protofibrils typically comprise 10 to 50 monomers, depending on the protein involved, and appear to be spherical in nature. These spheres may anneal to form chainlike protofibrils, which can further form annular pore-like species or proceed to amyloid fibrils (Harper et al., 1999; Ding et al., 2002; Lashuel et al., 2002a; Lashuel et al., 2002b; Nichols et al., 2002).

Cellular studies with several amyloidogenic proteins suggest that the pathogenic species on this kind of disorders is an ordered oligomeric intermediate and not the fibrillar end-product of the protein aggregation pathway (Caughey and Lansbury, 2003). In particular for A $\beta$  and  $\alpha$ S, a possible link between a subpopulation of circularized chain-like protofibrils, the so-called amyloid pores, and neuronal death, has been proposed (Lansbury, 1999; Goldberg and Lansbury, 2000; Haass and Steiner, 2001; Lashuel et al., 2002b). The toxicity of protofibrils is also supported by studies demonstrating that antibodies raised against soluble A $\beta$  oligomers are capable of blocking the toxicity of these fractions to cultured neurons (Lambert et al., 2001).

It appears that the toxicity of protofibrils is related to their structure, not their sequence, as protofibrillar material comprising unrelated proteins showed similar toxicity in cell culture, while amyloid fibrils were non-toxic (Bucciantini et al., 2002; Fezoui and

Teplow, 2002). The generic nature of such aggregates and their effects on cells has recently been supported by the development of antibodies that can cross-react with protofibrils of different amyloidogenic peptides and proteins, and moreover inhibit their toxicity (Kayed et al., 2003).

**Figure 1.3. Conformational plasticity in amyloid formation.** **A.** Different conformational assemblies that may be populated during the amyloid conversion of a protein. From a completely unfolded monomer to a partially folded,  $\beta$ -sheet rich, monomeric or dimeric intermediates, up to oligomers and protofibrils, a extensive variety of states are populated by a protein until it reaches the formation of an amyloid fibril. **B.** Ideal traces for the time-dependent occurrence of the above mentioned species during aggregation. Monomer consumption (blue) is rapid, as oligomeric conformations are populated (orange). Depending on the stability of such high molecular species, oligomers coalesce into protofibrils which mature into amyloid fibrils (violet). Simultaneously, monomeric species are able to directly aggregate into fibrils (direct monomer addition), but monomer consumption is not complete as a critical concentration is always in equilibrium with the fibrils. **C.** Simplified nucleation-polymerization kinetic model for amyloid formation, considering a nucleation event ( $K_{nucleation}$ ) and a polymerization, or monomer addition, event ( $K_{elongation}$  and  $K_{shortening}$ ).

The search for the pathogenic conformation has practical implications because its formation and the proteins with which it interacts are potential targets for therapeutic intervention. Although the protofibril hypothesis has displaced the amyloid hypothesis, controversy still exists as to which is the pathogenic species. As recently suggested by Lansbury (Caughey and Lansbury, 2003), the “culprit” should have the following properties:

- (i) its stability and/or the rate of its formation should be sensitive to disease-associated mutations;
- (ii) it should also be accessible to the wild-type protein because most of these diseases are predominantly sporadic;
- (iii) it should be linked to a potential pathogenic mechanism (for example, sequestration of a critical protein, disruption of a membrane, or initiation of apoptosis);
- (iv) its formation/stability should be sensitive to the effects that distinguish the various cell types in the brain, since all of these diseases are selective with respect to the anatomical distribution of neurodegeneration; and
- (v) its formation/stability should be sensitive to cellular defense mechanisms that may play a role in determining disease susceptibility, such as heat shock, chaperones, proteasomal degradation, or aggregatesome formation”.

At first glance it is very unlikely that a single toxic species could account for such diverse features. However, a concerted action of the different intermediates in the amyloid formation, each of them challenging a different cellular target, may reconcile the current disparate views of these sorts of afflictions.

### 1.3. Protein misfolding in Parkinson's disease

Parkinson's disease (PD) is a progressive, neurodegenerative, and age-related movement disorder affecting more than 1% of the population over 65 years of age (Goedert, 2001). It arises from the loss of dopaminergic neurons in the *substantia nigra* pars compacta of the brain and is accompanied by the presence of eosinophilic intracellular inclusions known as Lewy bodies (LBs) and Lewy neurites, which are confined largely to nerve cells (Galvin et al., 1999). LBs are also found in other major neurodegenerative disorders that occur increasingly with aging, including dementia with LBs and Alzheimer's disease (Dawson and Dawson, 2003). Ultrastructurally, LBs are protein rich depositions in the form of long amyloid-like fibrils, the major component of which is the pre-synaptic protein  $\alpha$ -synuclein ( $\alpha$ S) (Spillantini et al., 1997). The second most common component of LBs is ubiquitin (Ub) (Forno, 1996) and other proteins that are predominantly found are heat shock proteins, neurofilaments, Tau, synphilin-1 and tubulin, among others (Shults, 2006).

The etiology of PD is not yet fully understood, but genetic analysis, neuropathologic investigations, and experimental models of PD have provided fundamental insights into its pathogenesis (Figure 1.4). Impairment of mitochondrial complex I, leading to an increase of reactive oxygen species, plays a central role in the pathogenesis of sporadic PD (Jenner and Olanow, 1998; Schapira et al., 1998; Sherer et al., 2002). PD models based on MPP+ administration feature loss of dopaminergic neurons due to inhibition of complex I with the presence of intracellular inclusions strongly immunoreactive for  $\alpha$ S and Ub (Vila et al., 2000), and other complex I inhibitors such as paraquat or rotenone also produce symptoms of Parkinson in various animal models (Thiruchelvam et al., 2000; Manning-Bog et al., 2002; Sherer et al., 2003).

In addition to oxidative stress, impairment in the ubiquitin-proteasomal system contributes to the disease condition in PD (McNaught et al., 2001), as has been linked to many neurodegenerative disorders (Ciechanover and Brundin, 2003). Failure of the UPS to adequately remove misfolded or abnormal proteins may underlie demise of nigral cells in sporadic PD (McNaught et al., 2001). Furthermore, deficits in the 26/20S proteasome pathways are accompanied by protein accumulation and aggregation, which may also cause neurodegeneration (Chung et al., 2001), and recently it has been demonstrated that soluble aggregated proteins can inhibit the UPS (Bence et al., 2001). These combined pieces of evidence have attracted much attention as they imply that LBs could originate from ubiquitin-

rich aggresomes that the proteasomal components may not be able to process (McNaught et al., 2002).

**Figure 1.4. Molecular pathways to Parkinson's disease.** PD is a complex disorder that involves impairment of cellular homeostasis at various levels. Three main events may trigger PD, (i) damage to mitochondria accompanied by an increase in reactive oxygen species, (ii) impairment of the ubiquitin proteasomal system, and (iii) misfolding of  $\alpha$ S. Evidence suggests that all of these disease-associated mechanisms are tightly interconnected in a single pathological pathway that causes the demise of dopaminergic neurons in the brain stem. Adapted from Dawson, 2003 (Dawson and Dawson, 2003).

### 1.3.1. $\alpha$ -Synuclein aggregation is linked to Parkinson's disease

Although PD is primarily a sporadic disorder, more than 10 different loci are responsible for rare Mendelian forms of PD, and the study of these gene products has provided new insights that assisted experimental models of neurodegeneration (Dawson and Dawson, 2003).

$\alpha$ S has been unequivocally linked to PD due to the discovery of genetic mutations. Three different missense mutations in the  $\alpha$ S gene result in early onset PD (A30P, E46K and A53T), and additionally, a locus triplication causing an increased dosage of the *wild type* (*wt*)  $\alpha$ S gene potentiates the disease (Polymeropoulos et al., 1997; Kruger et al., 1998; Singleton et al., 2003; Zarranz et al., 2004). The role of  $\alpha$ S in the formation of Lewy bodies and the pathogenesis of PD has been compared to the role of A $\beta$  peptide and amyloid plaques in Alzheimer's disease.

The appealing hypothesis for Lewy body formation is that  $\alpha$ S monomers combine to form oligomers (or protofibrils), which coalesce into fibrils and then co-aggregate with other proteins into Lewy body inclusions (Conway et al., 1998; Wood et al., 1999). While the

monomers and oligomers of  $\alpha$ S are soluble, the fibrils and Lewy bodies are insoluble in the neuronal cytoplasm. Some controversy arises from the roles of the various physical forms of  $\alpha$ S in PD pathogenesis. LBs have been proposed to be both neurotoxic (El-Agnaf et al., 1998; Giasson and Lee, 2001), and protective (Rochet et al., 2000; Mouradian, 2002). Other hypotheses state that the protofibrillar intermediates, made of  $\alpha$ S oligomers, are the main species toxic to dopaminergic neurons (Conway et al., 2000). Lansbury and co-workers have recently shown that  $\alpha$ S protofibrils can form elliptical or circular amyloid pores in cell membranes (Lashuel et al., 2002b; Volles and Lansbury, 2002), and cell culture studies found that they reduce cell viability, disrupt lysosomes and induce Golgi fragmentation (Stefanis et al., 2001; Gosavi et al., 2002). In line with these findings, the A30P and A53T mutants of  $\alpha$ S share an increased tendency to form soluble oligomeric intermediates, whereas the E46K and A53T mutants fibrillate faster than the *wt* protein (Conway et al., 2000; Choi et al., 2004).

Other important genetic mutations suggest the involvement of UPS in PD, and major interest arose with the identification of mutations in the E3 ubiquitin ligase Parkin as a cause of autosomal recessive PD (Kitada et al., 1998). Both the loss of E3 activity and the possibility of incomplete or aberrant ubiquitination are proposed as causes of Parkin-related PD (Giasson and Lee, 2003). A second member of the UPS involved in PD is the Ubiquitin Carboxy-Terminal Hydrolase-L1 (UCH-L1), and mutations in the *uch-l1* gene cause dysfunction of this enzyme and lead to accumulation of toxic products (Leroy et al., 1998).

The shared symptoms of PD associated with the different genetic mutations raises the possibility of a molecular intersection in the pathogenic mechanisms driven by both protein degradation and aggregation. One plausible mechanism would involve  $\alpha$ S mutations populating abnormal protein conformations and overwhelming the cellular protein degradation systems, whereas mutations in the UPS machinery would challenge the cell's ability to detect and degrade misfolded proteins that can result in the formation of toxic early aggregates (McNaught et al., 2002). The common outcome of this failure at different levels is thus expected to be a cellular buildup of such unwanted toxic species that should have been cleared in healthy conditions. Minimal defects in the crucial protein turnover machinery may suffice to cause a slow demise of dopaminergic neurons, which may explain the relentless, progressive nature of the disease (Vila and Przedborski, 2003).

### 1.3.2. The physiological role of $\alpha$ -Synuclein

$\alpha$ S is member of a closely related group of brain-enriched proteins ( $\alpha$ S,  $\beta$ S and  $\gamma$ S) that have been implicated in neurodegenerative disorders and cancer, among others (Clayton and George, 1998).  $\alpha$ S and  $\beta$ S are predominantly cytosolic proteins and co-localize in presynaptic nerve terminals, close to synaptic vesicles, while  $\gamma$ S appears to be axonal and cytosolic (Buchman et al., 1998).

Despite the involvement of  $\alpha$ S in neurodegenerative diseases, the normal biological function of this family of proteins is still unclear. Expression of both  $\alpha$ S and  $\beta$ S is minimal in the embryonic rat brain, thus the function of synucleins is more relevant for the adult than for the developing nervous system (Clayton and George, 1999). They are related to presynaptic terminal function, although not being vesicle proteins, yet being able to influence vesicle fusion and membrane trafficking at the presynaptic terminal (Clayton and George, 1998). In particular,  $\alpha$ S is proposed to regulate dopamine neurotransmission by modulation of vesicular dopamine storage (Lotharius and Brundin, 2002).

An overall role of  $\alpha$ S on brain neurotransmitter function is still elusive, since the absence of  $\alpha$ S in mice appears associated with only mild behavioral changes. Mice lacking  $\alpha$ S show only subtle changes in dopamine-dependent behavior and are not impaired in spatial learning (Abeliovich et al., 2000; Chen et al., 2002). In addition, mice deficient in either  $\alpha$ S or  $\beta$ S, or lacking both proteins are viable, fertile, and display no major phenotype (Chandra et al., 2004). Nevertheless,  $\alpha$ S overexpression rescues lethality associated with the lack of CSP $\alpha$ , a co-chaperone (HSP40 kind) associated with synaptic vesicles and implicated in folding of SNARE proteins, suggesting that  $\alpha$ S may act as an auxiliary chaperone preserving the function and integrity of the synapse (Chandra et al., 2005).

### 1.3.3. The native unfolded state of $\alpha$ -synuclein

$\alpha$ S is only 140 amino acid long and lacks a defined secondary structure in aqueous solution, populating random-coil conformations (Weinreb et al., 1996). Hence it belongs to the group of “natively unfolded” or “intrinsically disordered” proteins (Uversky et al., 2000). Three distinct regions are identified in the  $\alpha$ S polypeptide sequence (Figure 1.5):

- (i) the N-terminal domain (residues 1–60), which is positively charged and contains five imperfect repeats of the highly conserved KTKEGV motif,
- (ii) the central NAC domain (residues 61–95), which is highly hydrophobic

- (iii) The C-terminal region (residues 96–140), which is very acidic, containing 10 Glu, 5 Asp and 5 Pro residues.

**Figure 1.5. Structural features associated with the primary sequence of  $\alpha$ S.** From top to bottom: Domain organization (N-terminus, NAC and C-terminus) and amino acid sequence of  $\alpha$ S. Nature of residues colored as follows: blue (+), red (-), yellow (hydrophobic), light blue (Pro). Hydrophilicity plot (Kyte-Doolittle) calculated with a 9 residue window. Secondary structure propensity calculated using TANGO (red line  $\alpha$ -helix, green line  $\beta$ -sheet, blue bars  $\beta$ -turns). Aggregation propensity according to TANGO (Fernandez-Escamilla et al., 2004).

Due to the despair nature of its constitutive residues, each region on  $\alpha$ S displays a different feature associated with the disease-state. The N-terminus and the NAC region, up to residue 87, increase in  $\alpha$ -helical structure upon association with lipid vesicles, adopting a

broken amphipathic helix, important for the physiological state of the protein (Davidson et al., 1998; Jensen et al., 1998; Jo et al., 2000; Narayanan and Scarlata, 2001; Bussell and Eliezer, 2003; Chandra et al., 2003; Ulmer and Bax, 2005; Ulmer et al., 2005). The NAC region, due to its hydrophobic nature is proposed to initiate aggregation, and indeed includes a 12 residue stretch essential for fibril formation (Giasson et al., 2001). The C-terminus of the protein is responsible for the high thermostability of the protein and is essential for the chaperone function of  $\alpha$ S by serving as a solubilizing domain (Kim et al., 2000; Souza et al., 2000; Kim et al., 2002; Park et al., 2002b; Park et al., 2002a). Upon  $\alpha$ S binding to lipids the C-terminus remains disordered and does not interact with the micelles (Bussell et al., 2005; Ulmer et al., 2005). Moreover, it regulates aggregation of  $\alpha$ S since C-terminally truncated fragments are found to aggregate faster than the full-length protein (Crowther et al., 1998; Serpell et al., 2000; Murray et al., 2003). This later finding correlates with recent evidence from PD patients, in whom a C-terminal truncated  $\alpha$ S was isolated from brain-deposited fibrillar material (Li et al., 2005).

#### **1.3.4. Ligand induced aggregation of $\alpha$ -synuclein**

The idea that early steps in neuronal damage by PD are governed by the oligomerization of  $\alpha$ S is leading a number of groups to identify factors that induce a conformational change in the  $\alpha$ S molecule. Protein and other ligand-induced conformational changes on the native conformation of the polypeptide chain might have dramatic effects on its ability to interact with itself.

Indeed, various molecules and solution conditions of manifold chemical nature have been shown to accelerate  $\alpha$ S aggregation such as low pH, increased temperature (Uversky et al., 2001b), certain metal cations (Uversky et al., 2001c), pesticides (Uversky et al., 2001a), oxidized catecholamines (Conway et al., 2001), phospholipid vesicles, detergents and organic solvents (Perrin et al., 2000; Perrin et al., 2001). The aggregation promoting effects are suggested to be caused by a preferential population of a partially folded  $\alpha$ S conformation which constitutes a critical intermediate on the aggregation pathway (Uversky et al., 2001b).

#### **1.3.5. Polycation-induced $\alpha$ -synuclein fibrillation**

The transitions of monomeric  $\alpha$ S toward oligomeric amyloid structures have been extensively investigated in the laboratory where this thesis work was carried out. The diversity of aggregate morphology upon variation in solution conditions was studied employing different spectroscopy and microscopy techniques. It was found that upon pH

decrease from 7.0 to 4.0 or upon addition of polycations, fibril networks and amorphous aggregates are observed. Those aggregates retain characteristics of amyloid and presumably share a common nucleation event with the ordered fibrillar structures (Hoyer et al., 2002). The impact of the C-terminal region on the aggregation kinetics was assessed by comparing the full length with C-terminally truncated  $\alpha$ S under solution conditions affecting the C-terminal charge state. The solution dependence of aggregate morphology was attributed to charge shielding at the C-terminal region comprising the amino acids 109-140 (Hoyer et al., 2004). Moreover, the modulatory effect of solution conditions on A30P and A53T disease-related mutants of  $\alpha$ S was investigated. The aggregation kinetics of wild-type  $\alpha$ S, A30P, and A53T were modulated differently by changes of the solution conditions, suggesting long range interactions between the C-terminus with the central and N-terminal parts of the protein (Hoyer et al., 2004).

In addition to the above-mentioned conditions, work performed by our group recently demonstrated that natural polyamines promote the aggregation of  $\alpha$ S (Antony et al., 2003). Polyamines are cellular stabilizers of nucleic acids and membranes, being essential for growth and differentiation. In the central nervous system, they mediate channel and receptor gating, immune responses to infection (Soulet and Rivest, 2003) and are involved in neurodegenerative disorders as AD (Morrison and Kish, 1995). At high intracellular levels spermidine and spermine are toxic (Auvinen et al., 1992); they are significantly elevated in the red blood cells of AD and PD patients (Gomes-Trolin et al., 2002) and can produce oxidative intermediates during polyamine retro-conversion. For these reasons, it was postulated that at physiological concentrations and in a cellular context these natural compounds may modulate the propensity of  $\alpha$ S to form fibrils, thereby playing a significant role in the formation of cytotoxic aggregates (Antony et al., 2003).

**Figure 1.6. Structure of natural polyamines accelerating  $\alpha$ S aggregation.** The polyamines studied on this thesis work are depicted, whereas the net charge at neutral pH is consigned.

The binding site of polyamines to  $\alpha$ S was determined by high resolution Nuclear Magnetic Resonance (NMR), and chemical shift perturbations were detected on a defined region at the C-terminal domain of the protein (Fernandez et al., 2004). This report constitutes the first evidence that residue-specific changes in this domain are linked to the acceleration of fibrillation, and is in line with previously mentioned housekeeping effect that the C-terminus has on the aggregation of  $\alpha$ S. Binding constants were determined for the association of the different polycations to the protein, and ranged from 0.6 mM (Spermine) to 10 mM (Putrescine).

It was hypothesized that binding of polyamines might modulate structural and dynamic properties of the free protein and thereby influence intermolecular interactions required for the aggregation process. In the unliganded native conformation, the dynamic C-terminal domain could block the self-aggregating domain(s), assigned by many studies to the central core of the molecule, and C-terminal modifications such as charge neutralization by polyamine binding would release the self-aggregating domain and promote its transition to a  $\beta$ -sheet conformation. Further evidence supporting these findings is provided by intensity changes of the signals belonging to this domain upon polyamine binding (Fernandez et al., 2004), and by our own studies showing that C-terminally truncated  $\alpha$ S aggregates much faster than the *wt* protein (Hoyer et al., 2004).

**Figure 1.7. Biochemical cartoon model for the polyamine-induced aggregation of  $\alpha$ S.** The unliganded monomer is auto-inhibited for aggregation due to interactions between the NAC region and the C-terminus. Upon polyamine binding the C-terminus shielding effect is removed and the protein readily dimerizes, nucleating the aggregation process. Adapted from Hoyer et al. (Hoyer et al., 2004).

The  $\alpha$ S-polyamine system is very suitable for study since (i) it is physiologically relevant to the pathogenesis of PD; (ii) it allows characterization of the early transitions that lead to  $\alpha$ S fibrillation; (iii) the liganded protein is still soluble and do not readily associate at low temperature, permitting high resolution structural studies to be performed; and (iv) the charge-dependent effect on the binding affinity for the different polyamines allows a comparative assessment of the structural perturbations.

### 1.3.6. Metal induced $\alpha$ -synuclein fibrillation

Metal cations have been frequently recognized as risk factors in neurodegenerative disorders (Sayre et al., 1999; Bush, 2000). Brain lesions associated with Alzheimer's disease are rich in Fe(III), Zn(II) and Cu(II) (Lovell et al., 1998). Recent biophysical and structural studies of the amyloid precursor protein (APP) and the amyloid- $\beta$  peptide (A $\beta$ ) have provided strong evidence linking Cu(II) with AD (Atwood et al., 1998; Huang et al., 1999; Bush et al., 2003; Brown and Kozlowski, 2004). Furthermore, a role for copper in prion disease has also been suggested and the interaction of Cu(II) with fragments of the prion protein (PrP) was structurally characterized (Viles et al., 1999; Aronoff-Spencer et al., 2000; Garnett and Viles, 2003; Brown and Kozlowski, 2004).

Although less well defined, the metallobiology of PD is attracting increasing attention. Iron deposits have been identified in Lewy bodies in the *substantia nigra* (Castellani et al., 2000) and elevated Cu(II) concentrations have been reported in the cerebrospinal fluid of PD patients (Pall et al., 1987). Based on this evidence, a role was suggested for copper and iron in the catalysis of oxidative oligomerization and subsequent aggregation of  $\alpha$ S in the presence of hydrogen peroxide (Hashimoto et al., 1999; Paik et al., 2000).

A systematic analysis of the effect of various metal ions revealed that Al(III), Fe(III) and Cu(II) accelerate AS fibrillation *in vitro* (Uversky et al., 2001c) and another study showed that Cu(II) is the most effective ion in promoting  $\alpha$ S oligomerization (Paik et al., 1999). The enhancement of fibrillation by metals has been attributed to Coulombic screening of charge-charge repulsion associated with the highly acidic C-terminal domain (Paik et al., 1999; Uversky et al., 2001c). Cu(II), Fe(II) and Mn(II) quench tyrosine fluorescence and are presumed to form stable metal-protein complexes with  $\alpha$ S and cause a significant acceleration of  $\alpha$ S fibril formation (Uversky et al., 2001c; Golts et al., 2002).

## 1.4. The unfolded state of proteins

As stated before, the unfolded state of a protein represents the starting conformation for the folding pathway, and partially or completely unfolded conformations are also key intermediates in amyloid formation. In addition, the proteins investigated in this thesis work are classified as natively unfolded proteins. It is thus instructive to comment at this point on the particular characteristics of this conformational state of the polypeptide chain.

### 1.4.1. Intrinsic conformational restrictions in the unfolded state

As originally defined by Tanford (Tanford, 1968), the conformations populated by an unfolded polypeptide chain are true random coils, retaining no element of their original native structure. Nevertheless, even in the most expanded unfolded protein sequence, local elements of the chain are held in proximity via the peptide bond, leading to the Flory isolated pair hypothesis (Flory, 1969), which states that in a random coil conformational restrictions do exist, but are limited to nearest neighbor interactions. However, it was recently suggested that systematic local steric effects can extend beyond nearest-chain neighbors and may restrict the size of accessible conformational space (Pappu et al., 2000). Shortle has recently restricted the definition of a random coil state of a polypeptide as the well defined reference (and perhaps ideal) state in which no sidechain-sidechain interactions occur (Shortle, 1996). Thus the characteristics of a random coil state of a protein will depend on the intrinsic molecular features of the amino acids that compose the particular polypeptide chain.

In a polypeptide chain the peptide bond is planar, and the main-chain trace of the backbone can be described in terms of peptide planes connecting the  $C\alpha$  atoms. The relative orientation of two of these planes ( $i$  and  $i + 1$ ) will be determined by the pair of torsion angles  $\phi_i$  and  $\psi_i$ , defining the rotation about the bonds connecting the  $C\alpha_i$  (Figure 1.8).

**Figure 1.8. A polypeptide chain.** Schematic diagram of a polypeptide chain showing the torsion angles  $\phi$  and  $\psi$ , which determine the backbone conformation.

The combination of  $\phi$  and  $\psi$  angles for each of the amino acids composing the chain defines the specific conformation of the polypeptide backbone. Thus for proteins that retain a single structure, each residue populates a defined  $\phi$ ,  $\psi$  conformation, with small fluctuations, contrasting a random coil conformation, where there will be a distribution of  $\phi$ ,  $\psi$  angles for each residue, giving rise to an ensemble of conformers (Smith et al., 1996).

Ramachandran in the late 60's observed that steric considerations in the backbone atoms are sufficient to restrict the permissible  $\phi$ ,  $\psi$  values for a given amino acid in a polypeptide chain, providing the basis for the description of conformational spaces for secondary structure formation in proteins (Ramachandran et al., 1963). The Ramachandran plot depicts the distribution of  $\phi$ ,  $\psi$  torsion angles that are evidenced in a polypeptide and relates those values with the adoption of helical or sheet backbone conformations (Figure 1.9). Thus the measurement of torsion angles for a given residue may, in general, report on the conformation in which a certain amino acid is embedded.

**Figure 1.9. Ramachandran plot and dihedral angles for secondary structure conformations in polypeptides.** Diagram of the  $\phi$ ,  $\psi$  torsion angles distribution for residues in a polypeptide chain. The average conformational parameters are consigned for each secondary structural element.

In the absence of secondary structure, the values of  $\phi$ ,  $\psi$  torsion angles for a given residue will not be correlated with the  $\phi$ ,  $\psi$  angles for all the other residues, and will exclusively report on the conformational space that the residue is sampling (Smith et al., 1996). A database analysis of residues in coil regions of known structures of proteins, i.e. residues not in  $\alpha$ -helices and not in  $\beta$ -sheets, has determined the intrinsic residual preferences for amino acids, in the absence of interactions stabilizing secondary structural motifs. The striking conclusion from such studies is that the distribution of  $\phi$ ,  $\psi$  angles in coil regions of

proteins is far from random, with backbone angles heavily biased to those corresponding to  $\alpha$ -helices and  $\beta$ -sheets. (Serrano, 1995; Swindells et al., 1995). Within this framework, specific residues have preferences for particular areas of conformational space, and these preferences are heavily influenced by neighboring residues (Griffiths-Jones et al., 1998). Nevertheless, the high population of  $\alpha$  and  $\beta$  space predicted for residues in a random coil does not itself imply a persistent population of  $\alpha$ -helices or  $\beta$ -sheets, since such population requires repeated values (at least five) of the appropriate  $\phi$ ,  $\psi$  dihedral angles along a given sequence (Smith et al., 1996). Questions remain, however, regarding the length scale over which the distribution of  $\phi$ ,  $\psi$  torsion angles becomes uncorrelated, giving rise to the concept of persistence length of the chain, which could define some sequence-local structure (McCarney et al., 2005).

#### **1.4.2. Structural studies on the unfolded state of proteins**

Investigation of non-native states of proteins is now possible through a wide variety of techniques, which provide information on global parameters, such as the radius of gyration or sedimentation coefficient, and on local properties of the chain, like the NMR-derived constraints (Table 1.2).

The concerted use of several of these techniques is necessary, due to the very flexible nature of the chain and to the absence of a defined conformation. Different properties of the polypeptide are probed by each of these methods which provide complementary information to characterize such dynamic state. However, in particular for the study of the denatured state of proteins, it has been difficult to reconcile the results arising from many of these methods. For example, the overall topology of the unfolded state fits the expected for a random coil polymer, deprived of conformational preferences, challenging fluorescence and NMR-derived parameters, which unequivocally show the presence of long-range and residual local structure (Smith et al., 1996; McCarney et al., 2005).

This scenario rise the important question as to what extent are the structures of unfolded proteins disordered. It also points towards how general are structural propensities in unfolded proteins, questioning whether they are sequence-specific or denaturant-induced (Baldwin, 2002). Recently, computer simulations on ensemble-averaged structural coil models have reconciled this view (Bernado et al., 2005b; Jha et al., 2005a). The presence of defined local backbone structure in unfolded proteins suggests that conformations populated under strong denaturing conditions are not as heterogeneous as previously supposed, with a

consequent reduction in the entropy of the unfolded state relative to predictions from the random coil model (Fitzkee and Rose, 2004).

Technique	Information content
Ultracentrifugation	Sedimentation coefficient, shape.
Dynamic Light Scattering	Diffusion coefficient, hydrodynamic radio
X-ray, Neutron Scattering	Radius of gyration (small angle scattering)
Circular Dichroism	Secondary structure content
FTIR Spectroscopy	Secondary structure content
Raman Spectroscopy	Secondary structure content
EPR Spectroscopy	Local order, distances via couplings.
Fluorescence Spectroscopy	Denaturation by exposure of Trp residues or by binding of fluorescent dyes. Distribution of distances by FRET. Size changes by anisotropy.
NMR Spectroscopy	Hydrodynamic radio by pulse field gradient NMR. Secondary structure by backbone chemical shifts. Order parameters and fast backbone dynamics by $^{15}\text{N}$ and $^{13}\text{C}$ relaxation. Slow backbone dynamics and local structure by RDCs Long range distance information on the ensemble by paramagnetic spin labels. $\Phi / \Psi$ angles via coupling constants and NOEs. Low populated states by relaxation dispersion.

**Table 1.2. Methods to study conformational properties of the unfolded state of proteins.** Adapted from (Smith et al., 1996; Dyson and Wright, 2004).

A considerable body of data has been generated to date on the denatured state of proteins, providing structural details on the conformations that are particularly populated. The

most important characteristics of unfolded polypeptides can be summarized as follows: (i) the global dimensions of the denatured states of proteins exhibit the size dependence expected for self-avoiding random coil polymers, as measured by hydrodynamic methods and small angle X-ray scattering (SAXS); (ii) they possess very little residual secondary structure as probed by circular dichroism (CD), Fourier-transform infrared spectroscopy (FTIR), although Raman spectroscopy suggests the existence of some PII helical conformations, as is often supported by CD; (iii) the random coil behavior of the backbone is observed through NMR measurements of chemical shifts, though  $\phi$  dihedral angles measured through  $^3J_{\text{HNH}\alpha}$  couplings suggest preferential sampling of helical conformations, indicative of  $\alpha$ -helix or PII conformations; (iv) significant degrees of local residual structure are detected by NMR Residual Dipolar Couplings (RDCs), which probe the orientation of bond vectors relative to an alignment tensor fixed in the molecular frame; (v) the long range interactions and native-like topology are evidenced for some proteins, even at high denaturant concentration, detected by NMR Paramagnetic Relaxation enhancement (PREs) and single-molecule Förster resonance energy transfer (FRET); and (vi) the persistence of hydrophobic clusters could be probed by NMR relaxation or Trp fluorescence quenching.

### **1.4.3. Structural studies on $\alpha$ -synuclein**

Intrinsically unstructured proteins have challenged the paradigm of the structure-function relationships in current biology since they are now recognized to play essential roles in transcription, translation and signal transduction pathways. A disorder-to-order transition induced in natively unfolded proteins during the binding of specific targets in vivo represents a simple mechanism for the regulation of numerous cellular processes (Dyson and Wright, 2005). The absence of defined structure allows disorder regions of proteins to attain functional plasticity in physiological states of cells but also represents an easy target for misfolding, leading often to disease conditions (Uversky, 2002).

High resolution structural studies of natively unfolded proteins are very difficult, since they can not be studied by means of crystallography or standard NMR spectroscopic techniques. It is only now, with the advent of higher field spectrometers and more powerful computer methods, that NMR spectroscopy is able to reveal the unfolded state of proteins at atomic resolution (Dyson and Wright, 2004).

A large variety of biophysical and biochemical methods has been applied for the structural description of these proteins, and  $\alpha$ S is no exception. Briefly,  $\alpha$ S has been studied using CD, intrinsic and extrinsic fluorescence, SAXS, light scattering, FTIR and

heteronuclear NMR (reviewed in (Uversky, 2003)). These data demonstrate that  $\alpha$ S is essentially disordered but surprisingly adopts a more compact conformation than the one expected for a random coil configuration (Uversky et al., 2002). Nevertheless, previous NMR determinations were unable to provide evidence for structural constraints in  $\alpha$ S, only suggesting a slight tendency of the N-terminal domain to adopt  $\alpha$ -helical conformations (Eliezer et al., 2001). Changes in secondary structure are visible in the far-UV CD spectrum of  $\alpha$ S, when the protein is exposed to conditions of high temperature or low pH, data that correlate with the increment of fibrillation. This conclusion led to the hypothesis that the process of  $\alpha$ S fibrillation may be dramatically accelerated by the partial folding of the intrinsically unstructured protein, and suggests that this conformation is a key intermediate along the fibril-forming pathway (Uversky et al., 2001b). However, all these methods have failed to reveal information regarding the early structural transitions that take place on  $\alpha$ S under fibrillation conditions.

Inasmuch as there is not structural model for the ensemble of conformers that  $\alpha$ S populates, no information is available on the transitions that take place on the protein under conditions conducive to self-oligomerization. Such information is necessary to shed light into the mechanism of amyloid deposition and toxicity in PD, as it will be very valuable for the rational design of therapeutic agents.

## *Aims of the Thesis*

---

## 2. Aims of the thesis

The misfolding, oligomerization and amyloid formation of the small pre-synaptic protein  $\alpha$ S are believed to be central to the development of neurodegenerative disorders as Parkinson's disease (PD) and dementia with Lewy bodies. The mechanisms by which the innocuous, presumably natively unfolded,  $\alpha$ S protein oligomerizes and forms neurotoxic species are yet elusive, mainly due to the conformational flexibility inherent to this kind of proteins.

Since PD is primarily a sporadic disease, and  $\alpha$ S is an abundant protein in the neuronal cytoplasm of healthy individuals, it is believed that a conformational change has to occur in the protein in order to trigger its oligomerization. The hypothesis of this thesis work was that, although devoid of secondary structure, the ensemble of conformations that  $\alpha$ S populates may account for long-range interactions which aid the protein to remain soluble and avoid aggregation. Thus we have sought to employ high resolution NMR to determine the presence of contacts between different domains of the polypeptide chain in the native state of the protein. In addition, the study of the protein under aggregation prone states, namely binding of polyamines or transition metals, high temperature, or presence of genetic mutations, would provide information on the early structural transitions that render  $\alpha$ S oligomerization.

The results obtained in this study are divided in 4 chapters. The first chapter describes that  $\alpha$ S is not a true random coil and rather populates compact conformations which account for long range interactions. We report the application of a set of NMR-based experiments optimized for the study of unfolded states of polypeptides, which provide residue-specific information on the structure and dynamics of the ensemble of conformations that  $\alpha$ S adopts in solution. We further prove that these long range interactions are impaired upon chemical denaturation of the protein or upon binding of polycations or increase of temperature.

Chapter 2 describes the application of the above mentioned set of experiments to two mutants of  $\alpha$ S linked to early-onset PD. We show that long range contacts are altered in the A30P and the A53T  $\alpha$ S mutants and that these proteins populate destabilized conformations and easily overcome the energetic barrier for self association.

A comprehensive NMR-based characterization of the homologous protein  $\beta$ S is provided in chapter 3. This protein, a member of the synuclein family of proteins, does not aggregate and is proposed to inhibit  $\alpha$ S neurotoxicity. We assigned the backbone resonances of  $\beta$ S and studied the conformations populated by this natively unfolded protein. We show

the absence of long range interactions in  $\beta$ S and identify regions with a particular tendency to adopt conformations rich in residual structure.

In chapter 4 the formation of complexes between  $\alpha$ S and transition metals, known from epidemiological studies to increase the risk of neurodegeneration, is systematically studied. We report that the only divalent metal ion which significantly interacts with  $\alpha$ S at physiological conditions is Cu(II), and show that it binds to the N-terminal domain of the protein. Based on different low and high resolution spectroscopic techniques we propose a common link between Cu(II) binding to  $\alpha$ S and the formation of Cu(II) complexes in other amyloid proteins.

A final summarizing discussion provides evidence for the origin of the long-range interactions in the native state of  $\alpha$ S and suggests that conformational restrictions in  $\alpha$ S arise in the ns to  $\mu$ s timescale, only probed successfully by our experimental setup. The biological significance of our findings is discussed herein and the implications for the design of wide-ranging anti- $\alpha$ S oligomerization drugs are further commented.

In the Appendix, the set up of a variety of fluorescence-based techniques to study  $\alpha$ S is shown. Lifetime and time-resolved anisotropy measurements were taken on fluorescently labeled  $\alpha$ S and  $\beta$ S proteins, and information on the local motions of the polypeptide chain was obtained. The data, although preliminary, is complementary to the main results of this thesis, and represent the first steps towards the characterization of the aggregation mechanism of  $\alpha$ S by means of intrinsic fluorescence probes.

## *Materials and Methods*

### 3.1.3. Reagents.

During the development of the present thesis work the following reagents from the mentioned suppliers were employed:

Restriction enzymes and buffers used for digestion of DNA were from NEB, while the site directed mutagenesis kit was from Stratagene. Primers were synthesized by Metabion, Martinsried Germany. Agarose gels (1.5 %) were prepared with agarose (Gibco, Invitrogen) dissolved in 1 x TBE buffer (Roth, Karlsruhe, Germany) and supplemented with 1  $\mu$ g/ml ethidium bromide (Merck, Darmstadt, Germany).

SDS-Polyacrylamide gel electrophoresis was performed with buffers (SDS-MES), pre-cast ready-to-use gels (10 % and 12%) and Coomassie stain (Simply Blue safe stain) from Invitrogen, following instructions from the supplier.

For NMR measurements,  $^{15}\text{NH}_4\text{Cl}$ ,  $^{13}\text{C}$ -D-glucose and  $\text{D}_2\text{O}$  were purchased from Cambridge isotope laboratories, Andover, MA. The paramagnetic nitroxide spin label MTSL (1-oxy-2,2,5,5-tetramethyl-D-pyrroline-3-methyl)-methanethiosulfonate was from Toronto Research Chemicals, Toronto, Canada. The phages solution employed for the alignment of proteins was Pfl from Asla, Riga, Latvia, and the liquid crystal phase employed for alignment were prepared with *n*-octyl-penta(ethylene glycol) ( $\text{C}_8\text{E}_5$ ) and octanol, or with *n*-dodecyl-penta(ethylene glycol) ( $\text{C}_{12}\text{E}_5$ ) and hexanol, all from Sigma.

The natural polyamines spermine, spermidine and putrescine were from Sigma and Fluka, while urea and guanidinium hydrochloride were from Sigma.

The salts employed for the studies with metal ions were  $\text{CuSO}_4$ ,  $\text{NiSO}_4$ ,  $\text{MnCl}_2$ ,  $\text{CoCl}_2$ , and  $\text{FeCl}_2$ , of the highest purity available, from Merck or Sigma. The reagents employed for quantization of the metals in solution were 4-(2-pyridylazo)resorcinol (PAR), Fura-2 pentapotassium salt and 1,10-Phenanthroline, and were purchased from Sigma, Molecular Probes (Invitrogen) and Fluka (Sigma), respectively.

## 3.2. Methods.

### 3.2.1. Molecular biology.

All molecular biology experiments described here were performed at the Department of Molecular Biology, MPI-BPC.

#### 3.2.1.1. $\alpha$ S-containing plasmids.

The coding sequences for wild type (*w*t) human  $\alpha$ S and the two genetic mutants A30P and

A53T were kindly provided by Dr. Peter Lansbury, Harvard Medical School, Cambridge, MA. All the three constructs were cloned *NdeI/EcoRI* in the plasmid PT7.7 (Tabor, 1990), under the strong promoter T7.

The construction of the C-terminal deletion of  $\alpha$ S ( $\alpha$ S1-108) was already reported elsewhere (Hoyer et al., 2004).

### 3.2.1.2. $\beta$ S-containing plasmids.

The cDNA sequence of human  $\beta$ S was isolated from a cDNA sample obtained from RT-PCR of total mRNA from human brain (a kind gift from Dr. L. Pardo, MPI-EM, Göttingen), via PCR using the specific primers  $\beta$ S-*wt*-Fwd and  $\beta$ S-*wt*-Rev, containing *NdeI* and *HindIII* restriction sites for cloning (Figure 3.1). The amplified product was ligated in the plasmid pT7-7 employing *NdeI/HindIII* sites and transformed into *E. coli* DH5 $\alpha$ . The nature of the DNA cloned product was validated by DNA sequencing.

**Figure 3.1. Amplification of the cDNA coding for  $\beta$ S.** **A.** Primers used for amplification of  $\beta$ S cDNA. **B.** 1.5% agarose gel showing successful PCR-based amplification of  $\beta$ S DNA on the sample using as template cDNA derived from coding mRNA (+). Negative control shows no amplification on the sample using cDNA derived from non coding mRNA (-) as template.

### 3.2.1.3. Construction of $\alpha$ S and $\beta$ S Cys-containing mutants.

In order to provide an attachment site for the nitroxide spin label employed in PRE studies, three different  $\alpha$ S cysteine-containing mutants Ala<sup>18</sup>Cys (A18C), Ala<sup>90</sup>Cys (A90C), and Ala<sup>140</sup>Cys (A140C) were constructed on the *wt*, A30P and A53T protein using the Quick-Change site directed mutagenesis kit (Stratagene, La Jolla, CA) and following the manufacturer's protocol. Briefly, for each mutant two complementary 20-30 bp DNA primers are designed, containing the point mutation in the center of the primer plus long (~ 12 basis) flanking sequences on both 5' and 3' directions. These 5' and 3' branches are complementary

to the sequence flanking the site of the mutation, allowing the annealing of the primers to the *wt* DNA (parental).

**Table 3.1. DNA primers employed for the construction of Cys-containing mutants.** Sequence of DNA primers forward (F) and reverse (R) employed for the construction of the Cys-containing mutants in αS and βS. The combination of primers used in *wt* αS was further employed for the construction of the same substitution mutants in A30P and A53T αS.

The PCR is carried out with sense and antisense primers in the same reaction tube, each of them promoting the full-length amplification of the two strands of the DNA plasmid. After the amplification, two populations of DNA are found, the parental circular DNA, which does not contain the mutation, and the amplified linear DNA which harbors the substitution. The parental, *wt*, DNA is selectively degraded by addition of the enzyme *DpnI*, an exonuclease recognizing methylated DNA (only the one synthesized in bacteria). The amplified mutant DNA is then transfected into chemically competent bacteria (*DH5α*), which recognize the DNA as a plasmid and catalyse both the circularization and synthesis of the complementary strand. Successful transformation is determined by the selection marker of the vector, ampicilline resistance. Ten transformants are selected for screening and plasmid DNA is obtained through a small scale preparative procedure (miniprep). Incorporation of the desired modifications are afterwards verified by DNA sequencing. The rate of success of the methodology was greater than 80 % in all the cases. Once sequenced, plasmids are transfected into *E. coli* BL21(DE3) in order to achieve a high level of protein expression.

The cysteine-replacements on βS mirror the ones employed for αS studies, and were selected to report long range interactions on the protein. The Ala<sup>18</sup>Cys (A18C) and Ala<sup>79</sup>Cys (A79C) βS cysteine-containing mutants were constructed using the same protocol as for αS

mutants. The primers employed are described on table 1. The introduced modifications were further verified by DNA sequencing.

### **3.2.2. Protein biochemistry**

All experiments described in this section were performed at the Department of Molecular Biology, MPI-BPC.

#### **3.2.2.1. Expression and purification of $\alpha$ S and $\beta$ S.**

The same protocol was applied for purification of all the  $\alpha$ S variants, as well as for  $\beta$ S production. Following transformation, *E. coli* BL 21 cells were grown overnight in 10 ml of LB medium containing 100 $\mu$ g/ml ampicillin. The pre-culture was diluted (10 ml in 1 l LB containing 100  $\mu$ g/ml ampicillin) and allowed to grow at 37°C until an O.D of 0.6-0.8. Expression of the desired gene construct was then induced with 1 mM IPTG (Roth, Karlsruhe, Germany). Cells were then harvested, after 3-4 hours of incubation at 37 °C, by centrifugation at 3000 x g for 10 minutes.

The bacterial pellet was resuspended in 10 ml of 10 mM Tris-HCl, pH 8.0, 1 mM EDTA and 1 mM PMSF, and lysed by multiple freeze-thaw cycles and sonication. The cell lysate was boiled for 20 minutes and centrifuged at 20000 x g (30 minutes at 4 °C), in order to precipitate the heat-sensitive proteins (synucleins remain soluble). Streptomycin sulphate (Sigma) was added to the supernatant from the previous step (final concentration 10 mg/ml) for precipitation of DNA. The mixture was stirred at 4 °C for 15 minutes, followed by centrifugation at 20000 g (30 minutes at 4 °C). The synuclein protein ( $\alpha$ S or  $\beta$ S) was then precipitated by addition of ammonium sulphate (Merck, Darmstadt, Germany) (361 mg/ml) to the supernatant from previous centrifugation. The solution was stirred at 4°C for 15 minutes and centrifuged once again at 20000 x g (30 minutes at 4 °C).

The protein pellet was resuspended in 20 ml of 25 mM Tris-HCl, pH 7.7, and loaded onto a POROS HQ/M anion exchange column (PerSeptive Biosystems, Cambridge, MA) in a Biocad 700E perfusion chromatography workstation (Applied Biosystems, Foster City, CA), equilibrated with 25 mM Tris-HCl, pH 7.7. Full length  $\alpha$ S and  $\beta$ S proteins were eluted with a salt gradient at ~ 300  $\mu$ M NaCl. The C-terminal truncated mutant of  $\alpha$ S was eluted in the flow trough, since lacking the acidic C-terminus impaired ability of the protein to bind to the column. The fractions containing protein (determined spectrophotometrically) were pooled together and concentrated using Centriprep YM-10 filter devices (10000 Da molecular weight cut off) (Amicon, Bedford, MA) to a final concentration of ~ 300 mM. Concentrated

proteins were dialyzed overnight against the desired buffer (buffer A, 25 mM Tris-HCl, pH 7.4, 100 mM NaCl or buffer B, 20 mM MES, pH 6.5, 100mM). Purity of the protein was assessed by SDS-PAGE and the concentration was determined with absorbance at 275 nm using an extinction coefficient of  $5600 \text{ M}^{-1} \text{ cm}^{-1}$ , for the full length proteins, or  $1460 \text{ M}^{-1} \text{ cm}^{-1}$  for the C-terminally truncated. Proteins were aliquoted, flash frozen in liquid  $\text{N}_2$  and stored at  $-80 \text{ }^\circ\text{C}$ .

Purification of Cys-containing mutants was performed similarly to *wt* proteins but 1 mM dithiothreitol (DTT) (Roth, Karlsruhe, Germany) was included throughout the different purification steps in order to avoid Cys oxidation and disulfide-linked dimer formation.

Preparation of  $^{15}\text{N}$ - and  $^{13}\text{C}/^{15}\text{N}$  labelled proteins was carried out exactly as for the non-labelled proteins with the only difference that LB medium was replaced by M9 minimal medium supplemented with  $^{15}\text{NH}_4\text{Cl}$  or  $^{15}\text{NH}_4\text{Cl}$  and  $^{13}\text{C}$ -D-glucose (Cambridge Isotope Laboratories, Andover, MA). A 5x stock solution of M9 salts, with the absence of  $\text{NH}_4\text{Cl}$ , was prepared adding 64 g  $\text{Na}_2\text{HPO}_4\cdot 7\text{H}_2\text{O}$  (Sigma), 15 g  $\text{KH}_2\text{PO}_4$  (Sigma), 2.5 g NaCl (Sigma), adding water to a final volume of 1 l and autoclaving. For 500 ml of final culture media 100 ml of M9 5x stock salt solution are mixed with 1 ml of 1M  $\text{MgSO}_4$ , 50  $\mu\text{L}$  of 1 M  $\text{CaCl}_2$ , 0.5 g of  $^{15}\text{NH}_4\text{Cl}$ , 10 ml of 20 % D-glucose ( $^{13}\text{C}$ -D-glucose for double labelled proteins) and autoclaved  $\text{H}_2\text{O}$  to a final volume of 500 ml. The pH of the solution was adjusted to 7.3 and the media was filter-sterilized (0.2  $\mu\text{m}$  filter). Previous to culture, 100  $\mu\text{g}/\text{ml}$  of ampicillin were added.

**Figure 3.2. Expression and purification of  $\beta\text{S}$  in *E.Coli*.** SDS-PAGE following the outcome of the set up protocol for purifying recombinant human  $\beta\text{S}$  from *E. coli*. ### 3.2.2.2. Synthesis of C-terminal peptides of $\alpha$ S.

The C-terminal  $\alpha$ S peptides were kindly synthesized by Kerstin Overkamp at the Department of NMR-based Structural Biology, MPI-BPC. Peptides comprising residues 105 to 136 and 95 to 136 of *wt*  $\alpha$ S were synthesized employing standard solid-phase Fmoc chemistry. The peptides were purified by semipreparative reverse phase HPLC and the purity (>95%) were analyzed by mass spectrometry.

### 3.2.2.3. Spin-labelling of proteins.

Studies of paramagnetic relaxation enhancement by nitroxide spin labels involve the site-directed addition of a nitroxide radical in the evaluated position of the protein. An easy procedure to achieve such a task is to engineer a Cys replacement in the residue that is investigated, with the condition that this one is the only Cys amino acid present in the protein. Thus, a methanethiosulfonate-based nitroxide spin label can be efficiently coupled to the reduced sulfhydryl of the cysteine under physiological buffer conditions.

**Figure 3.3. Reaction of the nitroxide-maleimide MTSL with a Cys residue in the target protein.** Chemical structure of the spin label reagent MTSL and the disulfide bond adduct formed with the side-chain of the single Cys residue in the protein.

The reaction of  $\alpha$ S and  $\beta$ S Cys-containing mutants with the nitroxide spin label MTSL (1-oxy-2,2,5,5-tetramethyl-D-pyrroline-3-methyl)-methanethiosulfonate was carried out essentially as described in Der-Sarkissian et al. (Der-Sarkissian et al., 2003) with some modifications. Briefly, DTT was removed prior to labelling from the buffer using Sephadex-G25 fast desalting columns (PD-10 columns, Amersham Biosciences) and the proteins were equilibrated in 20 mM Tris-HCl, pH 7.4, 100 mM NaCl (or 20 mM MES, pH 6.5, 100 mM NaCl). Free sulfhydryl groups were reacted with a 5-fold molar excess of the MTSL-

maleimide reagent solubilized in acetone, at 4 °C for 16 h, in the dark. Unreacted spin label was removed using PD-10 columns and spin-labeled proteins were concentrated using Microcon YM-3 filter devices (3000 Da molecular weight cut off) (Amicon, Bedford, MA). Complete labelling with the nitroxide radical was verified by mass spectrometry or reaction with DTNB to measure unreacted sulfhydryls. Proteins were aliquoted, fast frozen in liquid N<sub>2</sub> and stored at -80 °C

Importantly, all the buffers employed through the labelling procedure were de-gased under N<sub>2</sub> in order to avoid the presence of oxygen which readily oxidizes the free sulfhydryl of the Cys residue.

#### **3.2.2.4. Alignment of $\alpha$ S in anisotropic media.**

Residual dipolar couplings are orientational restraints that report on the degree of orientation of a <sup>15</sup>N-<sup>1</sup>H or <sup>13</sup>C-<sup>1</sup>H bond respect a molecular alignment tensor. In order to observe non vanishing RDCs the solution in which the protein is dissolved has to be slightly anisotropic, causing all orientations of the protein not to be equally probable (Bax, 2003). Thus RDCs are measurable in solution conditions in which a relatively small population of molecules adopts a net orientation with respect to the externally applied magnetic field. In solution this is possible when the protein experience an asymmetric environment, such as in the presence of liquid crystals. Under such circumstances, a protein will tumble anisotropically, preventing the one-bond internuclear dipoles average to zero. The RDC signal will depend on the degree of asymmetry of the anisotropic environment, and on the defined orientation(s) adopted by the bond vector (Prestegard et al., 2004).

Alignment media for the measurement of RDCs include charged or uncharged lipid bicelles, ether/alcohol lamellar phases, Pfl filamentous phage, purple membranes, and mechanically stressed polyacrylamide gels. We selected for our studies the ether/alcohol liquid crystalline phases, which are uncharged and relatively insensitive to pH and ionic strength (Rückert and Otting, 2000). As a second independent alignment medium we employed Pfl filamentous phage, which are rods 2 μm in length and 6.5 nm in diameter that align under the magnetic field (Hansen et al., 1998). While ether/alcohol phases cause alignment by steric obstruction, Pfl has a negative surface charge and provokes the alignment by charge repulsion (Bax, 2003).

Thus, RDCs were measured in  $\alpha$ S or  $\beta$ S aligned in 10 mg/ml bacteriophage Pfl or in 5 % w/v *n*-octyl-penta(ethylene glycol)/octanol (C<sub>8</sub>E<sub>5</sub>). Pfl phages are commercially available and were used with no further treatment. The C<sub>8</sub>E<sub>5</sub>/octanol phase was prepared as

described by in Alexandrescu and Kammerer (Alexandrescu and Kammerer, 2003). Briefly, C<sub>8</sub>E<sub>5</sub> was added to the protein sample (5% vol/vol) and the pH was checked and further adjusted if necessary. Octanol was added in 1 µl increments to the protein incubated at 10 °C. Formation of the opalescent anisotropic phase was observed after 2-3 µl of added octanol and was stable after a total of 4-5 µl of octanol (final C<sub>8</sub>E<sub>5</sub>/octanol molar ratio 0.75 < *r* < 0.90).

Alignment in the presence of urea was performed by addition of octanol to the sample-urea- penta-ethylene glycol solution. Changing the alignment medium to 5 % w/v *n*-dodecyl-penta(ethylene glycol)/hexanol (C<sub>12</sub>E<sub>5</sub>) (*r* = 0.7) (Sigma) (Rückert and Otting, 2000) allowed RDCs measurements at higher temperatures.

In all cases, the homogeneity and stability of the anisotropic phase was assessed by determining the quadrupolar splitting of the deuterium signal in the NMR sample (Rückert and Otting, 2000).

### 3.2.2.5. Protein aggregation assays.

Aggregation measurements of αS were performed with 100 µM protein samples in buffer A (20 mM Tris-HCl, pH 7.4, 100 mM NaCl) plus 0.01% Na-azide (Sigma), or buffer B (20 mM MES, pH 6.5, 100 mM NaCl) in the case of the studies with metal cations. In all experiments 300 µl of protein sample were incubated in glass vials (Zinsser Analytik, Frankfurt, Germany) at 37 °C under constant stirring (300 rpm) with magnetic microbars.

Determination of the amount of fibril formation at different time points was carried out by the Thioflavin-T assay (Thio-T) (Sigma) (Conway et al., 2000; Hoyer et al., 2002). Briefly, 5 µl aliquots were withdrawn from the assay and diluted in 2 ml of 50 µM Thio-T in 50 mM Glycine buffer, pH 8.0 (or 50 mM MES, pH 6.5 for assays with metal cations). ThioT fluorescence was measured in a Varian Cary Eclipse spectrofluorimeter, with an excitation wavelength of 446 nm. Emission wavelengths from 460 to 600 nm were collected. Fluorescence at 480 nm was employed for determination of the relative content of αS fibrils in the sample.

Analysis of the aggregation traces were performed as previously described, assuming a nucleation polymerization model (Fernandez et al., 2004). Thio-T fluorescence values were normalized to the values at the end of the aggregation assay and the averaged data points were fitted to equation 1:

$$\alpha_{(t)} = \frac{1 - e^{-k_{app} t}}{1 + e^{-k_{app} (t-t_{1/2})}} \quad (1)$$

The quantities  $k_{app}$  and  $t_{1/2}$  are related to the aggregation reaction as follows:

$$K_{app} = k \times \varepsilon \times [\alpha S], \text{ and} \quad (2)$$

$$t_{1/2} = \frac{\ln(\varepsilon \times [\alpha S] / [nc])}{k_{app}}, \quad (3)$$

where  $k$  is the rate constant for incorporation of monomers into growth points located in aggregates,  $[\alpha S]$  = total concentration of  $\alpha S$  monomer units,  $[nc]$  is the concentration of nucleation centers and  $\varepsilon$  denotes the fraction of addition-competent monomer sites in already formed aggregates. This approximation assumes that  $[nc] \ll \varepsilon \times [\alpha S]$ . In all cases, the reported  $t_{1/2}$  values correspond to the average of three to five independent aggregation assays carried out simultaneously.

### 3.2.2.6. Metal content determination in $\alpha S$ -metal(II) complexes.

Cu(II) concentrations were measured using 4-(2-pyridylazo)resorcinol (PAR) (McCall and Fierke, 2000). The calibration curve yielded the relationship  $[\text{Cu(II)}](\mu\text{M}) = (27.1 \pm 0.3) \times \Delta A_{504\text{nm}} + (0.1 \pm 0.1)$ . To estimate  $[\text{Cu(II)}]$  in  $\alpha S$  aggregates, 150  $\mu\text{l}$  of the sample at the end of the aggregation assay were withdrawn and centrifuged at 90,000  $\times g$ . The pellets were separated from supernatants and re-dissolved in 150  $\mu\text{l}$  of 5.75 M GdnHCl. Cu(II) concentrations were then measured in both fractions (supernatants and re-dissolved pellets).

Co(II) and Ni(II) concentrations were also measured using PAR, whereas the fluorescence probe Fura-2 was used for Mn(II) and 1,10-Phenanthroline for Fe(II) (Margerum and Banks, 1954; McCall and Fierke, 2000). The calibration curves yielded the relationships  $[\text{Co(II)}](\mu\text{M}) = (17.3 \pm 0.2) \times \Delta A_{514\text{nm}}$ ,  $[\text{Ni(II)}](\mu\text{M}) = (24.4 \pm 0.2) \times \Delta A_{514\text{nm}}$ ,  $[\text{Fe(II)}](\mu\text{M}) = (84.0 \pm 0.2) \times \Delta A_{500\text{nm}}$  and  $[\text{Mn(II)}](\mu\text{M}) = (1.0 - F/F_0)/0.05$ , where  $F$  and  $F_0$  are the fluorescence of the Fura-2 probe in the presence and absence of the metal ion, respectively.

### 3.2.2.7. Equilibrium dialysis assays.

Equilibrium dialysis was used to determine the binding of transition metals to monomeric  $\alpha S$  at different metal(II) concentrations. 150  $\mu\text{l}$  of a 300  $\mu\text{M}$  metal-free  $\alpha S$  solution in Buffer A were dialyzed for 24 h against 500 ml of the same buffer containing 0, 0.1, 1 or 10  $\mu\text{M}$  solution of metals. The buffer solution was changed every 12 h. Anaerobic conditions were used in the experiments performed with Fe(II). Metal content was determined inside and outside the dialysis container with the above mentioned reagents.

### **3.2.2.8. Chemical modification of His residues in $\alpha$ S.**

The sole histidine residue of  $\alpha$ S was modified using diethylpyrocarbonate (DEPC). Pure DEPC (6.8 M) (Sigma) was diluted in ethanol to a final concentration of 68 mM and added to the protein solution to reach a molar ratio of 5:1 (DEPC:protein). Modification of the residue was monitored by studying the change in absorption at 240 nm. Excess of DEPC was removed from the protein solutions by gel filtration chromatography using spin columns (Biorad).

### **3.2.3. Spectroscopic determinations.**

#### **3.2.3.1. Absorption and CD spectroscopy.**

Visible electronic absorption spectra for the  $\alpha$ S-Cu(II) complexes were acquired from 800 nm to 240 nm on a Varian Cary 100 Scan spectrophotometer (Palo Alto, CA), while CD spectra, also from 800 nm to 240 nm, were acquired with a Jasco 720 spectropolarimeter (Groß-Umstadt, Germany), at the department of Molecular Biology, MPI-BPC.

Cu (II) titration experiments were performed on samples containing 300  $\mu$ M protein in buffer 20 mM MES, pH 6.5, 100mM. Aggregation did not occur under these conditions of low temperature and absence of stirring.

Data were expressed as difference absorbance ( $\epsilon$ ) or circular dichroism ( $\Delta\epsilon$ ) per molar concentration of protein. Spectrophotometric data were fit using the program DynaFit (Kuzmic, 1996).

#### **3.2.3.2. EPR spectroscopy.**

EPR spectra were recorded on a Varian Century-Line 9-GHz spectrometer at the department of Spectroscopy, MPI-BPC. Samples containing 300  $\mu$ M protein in buffer 20 mM MES, pH 6.5, 100 mM NaCl were placed in a standard quartz EPR tube, and immersed in a liquid-nitrogen dewar. The static magnetic field was measured with a Bruker ER 035M NMR magnetometer (Karlsruhe, Germany) and the microwave frequency with a Hewlett-Packard 5345A/5355A frequency counter (Palo Alto, CA).

#### **3.2.3.3. NMR spectroscopy.**

NMR spectroscopy was performed at the department of NMR-based structural biology, MPI-BPC. The following spectrometers, all from Bruker AG (Karlsruhe, Germany), listed in increasing field, were employed alternatively during the thesis work:

- Bruker DRX 600 MHz, triple axis gradient.
- Bruker Avance 600 MHz, with cryoprobe, z-axis gradient.
- Bruker Avance 700 MHz, triple axis gradient.
- Bruker 800 MHz, triple axis gradient.
- Bruker Avance 900 MHz, with cryoprobe, z-axis gradient.

NMR spectra were generally acquired at 15° C on a 100 μM sample of <sup>15</sup>N labeled αS or βS in Buffer A (25 mM Tris-Cl, pH 7.4, 0.1 M NaCl) or B (20 mM MES, pH 6.5, 100mM). Triple resonance experiments were acquired on <sup>15</sup>N-<sup>13</sup>C labeled αS or βS protein, and concentration was raised to 300 μM in order to improve signal to noise ratio and reduce the acquisition time. Aggregation did not occur under these conditions of low temperature and absence of stirring. All spectra were processed and analyzed using nmrPipe (Delaglio et al., 1995), nmrView (Johnson and Blevins, 1994) and SPARKY (Goddard and Kneller).

Several standard NMR-based experiments were acquired on αS and βS proteins, and a comprehensive description of them may be found in the book “150 and More Basic NMR Experiments” written by S. Braun, H.-O. Kalinowski & S. Berger (Braun et al., 1999). However, most of this thesis work was conceived as the application of non-standard NMR techniques, optimized for the study of unfolded states of polypeptides. Thus, a brief theoretical background and description of methods is included for residual dipolar couplings, paramagnetic relaxation enhancement and pulse-field gradient NMR. In addition, a short insight into the <sup>1</sup>H-<sup>15</sup>N HSQC, the most often standard-NMR experiment employed on this work is provided.

#### - <sup>1</sup>H-<sup>15</sup>N-HSQC.

Heteronuclear NMR involves the transfer of magnetization between nuclei of different nature (<sup>1</sup>H, <sup>15</sup>N, <sup>13</sup>C, etc.), however, from a sensitivity point of view, it is highly advantageous to excite the proton (<sup>1</sup>H), followed by polarization transfer to the heteronucleus (<sup>15</sup>N, for example), and subsequently reverse polarization transfer to the proton for detection. Two pulse sequences are based on this proton-detected heteronuclear correlation technique, the heteronuclear double quantum coherence (HMQC) (Bax et al., 1983) and the heteronuclear single quantum coherence (HSQC) (Bodenhausen and Ruben, 1980). The distinction between these two is that spin coherence is stored as multi-quantum (HMQC) or single-quantum (HSQC) during the evolution period (Bax et al., 1990).

The pulse sequence for a basic HSQC experiment is shown in figure 3.4. The experiment employs two INEPT magnetization transfers. The first one creates anti-phase heteronuclear coherence ( $I_Y \rightarrow 2 I_Z S_Y$ ) and the second is used to convert this coherence back to observable magnetization ( $2 I_Z S_Y \rightarrow I_Y$ ). It can be summarized as follows (Mandal and Majumdar, 2004):

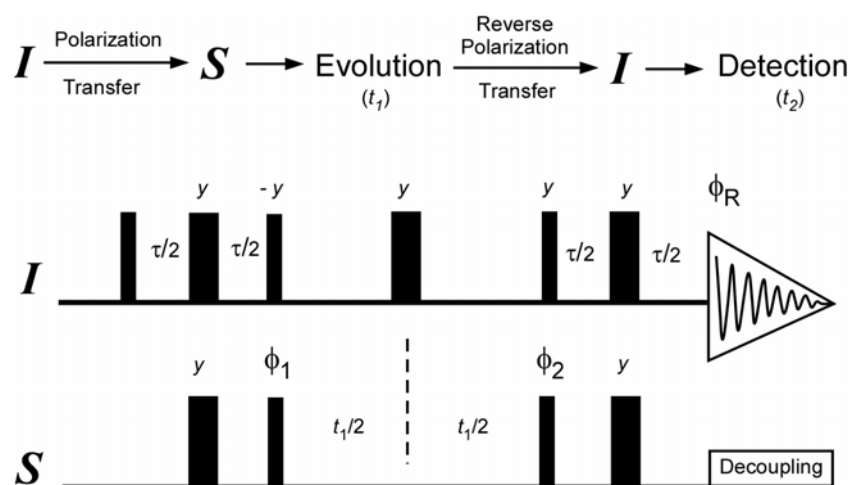

- The first INEPT step creates a proton anti-phase magnetization ( $2 I_X S_Z$ ) during  $\tau$ . To refocus chemical shift modulation during this period, a  $180^\circ$  pulse on both spins is introduced in the middle of  $\tau$  period.

- Coherence is subsequently transferred to the directly attached heteronucleus ( $^{15}\text{N}$  for example) by simultaneous  $90^\circ$  pulses on both spins ( $2 I_Z S_Y$ ).

- The S-spin coherence is frequency-labeled during the  $t_1$  period. The  $180^\circ$  pulse on the I-spin in the middle of  $t_1$  refocuses the evolution of heteronuclear  $J_{IS}$  coupling.

- A  $90^\circ$  pulse on both spins transfer the magnetization back to proton as anti-phase I-spin magnetization ( $2 I_Y S_Z$ ).

- The final spin-echo period converts this anti-phase term into in-phase proton magnetization ( $2 I_Y S_Z \rightarrow I_X$ ).

**Figure 3.4. Fundamental pulse sequence for a HSQC experiment.** Narrow and wide pulses correspond to  $90^\circ$  and  $180^\circ$  flip angles, respectively, with the indicated phase. The delay  $\tau$  is set to  $1/(2 J_{IS})$ . Decoupling of the S-spins during acquisition is accomplished using the Waltz-16 sequence. The basic phase cycling is  $\phi_1$  (x, -x, x, -x),  $\phi_2$  (x, x, -x, -x), and receiver  $\phi_R$  (x, -x, -x, x) is applied in the sequence.

In the conventional HSQC sequence, heteronuclear single quantum evolves under the influence of the S-spin chemical shift during  $t_1$  to yield two-orthogonal terms proportional to  $2 I_Z S_Y$  and  $2 I_Z S_X$ . One of the two anti-phase magnetization terms is not refocused by the reverse INEPT sequence and consequently does not contribute to the final observed

magnetization. Therefore, on average one-half of the initial *I*-spin polarization does not contribute to the detected signal. A sensitivity-enhanced version of this experiment enhances the signal to noise ratio by  $\sqrt{2}$  relative to the phase-cycled version (Palmer et al., 1991). In addition, pulsed-field gradients are used to suppress undesirable coherence pathways and to suppress solvent in a single transient (Zhu et al., 1998).

The outcome of such a pulse sequence is a signal, detected in the proton dimension (F2), which contains information on the chemical shifts of both  $^1\text{H}$  and  $^{15}\text{N}$  nuclei, for a given nitrogen frequency observed. The desired frequency space is sampled by repeating the pulse sequence for variable frequencies on the nitrogen dimension (F1), and the set of one-dimensional spectra is merged in a single bi-dimensional representation, the 2D  $^1\text{H}$ - $^{15}\text{N}$  HSQC spectrum. NH bonds will thus be seen as cross-peaks situated at the intersection between the  $^1\text{H}$  and  $^{15}\text{N}$  resonant frequencies or chemical shifts.

$^1\text{H}$ - $^{15}\text{N}$  HSQC experiments in  $\alpha\text{S}$  and  $\beta\text{S}$  were recorded using 256 x 1024 complex incremental data points in F1 ( $^{15}\text{N}$ ) and F2 ( $^1\text{H}$ ) dimensions, with 8 to 32 scans per increment and a relaxation delay of 1.2 s. The sampled frequency space (sweep width) was in general 26 ppm for the nitrogen dimension (from 106 to 132 ppm, centered in 119 ppm) and 8.6 ppm for the proton dimension (from 0.4 to 9.0 ppm, centered in 4.7 ppm).

*- Measurement of paramagnetic relaxation enhancement.*

Distance restraints between residues in the denatured state of proteins can be obtained by covalently attaching a probe containing a free radical to a unique cysteine residue introduced by mutagenesis. The magnetic interaction between the unpaired electron in the spin label and a proton in the same molecule is similar to the Nuclear Overhauser Effect (NOE) between pairs of protons. Unlike an NOE, whose measurable effect is limited to distances less than  $\sim 5$  Å, the electron-proton interaction extends over approximately 20 to 25 Å, making it a workable probe for distances in the range from 10 to 20 Å (Gillespie and Shortle, 1997a). The parameterization of the magnetic interaction of a free electron with a proton is described by the Solomon-Bloembergen equations (Kosen, 1989), which parameterize the enhancement of the proton's transverse relaxation rate due to the paramagnetic effect (1):

$$R_{2P} = \frac{K}{r^6} \times \left( 4 \tau_c + \frac{3 \tau_c}{1 + \omega^2 \tau_c^2} \right), \quad (1)$$

where  $K$  is  $1.23 \times 10^{-32} \text{ cm}^6\text{s}^{-2}$  for the interaction between a single electron radical and a proton,  $r$  is the vector distance between the spin label electron and the HN proton,  $\tau_c$  is the correlation time for the electron-proton vector (4 ns, as determined for the unfolded state of

---

staphylococcal nuclease, which has a similar size as  $\alpha$ S) (Gillespie and Shortle, 1997a), and  $\omega$  is the Larmor frequency of the proton (dependent on the field at which the NMR experiment is acquired). The equation is based on the assumptions that the vector between the electron and the proton is free to undergo isotropic rotational diffusion and that its length  $r$  is fixed.

The paramagnetic effect is consequently related to the intensity of an amide cross-peak as follows (2) (Battiste and Wagner, 2000):

$$\frac{I_{para}}{I_{diam}} = \frac{R_{2D} \times e^{(-R_{2P} t)}}{R_{2D} + R_{2P}} \quad (2)$$

, where  $I_{para}/I_{diam}$  is the ratio of peak intensities for an amide resonance between the paramagnetic and diamagnetic state of the spin label,  $R_{2D}$  is the transverse relaxation rate of the amide proton measured in the absence of the spin label,  $R_{2P}$  is the paramagnetic enhanced transverse-relaxation rate, and  $t$  is the duration of the INEPT delays ( $\sim 10$  ms) in the HSQC pulse sequence (the proton magnetization is in the transversal plane).

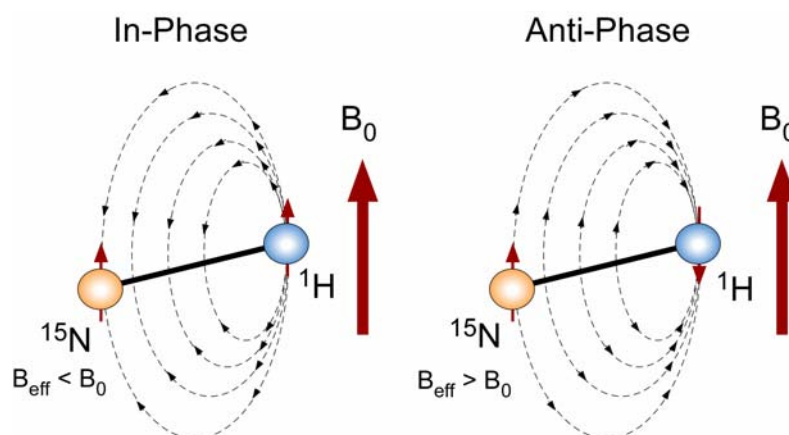

**Figure 3.5. Paramagnetic relaxation enhancement in protein studies.** **A.** The unpaired electron from a nitroxide spin label causes perturbation of amide resonances up to  $\sim 20 \text{ \AA}$  from the attachment site. The paramagnetic effect is measured as an enhancement of proton  $R_2$  transverse relaxation rates ( $R_{2P}$ ), and this effect is related to the distance between the affected amide proton and the spin label ( $r$ ) by the relationship  $R_{2P} \propto r^{-6}$ . **B.** The targeted placement of the spin label provides information on local compaction and long range interactions, useful for the structural characterization of the unfolded states of polypeptides

Paramagnetic relaxation enhancement effects in  $\alpha$ S and  $\beta$ S Cys-containing mutants were measured from the peak intensity ratios between two-dimensional  $^{15}\text{N}$ - $^1\text{H}$  HSQC

experiments acquired in the presence ( $I_{\text{para}}$ ) and absence ( $I_{\text{diam}}$ ) of the nitroxide radical attached to the Cys residue. HSQC experiments were recorded using 256 x 1024 complex data points in F1 and F2 dimensions with 8 scans per increment and a relaxation delay of 1.2 s. The removal of the spin label for measurement of the diamagnetic state was accomplished by addition of 0.5 mM DTT to the protein solution and 30 min incubation at room temperature. The reported intensity ratios are averages over repeated measurements for up to three different protein preparations.

- *Measurement of residual dipolar couplings.*

Dipolar couplings are large interactions caused by the magnetic flux lines of the spins of one nucleus affecting the magnetic field at the spin of another nucleus. The parallel component of the dipolar field of one nucleus ( $^1\text{H}$ , for example) to the external magnetic field ( $B_0$ ) will change the resonance frequency of the bonded nucleus ( $^{15}\text{N}$  for the amide bond), by an amount that depends on the internuclear distance ( $r_{\text{NH}}$ ), and on the orientation of the internuclear vector relative to  $B_0$ .

**Figure 3.6. Occurrence of dipolar couplings.** Magnetic dipole-dipole coupling for a  $^{15}\text{N}$ - $^1\text{H}$  spin pair is illustrated.  $^{15}\text{N}$  and  $^1\text{H}$  magnetic moments are aligned parallel or antiparallel to the static magnetic field  $B_0$ . The effective magnetic field in the  $B_0$  direction at the  $^{15}\text{N}$  position can increase or decrease relative to  $B_0$  depending on the orientation of the  $^{15}\text{N}$ - $^1\text{H}$  vector and the spin state of the proton (parallel or antiparallel to  $B_0$ ) (Bax, 2003).

Thus, for the amide bond, the  $^1\text{H}$  nuclear spin can increase or decrease the total magnetic field at the  $^{15}\text{N}$  nucleus, depending whether is parallel (In-Phase) or antiparallel (Anti-Phase). In an ensemble of molecules, half of the nuclei will be parallel to  $B_0$ , and the other half will be antiparallel, thus the  $^{15}\text{N}$  nucleus will show two resonances (doublet),

separated in frequency by the N-H dipolar coupling ( $D_{NH}$ ) (Bax, 2003). The magnitude of the  $D_{NH}$  is given by (1):

$$D_{NH} = D_{NH}^{\max} \times \langle (3 \cos^2 \theta - 1) / 2 \rangle, \quad (1)$$

where  $\theta$  is the angle between the internuclear bond vector and  $B_0$ , and the brackets denote time and ensemble average. The maximum dipolar coupling for the amide bond is given by (2):

$$D_{NH}^{\max} = -\mu_0 (h / 2\pi) \gamma_N \gamma_H / (4\pi^2 r_{NH}^3), \quad (2)$$

where  $\mu_0$  is the magnetic permittivity of vacuum,  $h$  is Planck's constant, and  $\gamma_N$  and  $\gamma_H$  are the magnetogyric ratios of the  $^{15}\text{N}$  and  $^1\text{H}$  nuclei respectively. The value of the maximum  $D_{NH}$  is 21 KHz, observable only in solids, but it averages to zero in isotropic solution due to the rapid molecular tumbling, giving sharp single resonance cross-peaks for amides. The slight anisotropy provoked by the alignment media causes that not all orientations are equally to occur such that the order parameter  $\langle (3 \cos^2 \theta - 1) / 2 \rangle \neq 0$ , allowing measurement of RDCs in the range of few Hz.

RDCs are generally measured for N-H-groups in non-decoupled, spinstate separated, HSQC-based experiments like the In-Phase-Anti-Phase (IPAP) (Ottiger et al., 1998) or the Doublet Separated Sensitivity Enhanced (DSSE) (Cordier et al., 1999). These experiments are not proton-decoupled during nitrogen evolution and therefore yield the NH-splitting.

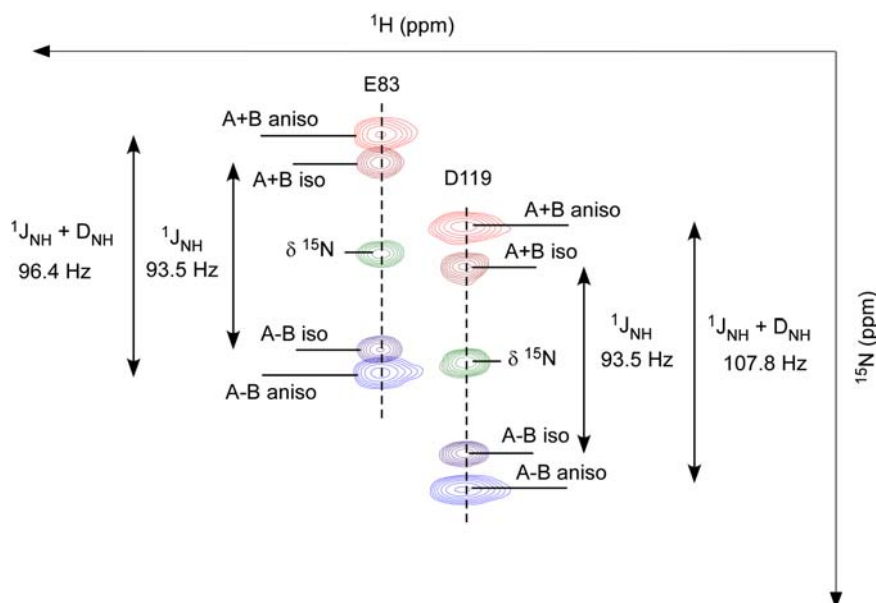

Since in the partial alignment condition used, the value of one-bond N-H RDCs ( $D_{NH}$ ) is rather small ( $< 15$  Hz), an accurate determination of these values is obtained by measuring them simultaneously with the larger one-bond N-H scalar coupling ( $^1J_{NH}$ ) of  $\sim 94$  Hz.  $D_{NH}$  are thus determined as the difference between the NH splitting measured in an anisotropic phase ( $D_{NH} + ^1J_{NH}$ ) and in isotropic solution ( $^1J_{NH}$ ). In addition, to a decreased spectral overlap in the determination of the NH splitting, the two components of the doublets are separated into two different spectra, and thus are recorded in an interleaved manner (A+B spectrum for the Anti-Phase condition and A-B spectrum for the In-Phase condition). Briefly, the IPAP strategy can be described as follows. First, a regular  $^1\text{H}$ -coupled  $^1\text{H}$ - $^{15}\text{N}$  HSQC generates in-phase doublets in the nitrogen dimension. A second HSQC experiment, with a  $^{15}\text{N}$  refocusing period  $\Delta = 2J_{NH}^{-1}$  inserted at the beginning of the evolution period plus a  $90^\circ$  phase decrement on the first  $90^\circ$   $S$  pulse, relative to the regular HSQC experiment, allows detection of anti-phase doublets (Figure 3.7). Evolution during this period is terminated by a  $^1\text{H}$  purge pulse.

**Figure 3.7. Pulse sequence for the IPAP  $^1\text{H}$ - $^{15}\text{N}$  HSQC experiment.** Narrow and wide pulses correspond to  $90^\circ$  and  $180^\circ$  flip angles, respectively, with phase  $x$ , unless indicated. The  $\Delta/2$ - $180^\circ(^1\text{H}/^{15}\text{N})$ - $\Delta/2$ - $90^\circ_{\phi_4}$  sequence (open pulses) is only used in the experiment for generating the anti-phase (AP) spectrum and is omitted for generating the in-phase (IP) spectrum. IP and AP spectra are recorded in an interleaved manner. The low power  $90^\circ_{-x}$  pulses surrounding the final  $^1\text{H}$   $180^\circ$  pulse are part of the WATERGATE solvent suppression scheme. Delay durations:  $\tau = 2.5$  ms;  $\Delta = 5.3$  ms. All gradients are sine-bell shaped with 25 G/cm at their center. Gradient durations:  $G_{1,2,3,4,5} = 2, 0.4, 2, 1, 0.4$  ms. Phase cycling:  $\phi_1 = -y, y$ ;  $\phi_2 = 2(x), 2(-x)$  for IP;  $\phi_2 = 2(-y), 2(y)$  for AP;  $\phi_3 = 4(x), 4(y), 4(-x), 4(-y)$ ;  $\phi_4 = 8(x), 8(-x)$ ;  $\phi_R = x, 2(-x), x$  for IP;  $\phi_R = x, 2(-x), x, -x, 2(x), -x$  for AP. Quadrature detection in the  $t_1$  dimension is obtained by altering  $\phi_2$  (IP) or  $\phi_2$  and  $\phi_3$  simultaneously (AP) in the States-TPPI manner.

We measured  $D_{\text{NH}}$  in  $\alpha\text{S}$  and  $\beta\text{S}$  proteins using the IPAP  $^1\text{H}$ - $^{15}\text{N}$ -HSQC sequence. Spectra were recorded with  $512 \times 1024$  complex data points in F1 and F2 dimensions with 32 scans per increment and a relaxation delay of 1.2 s. Each experiment consisted of the acquisition of a first IPAP determination (A+B-iso and A-B-iso spectra) for the protein in buffer solution, to determine the isotropic contribution to the NH splitting ( $^1J_{\text{NH}}$ ), and a second IPAP determination (A+B-aniso and A-B-aniso spectra) with the protein diluted in the alignment media, which provided the anisotropic + isotropic contributions ( $D_{\text{NH}} + ^1J_{\text{NH}}$ ).  $D_{\text{NH}}$  values were afterwards calculated as the difference between NH splittings measured in the aligned sample and those measured in an isotropic sample (i.e. the RDCs were not corrected for the negative gyromagnetic ratio of  $^{15}\text{N}$ ). RDCs observed under different conditions were normalized according to the size of the quadrupolar splitting of the deuterium signal (relative to RDCs for free  $\alpha\text{S}$ ).

**Figure 3.7. Measurement of residual dipolar couplings.** Scheme showing the different experiments carried out for the determination of NH RDCs ( $D_{NH}$ ) in proteins. A proton-decoupled standard HSQC provides single amide-cross peaks (green), positioned at the resonant frequency ( $\delta^{15N}$ ). The absence of proton decoupling in the nitrogen dimension allows determination of positive and negative  $^1H$  spin-state contributions to the externally applied magnetic field sensed by  $^{15N}$  nuclei (the peaks are split in two). The one-bond  $^1J_{HN}$  couplings are measured in isotropic solution (buffer) in an interleaved manner, employing the IPAP sequence, resulting in the spectra A+B iso (dark red) and A-B iso (dark blue). The same IPAP experiment is afterwards measured under slight anisotropic conditions (Pfl or  $C_8E_5$  alignment media) to determine  $^1J_{HN} + D_{NH}$ , and the spectra A+B aniso (light red) and A-B (light blue) are obtained, allowing calculation of  $D_{NH}$  by subtraction of the previously determined  $^1J_{HN}$  value. The broadening in the proton dimension observed in anisotropic conditions is caused by  $^1H$ - $^1H$  dipolar couplings.

- *Pulse field gradient NMR.*

Pulse field gradient NMR (PFG) techniques are used extensively to measure translational diffusion in solution (Bernado et al., 2004). In the presence of a spatially inhomogeneous field (a field gradient), transverse magnetization from nuclei located in different points of the sample acquire different phases. This spatially-encoded phase induced by a field gradient can be reversed by the application of a second field gradient with exactly the same spatial distribution and intensity but opposite sign. Due to diffusion, molecules will change their spatial localization between the application of the first and second gradient, and thus they will experience an inhomogeneous total field, causing an attenuation of the measured signal. For unrestricted diffusion of a molecule in an isotropic liquid, the PFG NMR signal amplitude,  $A$ , normalized to the signal obtained in the absence of gradient pulses, is related to the diffusion coefficient  $D$  by (1):

$$A = e^{-(\gamma^2 \delta^2 D (\Delta - \delta/3)) \times g^2}, \quad (1)$$

where  $\gamma$  is the gyromagnetic ratio of the observed nucleus,  $g$  and  $\delta$  are the magnitude and duration of the magnetic field pulses, and  $\Delta$  is the time between the gradient pulses (Stejskal and Tanner, 1965). The term  $\gamma^2 \delta^2 D (\Delta - \delta/3)$  is called the decay rate ( $d_D$ ) and is proportional to the diffusion coefficient. The determination of  $D$  is achieved by acquiring a series of 20 one-dimensional PFG spectra at different gradient strengths, and fitting the decay of the signal intensity to a Gaussian function with the form (2):

$$I_{(g)} = a \times e^{-d_D \times g^2}, \quad (2)$$

where  $I_{(g)}$  is the ratio between the intensity of the signal measured at gradient strength  $g$  and in the absence of gradient, and  $a$  is the pre-exponential factor ( $\sim 1$ ).

The Stokes-Einstein equation relates  $D$  to the hydrodynamic radius,  $R_H$ , as follows (3):

$$D = k_B T / 6 \pi \eta R_H, \quad (3)$$

where  $k_B$  is the Boltzman constant,  $T$  is the temperature of the sample and  $\eta$  is the viscosity of the solution. Thus determination of the  $R_H$  of a polypeptide chain requires the determination of the viscosity of the solution. In order to overcome this, a viscosity probe of known size is included in the determination, usually dioxane (Jones et al., 1997), providing the relationship (4):

$$R_H^{prot} = \frac{D^{ref}}{D^{prot}} \times R_H^{ref} \quad (4)$$

If the standard is placed in the measurement solution together with the protein, the determination of  $R_H$  is thus made relative to the measured decay rates of the individuals components, as follows (5):

$$R_H^{prot} = \frac{d_D^{ref}}{d_D^{prot}} \times R_H^{ref} \quad (5)$$

Pulse field gradient NMR experiments for  $\alpha$ S and  $\beta$ S were acquired at 15 °C on a 200  $\mu$ M unlabeled protein sample dissolved in 99.9 % D<sub>2</sub>O, 20 mM phosphate buffer pH 7.0 (uncorrected), and containing dioxane ( $\sim 20$  mM) as an internal radius standard and viscosity probe (Wilkins et al., 1999). Deuterium oxide was employed instead of water in order to minimize the power level necessary for water pre-saturation. Twenty one-dimensional <sup>1</sup>H spectra were collected as a function of gradient amplitude employing the PG-SLED sequence (Jones et al., 1997). The gradient strength was shifted from 1.69 to 33.72 Gauss cm<sup>-1</sup>, in a

linear manner. Each  $^1\text{H}$  spectrum comprised 32 scans plus 16 steady-state scans. Sixteen K complex points were acquired with a spectral width of 6,000 Hz. The signals corresponding to the aliphatic region of the  $^1\text{H}$  spectra (3.3-0.5 ppm) were integrated and the decay of the signal as a function of the gradient strength was fitted to a Gaussian function to determine  $d^{prot}$ . The same procedure was applied for the dioxane peak ( $\sim 3.6$  ppm) and the  $d^{ref}$  was measured. The  $R_H$  for the protein was calculated from the known  $R_H$  (2.12 Å) for the dioxane and the ratio between the measured  $d^{ref}/d^{prot}$ .

- *Determination of dissociation constants for polyamine-synuclein complexes.*

For the association of a ligand L to a receptor protein P to give the complex PL, the following equilibrium exists (1):

with  $K_{on}$  and  $K_{off}$  being the association (on) and dissociation (off) rate constants.

The dissociation constant  $K_D$  is given by (2):

$$K_D = \frac{[\text{P}] \times [\text{L}]}{[\text{PL}]} = \frac{K_{off}}{K_{on}} \quad (2)$$

where [P], [L] and [PL] are concentrations at equilibrium.

With  $[\text{P}]_0$  and  $[\text{L}]_0$  being the initial concentration of protein and ligand, the equation (2) can be written as follows (3):

$$K_D = \frac{([\text{P}]_0 - [\text{PL}]) \times ([\text{L}]_0 - [\text{PL}])}{[\text{PL}]} \quad (3)$$

Equation (3) can be transformed into a quadratic equation with the solution given in (4):

$$[\text{PL}] = 1/2(K_D + [\text{P}]_0 + [\text{L}]_0) - \sqrt{1/4(K_D + [\text{P}]_0 + [\text{L}]_0)^2 - [\text{P}]_0 + [\text{L}]_0} \quad (4)$$

For a ligand binding to a protein in slow exchange on the NMR chemical-shift time scale, the difference in chemical shift for a given nuclei between the bound and free state relates to the fraction of bound ligand by (5):

$$\frac{[\text{PL}]}{[\text{P}]_0} = \frac{\Delta^{15\text{N}}\delta}{\text{Max } \Delta^{15\text{N}}\delta} \quad (5)$$

where  $\Delta^{15\text{N}}\delta$  is the chemical shift difference of the observed amide nitrogen between the bound and free state and  $\text{Max } \Delta^{15\text{N}}\delta$  is the value at saturation. Equation (5) and can be written as follows to determine the concentration of complex (6):

$$[\text{PL}] = \frac{\Delta^{15\text{N}} \delta \times [\text{P}]_0}{\text{Max } \Delta^{15\text{N}} \delta} \quad (6)$$

Combining equations (4) and (6), the concentration of complex can be expressed in terms of the initial concentration of protein and ligand, and the change in chemical shift measured for the observed amide nitrogen (7):

$$\Delta^{15\text{N}} \delta = \frac{\text{Max } \Delta^{15\text{N}} \delta}{[\text{P}]_0} \times 1/2(K_D + [\text{P}]_0 + [\text{L}]_0) - \sqrt{1/4(K_D + [\text{P}]_0 + [\text{L}]_0)^2 - [\text{P}]_0 + [\text{L}]_0}$$

A non-linear global fit for  $[\text{L}]_0$  to the  $\Delta^{15\text{N}} \delta$  for amide nitrogens of each residue involved in the binding site provides a single  $K_D$  and the corresponding chemical shifts at saturation (Max  $\Delta^{15\text{N}} \delta$ ).

#### - Triple resonance experiments.

To obtain sequence-specific assignments for the backbone of  $\beta\text{S}$ , the following three-dimensional triple-resonance experiments were collected at 900 MHz, employing standard pulse sequences (Ikura et al., 1990):

	Spectrometer field (MHz)	Real points			Spectral width (ppm)		
		$^{15}\text{N}$	$^{13}\text{C}$	$^1\text{H}$	$^{15}\text{N}$	$^{13}\text{C}$	$^1\text{H}$
HNCACB	600	40	70	1024	23	60	9
CBCACONH	900	35	60	1024	23	60	9
HNCO	900	45	25	1024	22	8.8	9
HNCACO	900	64	40	1024	22	8.8	9
		$^{15}\text{N}$	$^{15}\text{N}$	$^1\text{H}$	$^{15}\text{N}$	$^{15}\text{N}$	$^1\text{H}$
HNN	900	35	62	1024	23	23	9
		$^{15}\text{N}$	$^1\text{H}$	$^1\text{H}$	$^{15}\text{N}$	$^1\text{H}$	$^1\text{H}$
HNHA	900	60	128	1024	26	9	9

**Table 3.2. Triple resonance experiments acquired to facilitate the backbone assignment of  $\beta\text{S}$ .** Briefly, the information provided by each experiment is as follows: HNCACB, sequential connectivity via  $\text{C}\alpha$  and  $\text{C}\beta$  ( $i-1$ ,  $i$ ) and  $^{13}\text{C}\alpha$  and  $^{13}\text{C}\beta$  chemical shifts; CBCACONH, complement to HNCACB, shows connectivity via  $\text{C}\alpha$  and  $\text{C}\beta$  ( $i-1$ ), HNCO, sequential connectivity via CO ( $i-1$ ,  $i$ ); HN(CA)CO, sequential connectivity via CO ( $i$ ) and  $\text{C}'$  chemical shifts; HNN, sequential connectivity via amide  $^{15}\text{N}$  ( $i-1$ ,  $i$ )

solves overlap in unfolded proteins; HNHA ( $^3J_{\text{HNH}\alpha}$  coupling constants and  $\text{H}\alpha$  chemical shift constraints). All these experiments were acquired at 15 °C on a 400  $\mu\text{M}$   $\beta\text{S}$  protein sample in buffer B.

Secondary shift values were calculated as the differences between the measured  $\text{C}\alpha/\text{C}\beta$  chemical shifts and the empirical random coil values reported by Wishart *et al.* (Wishart and Sykes, 1994).

$^{15}\text{N}$  relaxation data were acquired with modern versions of pulse sequences based on those described by Farrow *et al.* (Farrow *et al.*, 1995). Spectra used for longitudinal relaxation  $R_1$  analysis were collected using the following relaxation delay times (in ms): 20, 100, 200, 500, 100, and 20.  $R_2$  data were measured using a pulse sequence employing a CPMG pulse train with the following relaxation delays (in ms): 3.8, 19, 38, 57, 114, 228, 2.8, and 228. Duplicate spectra were collected at several time points to estimate uncertainty. The delay between 180 °C pulses in the CPMG pulse train was  $\sim 1$  ms. Resonance heights were extracted and fit as a function of the relaxation delay time using Sparky routines in order to determine  $R_1$  and  $R_2$  relaxation rates. Steady state NOE values are reported as the ratio of peak heights in paired spectra collected with and without an initial period (4 s) of proton saturation during the 5-s recycle delay.

In the case of  $\alpha\text{S}$ , a three-dimensional HNCACB experiment was used to facilitate backbone assignments under denaturing conditions (Bax and Grzesiek, 1993).

#### - Metal-induced paramagnetic broadening.

In a similar manner as occurs with the effect of a nitroxide spin label, the interaction of the free electron from a paramagnetic metal ion with the side chains of residues in a protein causes a perturbation of the magnetic field that is sensed by the nuclei. Thus, through bond or through space electronic interactions account for the broadening of amide resonances up to  $\sim 11$  Å from the binding site of the metal.

For studies of the formation of  $\alpha\text{S}$ -metal complexes  $^1\text{H}$ - $^{15}\text{N}$  HSQC spectra were recorded using 256 x 1024 complex data points in F1 and F2 dimensions with 16 scans per increment and a relaxation delay of 1.0 s. In general, spectra were acquired on 100  $\mu\text{M}$  protein samples in buffer B at 15 °C to avoid protein aggregation. Similarly to PRE studies, for the determination of the paramagnetic broadening caused by binding of the paramagnetic ion, intensities of amide cross-peaks were compared in the presence ( $I_{\text{para}}$ ) and absence ( $I_{\text{dia}}$ ) of the metal in the protein solution. The  $I_{\text{para}}/I_{\text{dia}}$  ratios of 95-105 non-overlapping cross peaks were plotted as a function of the protein sequence to obtain the intensity profiles.

- *Measurement of metal-induced relaxation enhancement.*

Proton longitudinal relaxation rates ( $R_1=1/T_1$ ) were measured with the standard inversion recovery pulse sequence, and the paramagnetic relaxation rate enhancement ( $R_{1p}$ ) determined on samples containing 5  $\mu\text{M}$  Mn(II) and increasing concentrations of  $\alpha\text{S}$  (100-800  $\mu\text{M}$ ). The Mn(II) binding affinity was estimated according to the following equation (1):

$$C_L = C_M (R_{1M}/R_{1p}) - K \quad [1]$$

where  $C_L$  is the protein concentration,  $C_M$  is the metal ion concentration,  $R_{1M}$  is the longitudinal relaxation rate in the paramagnetic site,  $R_{1p}$  is the longitudinal relaxation rate enhancement and  $K$  is the dissociation constant (Bertini and Luchinat, 1996). Equation 1 is valid under fast exchange conditions and if the concentration of the  $\alpha\text{S}$ -Mn(II) complex is always much smaller than  $C_L$ . In these cases, from constant  $C_M$ , a plot of  $1/R_{1p}$  against  $C_L$  gives a straight line;  $R_{1M}$  can be obtained from the slope, and  $K$  can be found from the intercept on the  $C_L$  axis.

### 3.3. Miscellaneous

#### 3.3.1. Calculation of distance restraints from PRE.

Distance restraints were calculated as previously described from the intensity ratio between two  $^{15}\text{N}$ - $^1\text{H}$  HSQC NMR spectra, in the diamagnetic and paramagnetic state of the protein (Gillespie and Shortle, 1997b). The paramagnetic enhanced transverse relaxation rate ( $R_{2p}$ ) was calculated using equation (2) described in PREs measurement section. Experimental values for the diamagnetic transverse relaxation rates ( $R_{2D}$ ) (Bussell and Eliezer, 2001) and the measured intensity ratios for each resonance were used to linearly fit for  $R_{2p}$  (Battiste and Wagner, 2000). This value was inserted into equation (1) (section 3.2.3.3, Measurement of PREs) to calculate the distance  $r$  between each proton and the unpaired electron on the nitroxide radical. The correlation time for the electron-nuclear interaction  $\tau_c$  was set to 4 ns, in agreement with previous studies (Gillespie and Shortle, 1997a). For amides that were broadened beyond detection in the oxidized spectra, an upper limit for the intensity ratio was estimated from the spectral noise in the oxidized spectrum.

#### 3.3.2. Structure determination and analysis.

Structure calculations were performed using Xplor-NIH version 2.0.6 (Schwieters et al., 2003). Torsion angle dynamics were started at 3000 K from a random coil conformation with the temperature reduced to 20 K during simulated annealing, followed by a short energy

minimization. An all atom representation of  $\alpha$ S was used. Structural energy terms from steric repulsion, bond length, bond angles, dihedral angles and favored regions of the Ramachandran map were used.

Intensity ratios for almost the whole N-terminus of  $\alpha$ S A140C were below 0.8. In order to avoid an overly restrained structure, only intensity ratios  $< 0.75$  were regarded as significant for this mutant, whereas a cutoff of 0.8 was allowed for the A18C and A90C mutants. However, changing these cutoff values in a reasonable range did not change the main structural features. Peaks with intensity ratios below these cutoffs were restrained to the calculated distance  $\pm 5 \text{ \AA}$  using a harmonic square well potential. For intensity ratios above these cutoffs, a target distance was calculated from an intensity ratio of 0.9 and the lower distance bound was restrained to  $-5 \text{ \AA}$  of the calculated value. All distances were imposed as restraints between the backbone amide proton of the residue with the cysteine-MTSL group and residue-specific amide protons.

Structure calculations were also performed with a modified version of the *ab initio* structure prediction program ROSETTA that allows inclusion of experimental distance restraints (Simons et al., 1997; Bowers et al., 2000). In using ROSETTA we assumed that despite the high conformational flexibility present in  $\alpha$ S all residues favor a distribution of dihedral angles corresponding to those seen in structures of native proteins in agreement with previous studies (Bolin et al., 1996). Distance restraints were imposed as described above with the modification that no lower bounds were enforced.

Clustering was performed using the molecular dynamics program GROMACS version 3.2.1 with a cutoff of 0.9 nm and 1.0 nm for Xplor-NIH and Rosetta structures, respectively (Lindahl et al., 2001). Atom density maps were calculated using VMD-XPLOR (Schwieters and Clore, 2002) and represent a 5 % amplitude isosurface of the density of atoms in the peptide main chain of the structures comprising each cluster. Average contact maps were generated using MOLMOL (Koradi et al., 1996) and are for structures calculated using Xplor-NIH and ROSETTA.

### **3.3.3. Electron microscopy**

An aliquot was removed from the aggregation incubation mixture and adsorbed onto a carbon film as described (Hoyer et al., 2002). The samples were analyzed with a Philips CM12 electron microscope in an angular dark-field mode.

*Results*

---

#### **4. Results. Chapter I: “NMR identifies long-range auto-inhibitory interactions in the native state of $\alpha$ S”.**

NMR spectroscopy is a very powerful tool for studying the conformation and dynamics of proteins at atomic resolution. In the case of natively unfolded proteins like  $\alpha$ S, heteronuclear NMR is the most suitable methodology to investigate the ensemble of conformations populated by the disordered polypeptide chain (Dyson and Wright, 2004).

With the fundamental aim of elucidating the ensemble of conformations populated by  $\alpha$ S in solution we employed NMR methods developed for the study of denatured and transition states of folded protein, namely paramagnetic relaxation enhancement by nitroxide spin labels and residual dipolar couplings. Thus PREs would report on long range contacts in the protein, and RDCs would detect residual structure in the polypeptide chain. The hierarchy of such structural elements will be assessed by comparison of native and amyloidogenic conditions of the protein.

##### **4.1 Heteronuclear 2D NMR spectroscopy probes conformational transitions on $\alpha$ S.**

$\alpha$ S has been previously studied by NMR both in its native unfolded state and in the state associated to vesicles (SDS-micelles), therefore the assignments of backbone resonances corresponding to both states was available at the beginning of this thesis work (Bussell and Eliezer, 2001; Chandra et al., 2003). In addition, work performed in our laboratory had independently corroborated the assignment of  $\alpha$ S in physiological aqueous solution (Fernandez et al., 2004).

In figure 4.1 a  $^1\text{H}$ - $^{15}\text{N}$  Heteronuclear Single Quantum Coherence (HSQC) spectra of  $^{15}\text{N}$ -labelled  $\alpha$ S is shown. This spectra is acquired with a particular sequence of magnetic pulses and time delays which allows the transfer of magnetization between amide protons and the amide nitrogens of amino acids, and detects the resonances corresponding to the H-N amide bond of each residue in the polypeptide chain (including amino acids side chains and excepting Pro which does not contain any amide proton). Changes in the chemical environment surrounding a particular amino acid can thus be efficiently evaluated by means of intensities or chemical shifts perturbations on resonances of amide protons. Thus, the HSQC sequence will be the method of choice in most of the experiments throughout this work, providing also a combination of adequate spreading of signals and low time required for acquisition of the spectra (45 minutes for a solution of 100  $\mu\text{M}$   $\alpha$ S). However, this type of

experiment does not provide quantitative information about secondary structure propensities, therefore requiring in most cases recourse to triple resonance experiments (Chapter 3).

**Figure 4.1.  $^1\text{H}$ - $^{15}\text{N}$  HSQC spectra of  $\alpha\text{S}$ .** An HSQC spectrum of a 100  $\mu\text{M}$  solution of  $\alpha\text{S}$  protein was acquired at 600 MHz. Solution conditions were Tris-HCl 20 mM, pH 7.4, 100 mM NaCl (buffer A), and the temperature was 15  $^\circ\text{C}$ .

Several features of the polypeptide chain may be evaluated by the mere observation of the characteristics of this spectrum. For example, the lack of defined secondary structure in  $\alpha$ S is evident from the narrow distributions of the resonance on the proton dimension ( $\sim 0.8$  ppm). Another signature of the state of the polypeptide chain is the cluster of resonances as a function of the residue nature, as Gly, Ser and Thr amide crosspeaks, for example, are detected into regions typical of the residue random coil positions (Figure 4.1). These signatures are identical to those of strongly denatured ubiquitin (Peti et al., 2001).

For a completely unfolded polypeptide, most resonances would be expected to be very sharp and detectable (except the ones from the first and second residues). For  $\alpha$ S, under the conditions of pH and temperature evaluated, several peaks diminished in intensity, or were not detected at all. This suggests that the some regions of the protein could be involved in conformational exchange, as observed with molten globules states of proteins or for the natively unfolded HIV-TAT (Schulman et al., 1997; Shojania and O'Neil, 2006b). Indeed, it has been suggested for  $\alpha$ S a reversible intermediate conformational exchange involving the first 100 amino acid residues of the protein (McNulty et al., 2006b).

The affected resonances correspond to residues Met<sup>5</sup>, Lys<sup>6</sup>, Gly<sup>7</sup>, Ser<sup>9</sup>, Lys<sup>10</sup>, Ala<sup>11</sup>, Lys<sup>21</sup>, Thr<sup>22</sup>, Ala<sup>30</sup>, Gly<sup>31</sup>, Lys<sup>32</sup>, Thr<sup>33</sup>, Lys<sup>35</sup>, Ser<sup>42</sup>, Lys<sup>43</sup>, Thr<sup>44</sup>, His<sup>50</sup>, Asn<sup>65</sup>, Gly<sup>73</sup>, Gly<sup>84</sup>, Gly<sup>86</sup>, Ser<sup>87</sup>, Gly<sup>93</sup>, Asn<sup>103</sup> (Figure 4.2, green bars). The weak and medium intensity peaks fall all at the N-terminus and NAC region of the protein, whereas Val residues and the whole C-terminus feature resonances 2 to 4 times higher than the average for the protein.

Interestingly, the intensity of the signals increased at lower pH, but diminished upon increasing the temperature. As shown on figure 4.2 (blue line), a relative increase ( $\sim 2$  folds) was observed for the N-terminal and NAC resonances when the pH in  $\alpha$ S was decreased from 7.4 to 6.5. Conversely, the increase of the temperature to 47 degrees caused a selective and strong reduction of those resonances (Figure 4.2, red line).

**Figure 4.2. Peak height profile for  $\alpha$ S (I).** Peak intensity plot of amide backbone resonances from the spectra of  $\alpha$ S acquired at different solution conditions. **A:** pH 7.4, 288 K (green bars). **B:** pH 6.5, 288 K (blue line). **C:** pH 7.4, 320 K (red line). Several resonances feature reduced intensities, which are not residue-specific (see text). However highest resonances at the N-terminus correspond to Val residues (Val<sup>3</sup>, Val<sup>15</sup>, Val<sup>26</sup>, Val<sup>37</sup>, Val<sup>40</sup>, Val<sup>52</sup>, Val<sup>55</sup>, Val<sup>66</sup>, Val<sup>70</sup>). Number of scans for acquisition were not similar in all the three experiments, thus peak height scales are set at equivalent maximum (resonance corresponding to Ala<sup>140</sup> in all cases).

There are two possibilities to explain the temperature-induced changes, one in terms of the size of the ensemble of conformations populated by  $\alpha$ S, and the other assuming a modulation of the dynamics of partition between conformers of the ensemble. The first line of reasoning would suggest that the backbone of  $\alpha$ S samples a restricted number of conformations at physiological pH and low temperature, since most of the peaks are observed ( $\sim 80\%$  at pH 7.4 and 310K), while a wider ensemble of conformations is accessible at high temperature as the total energy of the system significantly increases, and thus resonances become broader ( $\sim 20\%$  at pH 7.4 and 320 K). The second hypothesis would state that the ensemble of conformations remains identical, but at higher temperatures a greater extent of partitioning between different conformers is achieved, leading to lower signal intensities. Either mechanism would displace the equilibrium towards conformations of the protein that are not significantly populated at native conditions. For  $\alpha$ S it was found that increasing the temperature of incubation to 47 °C caused a radical acceleration of the self-assembly process of the protein, and fibrils form more rapidly ( $t_{1/2}$  of 60 h at 37 °C vs.  $t_{1/2}$  of 12 h at 47 °C). Thus partition towards amyloidogenic conformers is predicted at these conditions.

A different picture was observed at lower pH. Upon reduction of pH there is a significant change in the exchange rates of amide protons which may account for more residues becoming detectable ( $\sim 95\%$  at pH 6.5). However, chemical shifts perturbations were evidenced surrounding the sole residues which could be titrated at such neutral pH, the N-terminus or the His 50 (Pujato et al., 2005). Therefore, intensity changes may also be

caused by structural re-arrangement involving these residues. Indeed, this event has been found to strongly influence the amyloidogenic properties of  $\alpha$ S, since fibrillation rates increased almost 4 fold as the pH of the protein decreased from 7.0 to 6.0 ( $t_{1/2}$  of 80 h at pH 7.0 vs.  $t_{1/2}$  of 6.5 hs at pH 6.0) (Hoyer et al., 2002). It is likely that in  $\alpha$ S a slight change in the pH may facilitate population of particular backbone conformations of the protein.

In line with these findings, the intensity of particular resonances at the N-terminus and NAC region of the protein are enhanced similarly upon polyamine binding to the C-terminus of  $\alpha$ S (Fernandez et al., 2004). As observed in figure 4.3 (dark blue line), upon spermine binding, many resonances, mostly corresponding to Thr and Ser residues at the central hydrophobic domain of the protein, increased  $\sim 2$  fold in intensity. The addition of spermine did not perturb the pH of the solution and thus modulation of exchange rates was not the cause of these intensity changes. It is interesting to note that spermine increases nucleation of the aggregation process up to  $10^5$  folds, resulting in a fast fibrillation of the protein, and that the hydrophobic region selectively affected is the one responsible to initiate fibrillation (Giasson et al., 2001). Thus conformers with amyloidogenic characteristics are present in the ensemble populated by the protein under physiological conditions, and particular modifications on the protein could unbalance the equilibrium towards conformers with higher tendency to self-associate.

**Figure 4.3. Peak height profile for  $\alpha$ S (II).** Plot of peak intensities corresponding to amide backbone resonances from the spectra of  $\alpha$ S acquired at different solution conditions. **A:** pH 7.4, 288 K (green bars). **B:** pH 7.4, 288 K, 3 mM spermine (dark blue line). **C:** pH 7.4, 288 K, 8 M urea (orange line). Under these conditions several resonances feature reduced intensities, in particular at the N-terminus and NAC region. Peak height scales are set at equivalent maximum (resonance corresponding to Ala<sup>140</sup> in all cases) due to different number of scans during acquisition.

One hint on the nature of the ensemble of conformers may also be evaluated from the  $^1\text{H}$ - $^{15}\text{N}$ -HSQC spectrum of  $\alpha$ S under the presence of strong denaturing conditions (Urea 8M).

As observed on figure 4.4, the amide crosspeaks do not significantly deviate from those corresponding to the physiological buffer conditions, confirming the absence of secondary structure in  $\alpha$ S. What can be noticed is that almost all resonances become very sharp as the denaturant is added (Figure 4.3, orange-line), in a similar manner as evidenced with chemically unfolded structured proteins or molten globules (Wijesinha-Bettoni et al., 2001).

This would suggest that addition of denaturant to a native unfolded protein still causes slight structural perturbations able to re-distribute the ensemble of conformations. In addition, a possible scenario is that the mechanisms by which  $\alpha$ S aggregation is triggered could involve population of completely unfolded conformers, as evidenced for many folded proteins (Uversky and Fink, 2004). The mechanisms of urea denaturation are still largely unknown, and it could involve direct binding of urea to the protein surface or indirect perturbation of solvent-mediated hydrophobic interactions, or a combination of these mechanisms.

Altogether, these preliminary data indicate that a conformational change has to occur at the level of the backbone of the protein in order to trigger the transition of the ensemble towards a more aggregation-prone conformational state. It thus can thus be hypothesized that  $\alpha$ S, despite lacking a defined secondary structure, is not a random coil polypeptide, a perception leading to the quest for restricted auto-inhibitory conformations in the native unfolded state of the protein. At this juncture we foresee that the application of other NMR techniques for studying the native state of  $\alpha$ S would serve to uncover such structural rearrangements.

**Figure 4.4.**  $^1\text{H}$ - $^{15}\text{N}$  HSQC spectra of  $\alpha\text{S}$  in 8 M urea. An HSQC spectrum of a 100  $\mu\text{M}$  solution of  $\alpha\text{S}$  protein was acquired at 600 MHz. Solution conditions were buffer A + 8 M urea, and the temperature was 15  $^\circ\text{C}$ .

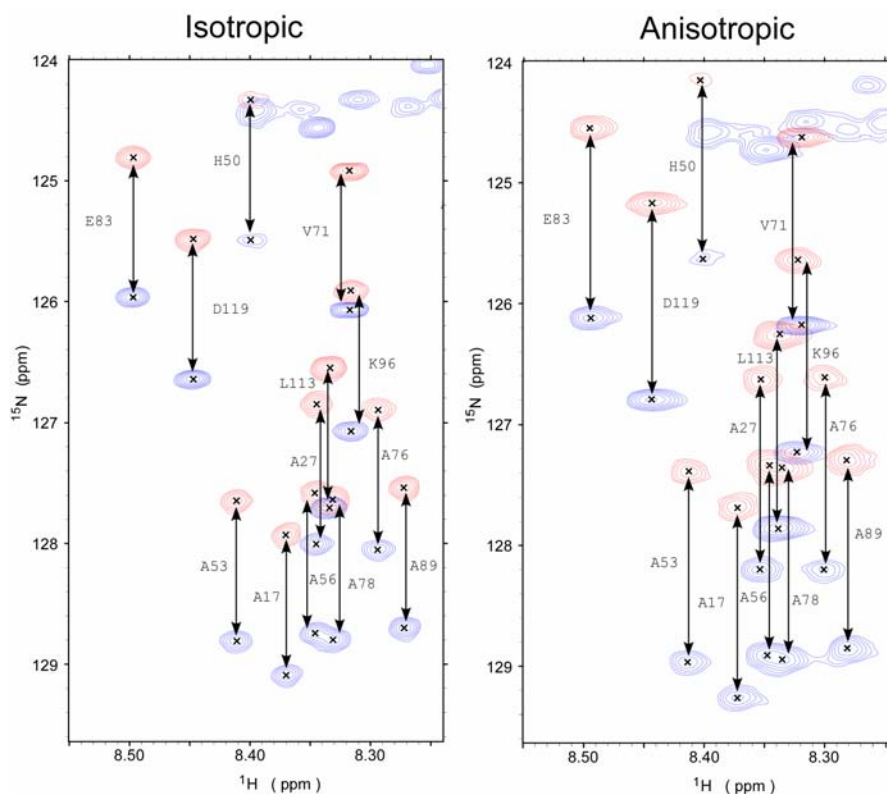

## 4.2. Residual dipolar couplings evidence residual structure in native $\alpha$ S.

The measurement of residual dipolar couplings in a weakly aligned protein, for which the large one-bond internuclear dipolar interactions no longer average to zero, provides long-range orientational information (Tjandra and Bax, 1997). On a folded protein, RDCs report on the orientation of each bond vector relative to the alignment tensor of the entire molecule, while for unfolded proteins, due to the absence of a global alignment tensor, RDCs are attributed to alignment of statistical or valence chain segments, or to transient elements of secondary structure (Louhivuori et al., 2003; Mohana-Borges et al., 2004). In addition, a recent report on a mutant variant of the protein acyl-coenzyme A binding protein (ACBP), showed how RDCs are also reporter on long range interactions in the denatured state (Fieber et al., 2004). Thus RDCs are excellent reporters of residual structure and conformational restrictions in the unfolded states of proteins (Shortle and Ackerman, 2001; Ackerman and Shortle, 2002; Alexandrescu and Kammerer, 2003; Ohnishi et al., 2004).

We decided to apply this technique in the search for structural constraints in the native state of  $\alpha$ S, first evaluating whether structural elements could be identified on the protein, and then whether those elements modulate the re-distribution of the ensemble of conformations upon the amyloidogenic conditions reported above. In addition, the use of urea denatured  $\alpha$ S will provide a reference frame for the observations.

The measurement of RDCs requires the introduction of a slight anisotropic media into the protein solution, in order to allow the net alignment of a fraction of the molecules respect the externally applied magnetic field. A modification of the HSQC pulse sequence has been implemented in order to measure  $^1D_{NH}$  (Ottiger et al., 1998). The so called In-Phase Anti-Phase sequence (IPAP-HSQC), allows measurement of  $^1D_{NH}$  as the parallel (positive) and anti-parallel (negative) contributions to the  $^1J_{NH}$  scalar coupling, providing better accuracy. Thus  $^1J_{NH}$  ( $\sim 93$  Hz) are measured in isotropic conditions (absence of alignment media) and  $^1D_{NH} + ^1J_{NH}$  are measured in anisotropic conditions.  $^1D_{NH}$  are determined as the difference between the couplings measured in the anisotropic conditions and those determined in the isotropic solution (Figure 4.5).

$^1D_{NH}$  were measured for  $\alpha$ S aligned in bacteriophage Pfl suspensions (Hansen et al., 1998) and in *n*-octyl-penta(ethylene glycol)/octanol ( $C_8E_5$ ) (Rückert and Otting, 2000) (Figure 4.6A). The highly reproducible RDC pattern in the two media and the absence of induced chemical shifts changes indicated that the alignment media did not appreciably perturb the ensemble of conformations (Figure 4.6B).

**Figure 4.5. Measurement of RDCs on  $\alpha$ S.** IPAP-HSQC spectra of  $\alpha$ S in buffer A (isotropic) and aligned in 5mg/ml of Pf1 phages (anisotropic). The In-Phase (blue) and Anti-Phase (red) spectra are overlapped to evidence the increment of the  $^1J_{\text{NH}}$  coupling due to the residual dipolar coupling  $^1D_{\text{NH}}$ .

In contrast to the bell-like smooth distribution of dipolar couplings expected for a random coil polypeptide chain (Louhivuori et al., 2003), a very specific distribution of positive couplings was observed for  $\alpha$ S (Figure 4.6). Five different domains could be identified. The N-terminus is subdivided into two regions with similar RDCs (domain I: residues 1-28; domain II: residues 33-65) with a linker sequence showing couplings close to zero (residues 28-32). The NAC domain (residues 61-95) exhibits large couplings about its central core, is flanked by two regions with reduced RDCs (residues 66-70 and 88-92) and is followed by a fourth domain (IV) comprising residues 95-101. The C-terminus (domain V) displays exceptionally large couplings with two major peaks for residues 115 to 119 and 125 to 129.

**Figure 4.6. Residual dipolar couplings in native  $\alpha$ S.**  $^1D_{NH}$  dipolar couplings measured on  $\alpha$ S at 15 °C. **A.** RDCs profile of  $\alpha$ S aligned with 5 mg/ml Pf1 (dark red). Five domains with concerted motions are identified by RDCs (I to V). Functional domains of  $\alpha$ S are display for comparison with the RDCs derived-domains (Bussell and Eliezer, 2001; Giasson et al., 2001; Der-Sarkissian et al., 2003; Fernandez et al., 2004). **B.** RDCs profile of  $\alpha$ S aligned with 5 % C<sub>8</sub>E<sub>5</sub>/octanol mixture (dark red) compared with the couplings profile measured in Pf1 (black line).

The five domains identified by RDCs are consistent with the interpretations of previous biophysical studies (Figure 4.6A, top). A weak  $\alpha$ -helical propensity has been determined for the first domain (Bussell and Eliezer, 2001), while RDC domain III overlays with the center of the NAC region. Domains II, III and IV represent the part of  $\alpha$ S that is highly ordered in fibrils (Der-Sarkissian et al., 2003) and domain V comprises the polyamine binding site (Fernandez et al., 2004).

The 100 N-terminal residues of  $\alpha$ S assume a  $\alpha$ -helical conformation upon binding to phospholipid membranes with helix fraying for residues 30 to 42, residues 60 to 65 and 82 to 100 (Chandra et al., 2003). These regions of helix fraying roughly correlate with the hinge regions between RDC domains I and II, II and III and the small RDC domain IV, indicating

that the manner in which  $\alpha$ S interacts with membranes is already encoded in its solution state.

Linker regions with couplings close to zero can be rationalized by the presence of residues with predominantly small side chains (Ala<sup>29</sup>-Ala<sup>30</sup>-Gly<sup>31</sup>, Gly<sup>67</sup>-Gly<sup>68</sup>-Ala<sup>69</sup> and Ala<sup>89</sup>-Ala<sup>90</sup>-Ala<sup>91</sup>). Local interactions between side chains and the backbone are minimized enabling higher flexibility of the polypeptide backbone and effectively decoupling the five domains exhibiting concerted motion.

Computer simulated RDCs on random coils reported earlier that a flexible polypeptide chain would give a flatten pattern of couplings, but recent refinement of the model including steric hindrance between residues, which limit the main chain  $\phi$  and  $\psi$  angles, demonstrated that RDCs are indeed sensitive to residue-based conformational restrictions (Louhivuori et al., 2004). Thus local regions with residual structure would adopt a defined alignment and display high RDCs, while stretches of residues with enhanced flexibility would decrease the magnitude of alignment and report lower coupling values. Our observations are in agreement with this theoretical framework, as well as with other experimental evidences (Mohana-Borges et al., 2004).

The highly acidic C-terminus of  $\alpha$ S exhibited very large dipolar couplings, which were modulated by the residual structure of this domain. Addition of 4 and 8 M urea progressively decreased the RDC values in this region down to a magnitude similar to the rest of the protein, while other features remained stable (Figure 4.7).

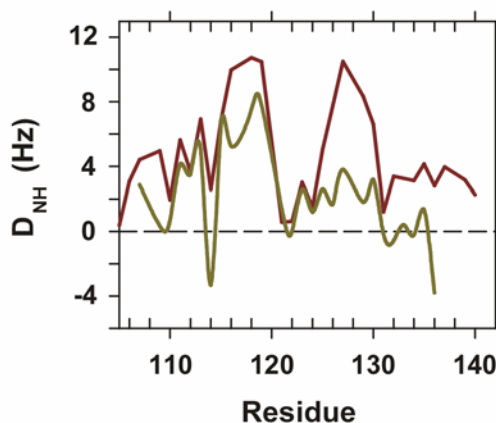

**Figure 4.7. Residual dipolar couplings in urea denatured  $\alpha$ S.**  $^1D_{NH}$  dipolar couplings measured on  $\alpha$ S aligned with 5 % C<sub>8</sub>E<sub>5</sub>/octanol mixture (dark red) and in the presence of 4 M Urea (cyan) and 8 M urea (dark blue).

Since urea mainly abolishes hydrophobic interactions, the RDCs are suggestive of a hydrophobic cluster in the C-terminus involving residues 115 to 119 (Met<sup>116</sup>, Val<sup>118</sup>) and 125

to 129 (Tyr<sup>125</sup>, Met<sup>127</sup>). The 30 % smaller RDC values for residues 75 to 81 in 8 M urea (Figure 4.7) and the strong paramagnetic broadening of the C-terminus for the A90C mutant (see below), identify the hydrophobic NAC region as major contributor.

Additional information about the long-range nature of the hydrophobic cluster was derived from RDCs measured for a C-terminal peptide of  $\alpha$ S (residues 105-136). Although the overall RDC patterns for the peptide and the full-length protein were similar (Figure 4.8), the two regions showing very large RDCs in case of the full-length protein were reduced, particularly for residues 125-129, suggesting that long-range interactions with other domains of the protein serve to stabilize this intrinsic structure.

<sup>105</sup> EGAPQEGILEDMPVDPDNEAYEMPSEEYQDY <sup>136</sup>

**Figure 4.8. Residual dipolar couplings of an  $\alpha$ S C-terminal peptide.** A peptide comprising residues 105 to 136 from  $\alpha$ S was synthesized and  $^1D_{NH}$  dipolar couplings were measured for the peptide aligned in 5 % C<sub>8</sub>E<sub>5</sub>/octanol mixture (dark yellow). Couplings are compared with RDCs from the C-terminal region obtained under the same alignment condition of the full length  $\alpha$ S protein (dark red).

### 4.3 Paramagnetic resonance enhancement on $\alpha$ S detects long range interactions.

The identification of long range interactions in  $\alpha$ S by RDCs prompt us to investigate further the occurrence of such contacts between different domains of the protein employing NMR paramagnetic resonance enhancement (PRE) by nitroxide spin labels. Site-directed spin labeling by nitroxide tags provides a valuable tool for determining long-range structure in denatured states of proteins, and has been widely used to study characteristics of the ensemble of conformations in folding intermediates (Gillespie and Shortle, 1997a; Lietzow et al., 2002; Teilum et al., 2002; Lindorff-Larsen et al., 2004). The interaction between a specifically attached paramagnetic nitroxide radical and nearby ( $< \sim 25$  Å) protons causes broadening of their NMR signals due to an increase in transverse relaxation rate (Gillespie

and Shortle, 1997a). This effect has an  $r^{-6}$  dependence on the electron–proton distance and thus allows the detection of long-range interactions in proteins.

To provide a specific attachment of the nitroxide probe, Cys-reacting derivatives, as maleimides or iodoacetamides are employed. Since the primary sequence of  $\alpha$ S lacks cysteine, three different cysteine-containing mutants (A18C, A90C and A140C) were constructed in order to provide attachment points for the nitroxide radical MTSL (maleimide). The design of the mutants was biased towards proving the interactions evidenced by RDCs, but taking care in not disrupting those (A90C and A140C mutants), while the selection of the A18C was intend to report on structural changes on the N-terminus of the protein. Neither the mere introduction of these mutations nor the addition of the MTSL radical modified the hydrodynamic radii or altered the time course of aggregation for  $\alpha$ S (Figure 4.9). In addition, the RDCs pattern for A18C was not significantly perturbed besides the site of mutation (Chapter 2).

**Figure 4.9. Aggregation kinetics for  $\alpha$ S Cys-containing mutants.** **A.** ThioT traces for the time-dependent aggregation of  $\alpha$ S wt (dark red), A18C (orange), A90C (dark yellow), A140C (dark green) and A140C-MTSL labeled (cyan). Solution conditions were buffer A plus 100  $\mu$ M DTT, except for the MTSL labeled mutant. A higher ThioT fluorescence for the sample containing MTSL was evidence from the starting of the assay, and could be attributed to an interaction between the dye and the paramagnetic tag. **B.** Normalized kinetic traces for the samples shown in A. The average half time of aggregation was 120 hs  $\pm$  5 hs, suggesting that the mutations do not perturb the fibrillation pathway of the wt protein.

In order to quantitatively assess the paramagnetic effect cause by the nitroxide tag, peak intensity ratios between two  $^{15}\text{N}$ - $^1\text{H}$  HSQC NMR spectra, i.e. in the presence and absence of the nitroxide radical ( $I_{\text{param}}/I_{\text{diam}}$ ), are determined, which permits the estimation of distances between the spin-label and the affected amide protons in the protein (Lietzow et al., 2002; Teilum et al., 2002). As observed in figure 4.10 for the A90C mutant, the paramagnetic

effect caused a distance-dependent broadening of amide resonances, which is reflected as a reduction of the peak heights.

**Figure 4.10. PRE effect on  $\alpha$ S-A90C.** The Cys containing mutant of  $\alpha$ S (A90C) was labeled with the nitroxide spin label MTSL and  $^1\text{H}$ - $^{15}\text{N}$ -HSQC spectra were acquired in the presence (blue) and absence (red) of the paramagnetic tag, resulting in the selective disappearance of peaks in the close vicinity of the probe. Ratios of peak intensities between both conditions ( $I_{\text{param}}/I_{\text{diam}}$ ) are plotted (black bars) and compared with the profile expected for a random coil polypeptide (black dashed line). Deviations from the coil state reflect chain compaction or long range contacts. In

red a mobile 5 residue average of the peak intensity ratio is plotted to account for small fluctuations in the measured values.

For a random coil polypeptide the PRE effects would be expected to be restrained to the close vicinity of the attachment site (up to  $\sim 15$  residues), and only upon chain compaction or long range interactions the effect would reach other resonances. Such features are reflected in the broadening effect caused by the nitroxide radical on the NMR spectra for the three studied Cys positions, as follows:

- (i) The profile of intensity ratios for the A18C mutant showed a broad paramagnetic effect extending to residue 60 and long-range interactions with the C-terminal residues 115 to 140 (Figure 4.11A).
- (ii) The paramagnetic tag at residue 90 strongly reduced the intensity ratios for all C-terminal residues (Figure 4.11B).
- (iii) The A140C mutant showed an unbroadened core in the C-terminus (residues 110-125), but a considerable PRE effect was present in the central region of the protein (residues 80-100) (Figure 4.11C).

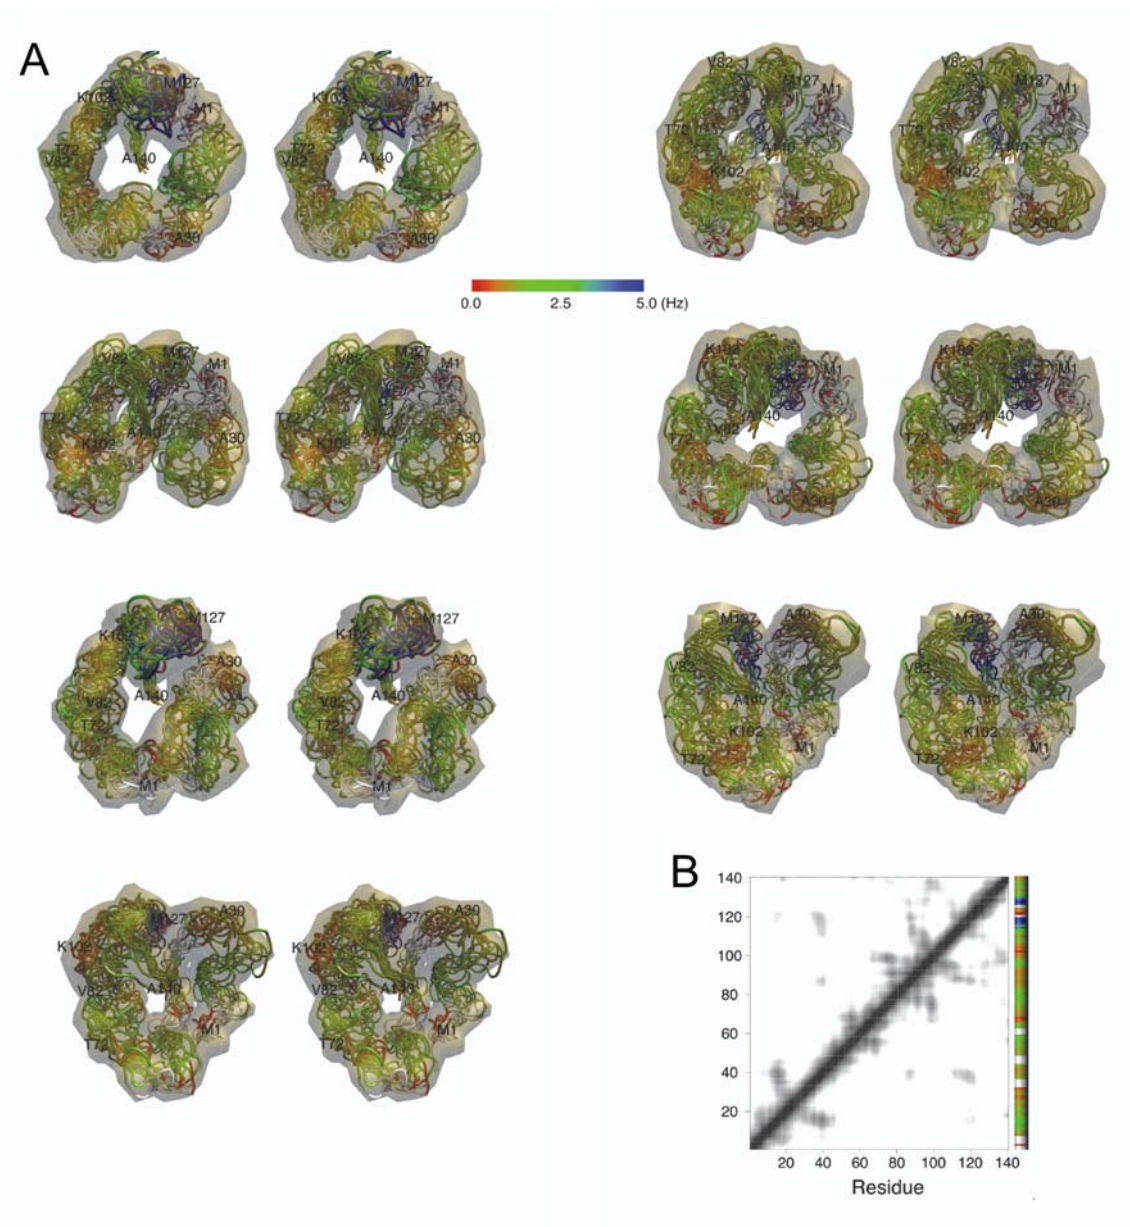

Addition of 8 M urea led to a restriction of paramagnetic broadening to 15 residues from the position of the nitroxide radical (Figure 4.11D and 4.11E), indicating that the protein was fully unfolded. Interestingly, in the case of the A18C a considerable paramagnetic effect on the C-terminus remained even under strong denaturant conditions. The extended relaxation enhancement observed in urea for the A140C (Figure 4.11F) was likely due to the very high flexibility of the C-terminal residue (Teilum et al., 2002).

**Figure 4.11. Paramagnetic relaxation enhancement of amide protons in spin-labeled  $\alpha$ S.** Three cysteine mutants of  $\alpha$ S (A18C, A90C and A140C) were labeled with MTSL. HSQC spectra in the presence (paramagnetic) and absence (diamagnetic) of spin label were recorded at 15 °C and the intensity ratio ( $I_{\text{param}}/I_{\text{diam}}$ ) of the resonance peaks was determined. **A, B and C.** MTSL-labeled cysteine mutants of  $\alpha$ S in buffer A (colored bars). **D, E and F.** MTSL-labeled cysteine mutants of  $\alpha$ S in buffer A + 8 M urea (colored bars), and the corresponding mutants of  $\alpha$ S in buffer A (bold black line). Dashed grey lines indicate paramagnetic effects expected for a random coil polypeptide with the paramagnetic tag in the same position as the  $\alpha$ S mutant (Teilmum et al., 2002).

#### 4.4. A conformational ensemble representative of the native state of $\alpha$ S.

In order to determine an ensemble of conformations consistent with the PRE measurements, intensity ratios were converted into distance restraints. Inasmuch as large errors are associated with distances calculated from PRE data and intensity ratios are averages over a broad ensemble of structures, the calculated distances were employed as semi-quantitative restraints in structure calculations using Xplor-NIH (Gillespie and Shortle, 1997a; Schwieters et al., 2003). The seven most representative conformations of the native state of  $\alpha$ S are shown in figure 4.12A.

**Figure 4.12. Structural models for native state conformations of  $\alpha$ S.** Representation of the native state of  $\alpha$ S calculated from paramagnetic relaxation enhancement data. **A.** Shown are the seven most populated clusters containing 80, 75, 46, 39, 25, 24 and 20 structures representing 50 % of all calculated conformations. The ten lowest energy structures of each cluster within an atomic density map (Schwieters and Clore, 2002) calculated from all conformations contained in each cluster are shown. Residual dipolar couplings were mapped onto the structures with the use of a continuous color scale. **B.** Average contact map for the centre structures of the seven most populated clusters representing 50% of all calculated conformations. A continuous grey scale from 3 Å (black) to 22 Å (white) is used. Residual dipolar couplings as a function of residue number are indicated by a color bar ranging from 0 Hz (red) to 5 Hz (blue).

The calculated structures represent temporal and distance-averages over an ensemble of conformations, and thus may combine structural features that may not necessarily coexist

in a given molecule and at a given time. In particular, calculated structures are overly compact due to the  $r^{-6}$  distance dependence of paramagnetic broadening.

Favorable long-range interactions were extracted by an average contact map calculated from the centre structures of these seven clusters representing 50% of 630 calculated structures (Figure 4.12B). The most important interaction is a hydrophobic cluster that comprises the C-terminal part of the highly hydrophobic NAC region (residues 85-95) and the C-terminus (residues 110-130), probably mediated by Met<sup>116</sup>, Val<sup>118</sup>, Tyr<sup>125</sup> and Met<sup>127</sup>. Within the C-terminal domain residues 120 to 130 contact residues 105 to 115, and the region about residue 120 also interacts with the N-terminus about residue 20.

The influence of the chosen computational strategy was tested by additional structure calculations using Rosetta (Figure 4.13B), in which hydrophobic burial and strand pairing as well as satisfaction of PRE restraints were favored (Simons et al., 1997; Bowers et al., 2000).

**Figure 4.13. Contact maps for the native state conformations of  $\alpha$ S.** Comparison of the computational strategy on determining PRE derived structures. The average contact maps for the centre structures of the seven most populated clusters calculated with XPLOR-NIH (**A**) and RosettaNmr (**B**) are shown. The seven clusters comprise 50 %(**A**) and 80% (**B**) of all calculated structures. A continuous grey scale from 3 Å (black) to 22 Å (white) is used.

These interactions presumably seem to inhibit spontaneous  $\alpha$ S oligomerization and are compatible with the influence in fibrillation exerted by methionine oxidation, tyrosine nitration and phosphorylation of Ser<sup>129</sup> (Fujiwara et al., 2002; Norris et al., 2003). Furthermore, shielding of the hydrophobic NAC region explains why the C-terminal acidic tail functions as a solubilizing domain for  $\alpha$ S (Souza et al., 2000) and truncated  $\alpha$ S is more amyloidogenic than the full-length protein (Crowther et al., 1998). The compact state of

native  $\alpha$ S also involves a turn in the N-terminus of the molecule (residues 20 to 30). This turn favors an ensemble of structures in which domain I, identified by RDCs (Figure 4.6), folds back onto domain II, a conformation that could be stabilized by the partial  $\alpha$ -helical character of domain I (Bussell and Eliezer, 2001). Dipolar couplings provide further support for key features visible in the calculated structures. Turn regions are mainly associated with small RDCs indicative of increased flexibility (e.g. residues 26-32), whereas more extended parts correspond to regions with large dipolar couplings (e.g. residues 72-82). The largest RDCs are located in the most compact structural region (residues 110-130) (Figure 4.6).

#### **4.5. Polyamine binding releases long-range interactions in $\alpha$ S.**

To address the functional relevance of these long-range, intramolecular interactions, we performed the same set of experiments as performed for the native state of the protein, but now for the previously examined conditions favoring aggregation, namely polycation binding, increased temperature and reduced pH.

The polycation spermine is a naturally occurring polyamine that increases the kinetic efficiency of  $\alpha$ S aggregation by 105 due to a specific interaction with the C-terminus of the protein (Fernandez et al., 2004). There was a general change in the PRE profiles of the three Cys-containing mutants upon addition of spermine. In particular the PRE effects of residues 18 to 60 (A18C mutant) were considerably reduced (Figure 4.14A), demonstrating that binding of polyamines to the C-terminal domain causes a release of the N-terminus and suggesting an opening of the  $\alpha$ S structure. This phenomenon is also consistent with the intensity increases of NMR signals of residues 22 to 93 resulting from polyamine binding (Figure 4.3) (Fernandez et al., 2004).

For the A90C mutant, binding of spermine led to a minimization of paramagnetic broadening in the C-terminus, achieving a profile similar to that of the denaturated state in 8 M urea (Figures 4.10E vs. Figure 4.13B). According to the A140C data, the presence of spermine also reduced the compactness of the region between residues 110 to 125 (Figure 4.13C). Broadening in other regions of the protein reflects the increased flexibility of the C-terminus and residual N-terminus/C-terminus interaction.

**Figure 4.14. PRE on polyamine-liganded spin-labeled  $\alpha$ S.** Intensity ratios between paramagnetic and diamagnetic states ( $I_{\text{param}}/I_{\text{diam}}$ ) for amide resonance peaks corresponding to A18C (A), A90C (B) and A140C (C) cysteine mutants of  $\alpha$ S labeled with MTSL and in the presence of 6mM Spermine (+4). Colored bars correspond to the intensity ratios measured in the experiment and are compared with the profile corresponding to the same mutants of  $\alpha$ S in the absence of the polycation (bold black line). Dashed grey lines indicate paramagnetic effects expected for a random coil polypeptide with the paramagnetic tag in the same position as the  $\alpha$ S mutant.

In line with these findings, the large RDCs observed for the C-terminus of the protein were reduced in the presence of polyamines (Figure 4.15). Greater polyamine charge – putrescine (+2) < spermidine (+3) < spermine (+4) – correlated with a stronger reduction in  $^1D_{\text{NH}}$  values, as well as with an enhancement of fibrillation (Fernandez et al., 2004).

In addition, binding of spermine to the C-terminus reduced RDCs for residues 12 to 26 by about 60 % indicating a long-range effect with the N-terminus, in agreement with intensity increases of NMR signals of residues 22 to 93 upon from polyamine binding (Fernandez et al., 2004). Such a decrease was not observed upon addition of urea, pointing to an electrostatic interaction between the negatively charged C- and the positively charged N-terminus. The persistent paramagnetic broadening in the C-terminus for the A18C mutant (Figure 4.13D) indicates that the N-terminus/C-terminus interaction is not abolished upon addition of polyamines but only weakened, and that RDCs and PREs possess different sensitivities to the strength of long-range interactions.

**Figure. 4.15. Residual dipolar couplings in polyamine-bound  $\alpha$ S.** **A.**  $^1D_{NH}$  dipolar couplings measured on  $\alpha$ S aligned with 5 mg/ml Pfl phage solution in buffer A (dark red), and in the presence of 3 mM putrescine (+2) (orange), 3 mM spermidine (+3) (green) and 3 mM spermine (+4) (cyan). **B.** RDCs measured for in 5 %  $C_8E_5$ /octanol mixture for  $\alpha$ S alone (dark red) and in the presence of 3mM spermine (+4) (cyan).

We further investigated whether hydrodynamic properties of the protein were affected upon polyamine binding, as suggested by the PRE profiles. By means of pulse-field gradient NMR it is possible to estimate the diffusion coefficient of polypeptides, and thus derive their hydrodynamic radius ( $R_h$ ) by comparison with standards of known size (Wilkins et al., 1999). Empirical relationships have been derived by using these method, which relate the length of a polypeptide chain protein with its hydrodynamic radii at folded ( $R_n = 4.75 \times N^{0.29}$  Å) and unfolded ( $R_d = 2.21 \times N^{0.57}$  Å) states. Thus, according to its 140 amino acids, the expected size for a collapsed state of  $\alpha$ S would be 18 Å, while the completely unfolded state would reach 34 Å.

Our determinations, showed on figure 4.16, demonstrated that  $\alpha$ S populates relatively compact conformations at physiological pH ( $R_h$  of 29.3 Å), and that it radius increases upon addition of 100 mM NaCl ( $R_h$  of 31.9 Å), which is in accordance with a  $\sim$  2-3 fold increase on the rate of aggregation of  $\alpha$ S in the presence of salt (Hoyer et al., 2002; Hoyer et al., 2004).

**Figure 4.16. PFG-NMR measurement of hydrodynamic properties of  $\alpha$ S under different solution conditions.** **A.** Hydrodynamic radius (Rh) of  $\alpha$ S was measured by PFG-NMR under the following conditions: pH 7.4, 100 mM NaCl, urea 8M and spermine 3mM. **B.** Comparison of Rh determinations for  $\alpha$ S with the dimensions expected for a globular protein or a random coil polypeptide of 140 residues. Errors in the determination are within 2%.

Upon polyamine binding we evidenced a significant increase in the apparent size of the conformations populated by  $\alpha$ S ( $R_g$  of 33.4 Å), dimensions similar to those determined for the urea denatured state of the protein ( $R_g$  of 33.9 Å). This suggests that upon conditions that significantly impair long range interactions there is a concurrent increase in the hydrodynamic dimensions of the ensemble of conformations populated by  $\alpha$ S. This could be rationalized in terms of adoption of more extended structures, as probed by PREs (Figures 4.11 and 4.14) and due to an increment on the dynamics of the backbone of the polypeptide chain, as probed by RDCs (Figures 4.6 and 4.15).

Taking together, these data demonstrate that long-range interactions involving the C-terminus and the NAC region, presumably of hydrophobic nature, as well as with the N-terminus, acting via electrostatic interactions, protect  $\alpha$ S from oligomerization. Docking of polycations to the C-terminus destabilizes these interactions. The high free energy of the extended conformation, in which the hydrophobic NAC region is exposed to the solvent, would favor the association of monomers, thereby increasing the extent of both the nucleation and propagation steps of aggregation (Fernandez et al., 2004).

#### 4.6. The residual structure of native $\alpha$ S is lost at elevated temperatures.

The rate of fibrillation increases when  $\alpha$ S is incubated at increasing temperatures (Uversky et al., 2001b), and we have already hints that suggest a re-distribution of the ensembles of conformations at higher temperatures, as amide resonances of  $\alpha$ S are strongly affected, and several cross-peaks, in particular those corresponding to the central region of the protein are vanished from the spectrum (Figure 4.2 and 4.17A). We therefore measured RDCs and PREs

on  $\alpha$ S at high temperatures in order to characterize the features of the conformers populated at this condition.

A comparison of RDCs measured at 15 °C and 37 °C showed a strong perturbation of the polypeptide backbone upon increment of the temperature (Figure 4.17C). Due to the lack of adequate signal-to-noise ratio, few data points were able to be sampled at the N-terminus and NAC region. Nevertheless it was observed that couplings at the NAC region were reduced, while a decrease in the coupling values for both sub-domains of the C-terminus was evidenced. Measurement of RDCs at higher temperatures (47 °C) were attempted, but were not suited due to the high aggregation tendency of protein combined with the long acquisition times required for the experiment (~ 20 h). However, this result correlated well with further evidence obtained from PRE studies on the A90C mutant. At 37 °C the paramagnetic effect on the C-terminus was only slightly perturbed at 15 °C, while at 47 °C, virtually no paramagnetic broadening remained for resonances beyond residue 105 (Figure 4.17.B).

It can be concluded that at 37 °C the ensemble of conformations that is populated display a more loose long range interaction between the NAC region and the C-terminus, according to the RDC data, although is not completely abolished, as reported by the PRE data. As the temperature is increased further, the C-terminus of  $\alpha$ S adopts a fully extended conformation, similar to the one achieved upon addition of denaturant or polycation. It is noteworthy that at 37 °C the changes in RDCs are already evident, but the PRE broadening remains unchanged. This result is in agreement with the proposal that destabilization of long-range interactions initially releases the stiffness of the polypeptide chain (as probed by the decrease in RDCs) followed by an opening of the tertiary structure (as monitored by PRE effects). We further conclude that RDCs provide a very powerful tool for probing structural transitions in unfolded proteins.

**Figure 4.17. Temperature-induced structural changes in  $\alpha$ S.** **A.**  $^1\text{H}$ - $^{15}\text{N}$  HSQC spectra for  $\alpha$ S acquired at 15 °C (288 K), 37 °C (310 K) and 47 °C (320 K). **B.** PRE effect on amide protons for MTSL labeled  $\alpha$ S A90C, at increasing temperatures 15 °C (288 K, red bars), 37 °C (310 K, green bars) and 47 °C (320 K, blue bars). At 37 °C and 47 °C the PRE effect at 15 °C is depicted for comparison in bold black line. Dashed grey lines indicate paramagnetic effects expected for a random coil polypeptide with the paramagnetic tag in the same position as the  $\alpha$ S mutant. **C.** RDCs profile for  $\alpha$ S aligned in 5 mg/ml Pfl at 15 °C (dark red) and at 37 °C (dark yellow).

#### 4.7. $\alpha$ S populates a native-like destabilized conformation at pH 6.5.

The last condition earlier evidenced to cause changes in the intensity of signals and with polyamines and temperature may have consequences in the redistribution of the ensemble of  $\alpha$ S conformers is pH. A strong reduction in the pH of the solution was reported by our group to have drastic consequences on the aggregation of the protein (Hoyer et al., 2002). We further studied the effect of such slight decrease in the pH of the solution in the aggregation properties of the protein. As evidenced on figure 4.18, there was a significant reduction in the half time for aggregation at pH 6.5 when compared with pH 7.5 (~ 40 h at pH 6.5 vs. ~ 58 h at pH 7.4). No differences in the lag times for aggregation were observed (~ 20 h for both conditions), but a 2-fold increase in the  $k_{app}$  (rate constant for monomer addition) was calculated, suggesting that  $\alpha$ S at pH 6.5 is incorporated into fibrils more rapidly than at pH 7.4.

**Figure 4.18.  $\alpha$ S at pH 6.5 aggregates faster than a pH 7.4.** Aggregation assay for  $\alpha$ S at pH 6.5 and 7.4. **A.** Normalized ThioT traces for  $\alpha$ S aggregation at pH 6.5 (orange) and 7.4 (dark red) in the presence of 100 mM NaCl (protein concentration is 100  $\mu$ M). **B.** Half time for aggregation for traces shown on A. **C.** Apparent rate constant for monomer addition derived from the traces shown in A.

Chemical shifts perturbations are exclusively localized to two defined regions surrounding residues 3 and residues 50 (Figure 4.19). The first zone could be attributed to changes in the protonation state of the terminal amine group, while the second one is unambiguously due to changes in the side chain of the sole histidine residue of the protein. N-terminal amines should have a higher pKa, thus another possibility is that the changes detected are only due to His protonation and long range interactions between the N-terminus and His50, i.e. such that hydrogen bonds nets cause the perturbations. This would have strong consequences on the ensemble of conformations and may account for the changes in

aggregation propensity. It would be interesting to probe whether natural ligands of His residues, namely metal cations are able to bind to  $\alpha$ S and cause changes in fibrillation.

**Figure 4.19. Amide chemical shift perturbations upon pH reduction in  $\alpha$ S.** Plot of mean weighted  $^1\text{H}$ - $^{15}\text{N}$  chemical shift differenced between  $\alpha$ S at pH 6.5 and 7.4.

In order to easily probe a general property of the ensemble, we first measure the hydrodynamic properties of the protein by PFG-NMR at pH 6.5 and 100 mM NaCl. No change on the Rh of the protein was found when compared with pH 7.4 and 100 mM NaCl (Rh of  $31.9 \pm 0.3 \text{ \AA}$  at pH 7.4 and Rh of  $32.0 \pm 0.5 \text{ \AA}$  at pH 6.4). Thus the ensemble is not perturbed significantly upon changes in pH.

Due to the absence of hydrodynamic changes we discarded the use of PRE to evaluate this condition, and solely employed RDCs to search for slight conformational changes on the protein. The RDCs profile of the protein at pH 6.5 is correlated with the one measured at pH 7.4, although it shows, in general, a reduction in the values of the couplings and an inversion in the sign of the RDCs for the very N-terminus (Figure 4.20). The reduced couplings over the whole polypeptide chain are likely caused by a slight decrease in the alignment properties of either the protein or the anisotropic phase. However local changes are observed for the first sub-domain of the C-terminus, where reduction of the couplings would be indicative of a reduction in the strength of the long range contacts, similarly to what was observed at  $37 \text{ }^\circ\text{C}$ . The inversion of the sign of the couplings suggests the presence of turns or that helical conformations are readily populated (Mohana-Borges et al., 2004).

**Figure 4.20. RDCs profile for  $\alpha$ S at pH 6.5.**  $^1D_{NH}$  dipolar couplings measured on  $\alpha$ S aligned with 5 %  $C_8E_5$ /octanol mixture for  $\alpha$ S at pH 7.4 (dark red) and at pH 6.5 (dark blue).

Overall these results suggest that the ensemble of conformations populated at pH 6.5 is not particularly different to the one populated at 7.4, but may favor the partition towards a defined sub-set of conformations that readily aggregates. A characteristic of these conformers populated at slight low pH is a perturbed local structure at the very N-terminus and on the region surrounding the His<sup>50</sup> residue, and the mechanism for an increased aggregation may not necessarily involve an impairment of long range tertiary contacts, as probed by RDCs.

## 5. Results. Chapter II: “PD-linked familial mutants of $\alpha$ S have a destabilized conformation”.

Two missense mutations in the  $\alpha$ S gene have been identified as causes of early on-set PD. The changes of Ala<sup>30</sup> to Pro and Ala<sup>53</sup> to Thr lead to an increase in the tendency to form toxic oligomeric species, and in particular the Ala<sup>53</sup> to Thr substitution increases the rate of fibril formation (Conway et al., 2000). Previous low and high resolution spectroscopic characterizations of these two proteins had not provided a structural rationale for such differential behavior. Thus we applied our set of NMR techniques to study the characteristics of the ensemble of conformations populated by these two proteins.

### 5.1. Conformations of familial mutants of $\alpha$ S studied by heteronuclear 2D NMR.

The HSQC spectra of both A30P and A53T genetic mutants did not differ significantly from the spectra of the *wt*  $\alpha$ S protein, aside from the immediate surroundings of the mutated residues (Figure 5.1).

**Figure 5.1.**  $^1\text{H}$ - $^{15}\text{N}$  HSQC spectra of  $\alpha$ S genetic mutants.  $^{15}\text{N}$ -labeled A30P

and A53T protein variants of  $\alpha$ S were subjected to 2D heteronuclear NMR. Both HSQC spectra show, besides the surrounding point of mutation, no significant perturbations in chemical shifts when compared with the wt protein.

However, some slight changes in the intensity of the signals were evident, in particular for the A30P mutant. As shown on figure 5.2, when compared with the *wt* protein (dark red), the amide cross-peaks for the A30P protein (cyan) showed a reduced intensity of the N-terminal resonances (from residue 20 to 70) and an increased intensity of the resonances corresponding to the C-terminus (amino acids 112 until 130). For A53T (green), the changes were minor, and only in evidence at the N-terminus (from residue 20 to 60).

**Figure 5.2. Intensity plots for HSQC-amide cross-peaks of *wt*  $\alpha$ S and its genetic mutants.** Normalized peak intensity, relative to signal average, for HSQC-derived amide resonances corresponding to  $\alpha$ S *wt* (dark red),  $\alpha$ S A30P (cyan) and  $\alpha$ S A53T (green). Average peak intensities were employed for normalization due to changes at the C-terminus of the A30P mutant.

A comparison of these results in terms of the findings described on chapter 1 for different conditions that alter the ensemble of conformations populated by  $\alpha$ S, reveal some similarities. The slight decrease of intensities of the N-terminal resonances for both mutants is similar to that observed under high temperature conditions for *wt*  $\alpha$ S (Chapter 1, Figure 4.1).

Furthermore, when we recorded HSQC spectra for *wt*  $\alpha$ S at 15 °C and 25 °C, for the same sample in the same conditions, there was an overall reduction of the intensity of peaks from the N-terminal and NAC regions (Figure 5.3A, 5.3B). The normalized peak intensity profile for the spectra recorded at 25 °C was very similar to that evidenced for the A30P mutant, and also displayed lower intensity of resonances in the region comprising residues 20 to 60, as with both the A30P and A53T  $\alpha$ S variants (Figure 5.3C).

**Figure 5.3. Intensity changes on the HSQC spectrum of *wt*  $\alpha S$  at 298 K.** **A.** HSQC spectra of *wt*  $\alpha S$  show a slight reduction in peak intensity upon raising the temperature from 15 °C to 25 °C, similarly to the effect evidenced on  $\alpha S$  genetic mutants. **B.** Profile of intensities of amide crosspeaks for  $\alpha S$  *wt* at 15 °C (blue) and 25

°C (red) obtained from the spectra shown on A. C. normalized peak intensity, relative to average, corresponding to the spectra shown on A. In blue are shown the values for  $\alpha$ S *wt* at 15 °C and in red those corresponding to 25 °C.

This kind of NMR determinations does not seem to be capable of determining differences between the ensemble of conformations populated by the A30P and A53T mutants and the *wt* protein. The overall signatures of the HSQC spectrum are conserved, i.e. peaks still clustering by residue nature, a narrow spread of signals in the  $^1\text{H}$  dimension is observed, and there are no chemical shifts perturbations between the native and mutant proteins. However, a detailed characterization of the profile of intensity of the signals provides some indication of a slight perturbation of the ensemble of conformers, similarly to the changes observed in the protein when the temperature is raised from 15 °C to 25 °C. Thus, there exists a small but finite probability that a redistribution of conformers in the ensemble may take place in the native soluble state of the A30P genetic mutants, and to a lesser extent with the A53T variant. Such preferential partition would likely be towards those conformers with increased amyloidogenic properties.

We consequently hypothesized whether such small perturbations in the ensemble of conformers would be observable by the suit of experiments that have been successful in probing residual structure and long range interactions in *wt*  $\alpha$ S, and decided to employ paramagnetic relaxation enhancement and residual dipolar couplings to study the native soluble state of both  $\alpha$ S-A30P and  $\alpha$ S-A53T.

## **5.2 The A30P and A53T familial mutations perturb tertiary interactions in the native state of $\alpha$ S.**

We have shown in chapter 1 how PRE of nuclear spin relaxation based on nitroxide spin labels is a very powerful technique for observing long range interactions in the native state of  $\alpha$ S.

Due to the attachment of a nitroxide radical to a Cys residue in the protein, a distance-dependent broadening of NMR signals extends as far as 20 Å, permitting the characterization of the ensemble of conformations that are populated. As  $\alpha$ S lacks cysteine, three different double mutants, containing variable single Ala to Cys replacements, were constructed for both the A30P and A53T mutant  $\alpha$ S, mirroring the *wt*  $\alpha$ S variants studied in chapter 1. Thus we evaluated the PRE effect on MTSL-labeled  $\alpha$ S A30P-A18C, A30P-A90C, A30P-A140C mutants, as well as A53T-A18C, A53T-A90C, A53T-A140C variants (Figure 5.4A).

**Figure 5.4 Constructs studied on the PRE-based characterization of familial mutants of  $\alpha$ S.** **A.** Double mutants of  $\alpha$ S, containing the A30P or A53T mutations and a variable Cys replacement (A18C, A90C or A140C) were constructed in order to provide attachment sites for nitroxide labels. **B.** Overlapped slices from two  $^1\text{H}$ - $^{15}\text{N}$  HSQC spectra acquired on  $\alpha$ S-A30P-A90C in the absence (diamagnetic) (black) and presence (paramagnetic) (red) of the nitroxide spin label MTSL.

The profiles derived from the PRE experiments on  $\alpha$ S familial mutants are largely similar to those obtained on the *wt* protein, but some particular differences were observed (Figure 5.5). In the A18C spin labeled mutant  $\alpha$ S, intensity ratios between the paramagnetic and the diamagnetic states ( $I_{\text{param}}/I_{\text{diam}}$ ) as low as 0.5 were observed in the C-terminus, similar to that of *wt*  $\alpha$ S (Chapter 1). In contrast, the relaxation enhancement of residues 40-60 decreased by about 20 % for both missense mutants compared to the *wt* protein (Figures 5.5A, 5.5D). The reduced paramagnetic broadening of residues 40-60 suggests that the compaction of the N-terminal region is slightly reduced in mutant  $\alpha$ S, in agreement with recent Trp fluorescence energy transfer measurements (Lee et al., 2004).

The attachment of the spin label MTSL to residue 90 greatly attenuated NMR signals of amino acids in the C-terminus of A30P mutant  $\alpha$ S with peak intensity ratios in the range of 0.5 to 0.9 (Figure 5.5B). This result indicates that the C-terminal domain of A30P  $\alpha$ S is very compact, as had been observed previously for *wt*  $\alpha$ S (Chapter 1) and also holds for the A53T mutant (Figure 5.5E).

When the spin label was attached to residue 140 in the *wt* protein, the NMR signals of residues located in the NAC region were considerably broadened, providing support for a back-folding of the C-terminus on this region in *wt*  $\alpha$ S (Chapter 1). Such a long-range interaction was not observed in either the A30P or A53T mutants as the broadening effect

exerted by the spin labeled was similar to the expected for a random coil polypeptide (Figures 5.5C, 5.5F).

**Figure 5.5. PRE profiles in Parkinsonism-linked mutant  $\alpha$ S.** Intensity ratios ( $I_{\text{param}}/I_{\text{diam}}$ ) of the resonance peaks in  $^1\text{H}$ - $^{15}\text{N}$  HSQC spectra in the presence (paramagnetic) and absence (diamagnetic) of the spin label MTSL at 15 °C. Dashed lines indicate intensity ratios simulated for a random coil polypeptide. Decreases in peak intensity ratios that occur far from the site of spin labeling (>10 residues) are indicative of intramolecular long-range contacts between the spin label and distant areas of sequence. Intensity ratios for A30P/A18C (**A**), A30P/A90C (**B**), A30P/A140C (**C**), A53T/A18C (**D**), A53T/A90C (**E**) and A53T/A140C  $\alpha$ S (**F**). Solid lines indicate the intensity ratios observed for *wt*  $\alpha$ S.

We further addressed the relative strength of the long range interactions present in mutant  $\alpha$ S by measuring PREs on urea denatured spin-labeled proteins. Of note in the case of the *wt* A18C variant was the persistence of residual long-range contacts between the N- and C-terminus in 8 M urea (Chapter 1). Both the A30P and A53T A18C-labelled variants displayed the absence of such persistent long range interactions under strong denaturing conditions, likely populating a fully random coil conformation (Figure 5.6A, 5.6B). The A90C variants, as expected, did not display significant differences between the *wt* and mutant

proteins due to the fact that in this particular case the profiles of the three proteins correlate well with the expected for a completely unfolded polypeptide (Figure 6.6C, 6.6D).

**Figure 5.6. PRE profiles in urea denatured  $\alpha$ S mutants.** Intensity ratios of the resonance peaks in  $^1\text{H}$ - $^{15}\text{N}$  HSQC spectra in the presence (paramagnetic) and absence (diamagnetic) of the spin label MTSL at 15 °C acquired in the presence of 8 M urea as denaturing agent. Dashed lines indicate intensity ratios simulated for a random coil polypeptide. **A.** A30P-A18C. **B.** A53T-A18C. **C.** A30P-A90C. **D.** A53T/A90C. Solid lines indicate the intensity ratios observed for the correspondent Cys-containing mutant of *wt*  $\alpha$ S in Urea 8 M. The A140C mutant was not particularly useful in studying the chemically denatured state of the *wt* protein and thus the genetic mutant variants on that position were not studied under urea 8 M.

If we consider the relative perturbation under chemical denaturant as a signature of the strength of the tertiary interactions preserving the native unfolded state, we could hypothesize that the A30P and A53T mutations provoke a partition in the ensemble conformations that are populated by the protein towards conformers with higher free energy. The increased population of such conformers is likely to facilitate misfolding and self-oligomerization, as occur with both mutant proteins.

### 5.3. A30P and A53T mutations destabilize $\alpha$ S.

Residual dipolar couplings are exquisitely sensitive to bond vector orientation and can be measured in a weakly aligned protein, for which the large internuclear dipolar interactions no longer average to zero (Bax and Grzesiek, 1993). As we reported in Chapter 4, RDCs identified five different domains in *wt*  $\alpha$ S with different degrees of residual structure, in some cases long-range-coded (domain I: residues 1-28; domain II: residues 33-65; domain III: residues 70-88; domain IV: residues 95-105; and domain V: the C-terminus). In particular, RDCs probed a hydrophobic core comprising the C-terminus and domain III and IV, which resulted to be a native gatekeeper for avoiding  $\alpha$ S aggregation. We intended to measure this NMR-derived parameter in order to obtain further evidence for differences between the backbone conformations populated by both mutant proteins.

RDCs in PD-linked mutant  $\alpha$ S were first observed by dissolving A30P and A53T  $\alpha$ S mutants in a dilute liquid crystalline phase of 5%  $C_8E_5$ /octanol. No significant differences in the chemical shifts of spectra in  $C_8E_5$ /octanol and free in solution were observed, suggesting that the anisotropic phase did not appreciably perturb the ensemble of  $\alpha$ S conformations. In general reduced couplings were observed for many residues in both genetic mutants when compared with *wt*  $\alpha$ S (Figure 5.7). Since both variant are just single point mutations, and due to the conservation of solution and conditions of anisotropic phase preparation, the differences are not ascribed to variations in protein alignment, rather are likely caused by changes at the level of the conformations sampled by these proteins with respect to the *wt*.

**Figure 5.7. RDCs in  $\alpha$ S genetic mutants.** Region of the  $^1H^{15}N$ - in phase-anti phase (IPAP)-HSQC spectrum corresponding to  $\alpha$ S *wt* (left) and  $\alpha$ S A30P (right) aligned in 5%  $C_8E_5$ /octanol mixture, showing the  $^1D_{NH}$  couplings for Glu<sup>83</sup> (E83) and

Asp<sup>119</sup> (D119). The upfield doublet components (anti-phase) are indicated in red, while the downfield components (in-phase) in blue.

RDCs in A30P and A53T mutant  $\alpha$ S were predominantly positive with regions displaying relatively large RDCs separated by residues with RDCs close to zero (Figure 5.8A, 5.8B), and slightly negative couplings were observed for some residues.

**Figure 5.8. Residual dipolar couplings in mutant  $\alpha$ S.** Backbone N-H dipolar couplings,  $^1D_{NH}$ , were measured in A30P and A53T mutant  $\alpha$ S oriented in a 5%  $C_8E_5$ /octanol mixture at 15 °C. Non-zero dipolar couplings are indicative of structural

and motional restrictions of the protein backbone. **A.**  $D_{NH}$  profile for A30P  $\alpha$ S (blue) and *wt*  $\alpha$ S (black) in buffer A. **B.**  $D_{NH}$  profile for A53T  $\alpha$ S (green) and *wt*  $\alpha$ S (black) in buffer A. **C.**  $D_{NH}$  couplings in the C-terminus of A30P  $\alpha$ S in buffer A (red) and of *wt*  $\alpha$ S in buffer A + 8 M urea (dark blue). **D.**  $D_{NH}$  couplings in the C-terminus of A53T  $\alpha$ S in buffer A (red) and of *wt*  $\alpha$ S in buffer A + 4 M urea (blue). RDC domains identified in *wt*  $\alpha$ S (domain I: residues 1-28; domain II: residues 33-65; domain III: residues 70-88; domain IV: residues 95-105; and domain V: the C-terminus) (Chapter 4) are indicated.

Despite the reduced values, the profiles corresponding to the mutant dipolar couplings correlate well with the RDC domain pattern of the *wt* protein. However, some differences were observed in particular domains. In contrast to *wt*  $\alpha$ S, the RDCs for domain II (residues 50-62) and domain III (residues 70-94) were strongly reduced. In the C-terminal domain, the magnitudes of RDCs were comparable to those in the rest of the protein, as opposed to the RDC profile of *wt*  $\alpha$ S, in which the values were almost twice as high. Rather the dipolar couplings of A30P  $\alpha$ S were similar to those of *wt*  $\alpha$ S in the presence of 8 M urea (Figure 5.8C), whereas the magnitude of RDCs of A53T  $\alpha$ S was comparable to that of *wt*  $\alpha$ S in the presence of 4 M urea (Figure 5.8D). Furthermore the profile of urea denatured A30P mutant is similar to *wt*  $\alpha$ S, but still differs from the pattern observed in native solution conditions (Figure 5.9A).

In the vicinity of both missense mutations, the dipolar couplings were considerably reduced, suggesting an increased mobility in these regions. For the A30P mutation, the increased flexibility is in agreement with the reduced heteronuclear  $^{15}\text{N}$   $R_1\rho$  relaxation rates of backbone amide groups and a reduced helical propensity for domain I (residues 18-31) (Bussell and Eliezer, 2001).

In line with the alteration of long-range interactions by PD-linked mutations, as suggested previously by PRE measurements, RDCs also evidenced a very strong reduction of couplings in the hydrophobic NAC region and at the C-terminal domain of mutant  $\alpha$ S. These results point toward a reduced shielding of the hydrophobic NAC region by the C-terminus in the A30P and A53T mutant  $\alpha$ S.

As an important control of those experiments, the couplings for A18C  $\alpha$ S, a non-amyloidogenic mutant of  $\alpha$ S with an unaltered time course of aggregation (Chapter 1), were nearly identical to that of *wt*  $\alpha$ S (Figure 5.9B).

**Figure 5.9. Control data for residual dipolar couplings in PD-linked mutant  $\alpha$ S.** Backbone N-H dipolar couplings,  $D_{\text{NH}}$ , were measured in  $\alpha$ S variants oriented in a 5% C8E5/octanol mixture at 15 °C. **A.**  $D_{\text{NH}}$  profile of A30P  $\alpha$ S (blue) and *wt*  $\alpha$ S (black) both in buffer A + 8 M urea. **B.**  $D_{\text{NH}}$  profile of A18C  $\alpha$ S (orange), a non-amyloidogenic mutant of  $\alpha$ S with an unaltered time course of aggregation, and *wt*  $\alpha$ S (black) both in buffer A.

In addition, the results presented in figure 5.8 were reproduced in Pfl phages as a second alignment medium (Figure 5.10A, 5.10B), confirming in general our findings. There was, as well, an overall reduction of the RDCs values for the polypeptide chain, confirming that the populated conformers differ. However, the strong reduction of the couplings observed for the C-terminus in C<sub>8</sub>E<sub>5</sub>/octanol phase was shown in Pfl media as a mild reduction, similarly to what we evidence upon raising the temperature on the *wt* protein, and confirming the reduced strength of long range interactions.

We further measured RDCs at higher temperature for the A30P mutant, in order to determine whether there was a difference between both proteins at physiological conditions. When the temperature was raised to 37 °C we still spotted the reduced value of C-terminal dipolar couplings suggesting that the destabilizing effect of the genetic mutations is also significant at physiological conditions (Figure 5.10C).

**Figure 5.10. Residual dipolar couplings in mutant  $\alpha$ S oriented in Pf1 bacteriophage.** A.  $D_{NH}$  profile for A30P  $\alpha$ S (blue) and *wt*  $\alpha$ S (black). B.  $D_{NH}$  profile for A53T  $\alpha$ S (green) and *wt*  $\alpha$ S (black). C.  $D_{NH}$  profile for the residues corresponding to the C-terminus of A30P  $\alpha$ S (blue and red) and *wt*  $\alpha$ S (black) at 15 °C (left panel) and 37 °C (right panel).

#### 5.4. Synergistic long range interactions occur in the native state of $\alpha$ S.

In chapter 1 we identified two types of long range interactions in the native state of  $\alpha$ S, a hydrophobic cluster between the NAC region and key residues at the C-terminus, and an interaction between the N-terminus and C-terminus. Despite the reduction of the shielding on

the NAC region, a strong paramagnetic broadening exerted by a spin label attached to either residue 18 or 90 on the C-terminal domain of the protein remained (Figure 5.5A, 5.5B, 5.5D and 5.5E), suggesting that long-range interactions are not completely abolished in the A30P and A53T  $\alpha$ S mutants. The remaining long range N-terminal/C-terminal interaction is predicted to be of electrostatic nature, due to the high positive net charge of the N-terminus and the high negative net charge of the C-terminus.

To further disclose which interactions are affected upon mutation, we investigated the hydrodynamic properties of the ensemble of conformations populated by both mutants employing pulse-field gradient (PFG) NMR. In order to probe the sole effect of the genetic mutations in the ensemble of conformations, the PFG-NMR experiments were measured in the absence of salt, which has been found to extend  $\alpha$ S conformations (Chapter 1).

As observed in figure 5.11, an unexpected finding from the hydrodynamic characterization of the  $\alpha$ S genetic mutants was that both A30P and A53T proteins display a smaller Rh than the *wt* protein ( $\sim 29$  Å for A30P and A53T, and 30.5 Å for *wt*  $\alpha$ S). This result is in line with the PRE findings on the tagged- $\alpha$ S A18C showing a slight increase of the paramagnetic broadening centered on position 130. Conversely, in both mutant proteins a dissociation of the C-terminus from the NAC region, as probed by the 140C position, was evidenced, suggesting an extend conformation. However, the C-terminus still remains compact, as shown on the PRE profiles of the mutant A90C variants.

**Figure 5.11. Changes on hydrodynamic properties upon denaturant addition for *wt* and mutant  $\alpha$ S.** **A.** Changes in Rh upon urea titration of *wt*  $\alpha$ S (dark red), A30P (blue) and A53T (dark yellow) genetic mutants. **B.** Calculation of changes in compaction factors upon urea titration for the measurements in A. Linear fits for the variation of compaction factor vs. urea addition are shown in bold lines.

Another interpretation of these results would suggest that the N-terminus and the NAC region compete for long range interactions with the C-terminus. Thus, the NAC/C-terminal hydrophobic interaction may disfavor the electrostatic N-terminal/C-terminal interaction, and in the absence of such hydrophobic cluster, the electrostatic interaction would prevail and favor a collapsed ensemble.

If the native state of the *wt* protein features both interactions, we could assume with a certain degree of confidence that the NAC/C-terminal contact is strongly perturbed in both genetic mutants. Thus we should be able to dissect the contributions of each interaction by comparing how urea destabilizes the ensemble for both *wt* and mutant proteins. When we measured stepwise the variation of Rh upon urea addition we observed that all the three proteins reached almost the same extended conformation at the last concentration of urea probed ( $\sim 35$  Å at 8 M urea).

Although the proteins displayed an almost linear dependence of compaction vs. urea addition, the manner in which the mutants achieved their chemically unfolded state differed from that of the *wt* protein. Considering that the protein would be 100% compact at an ideal, empirically determined, globular state, and that it would be 0% compact at an equally ideal, also empirically derived, chemically unfolded state, we can calculate compaction factors for each state of the ensemble (Wilkins et al., 1999). Thus the compactness of the mutants would be  $\sim 45\%$  in the absence of urea, and would decrease to 9% upon addition of 8 M, while for the *wt* protein it would change from 37 % to 11 % under the same conditions. The A30P and A53T mutants extended as well as denatured with a pseudo-rate of 4.4% per mole of urea added, whereas the value for *wt* protein was only 3.1% per mole of urea. These results imply that *wt*  $\alpha$ S is more resistant to the addition of denaturant than the mutant variants, suggesting a synergistic effect for both types of long range interactions despite their inherently antagonistic character.

Furthermore, since the mutant proteins still extended as urea was added, the mere absence of the hydrophobic cluster is not likely to trigger the unfolding of the protein, and rather a combined impairment of both long range interactions would be required, likely the scenario upon polyamine binding.

### **5.5. Competition of electrostatic and hydrophobic interactions in the native state of $\alpha$ S.**

To further probe the strength of distant N- and C-terminal electrostatic interactions in the A30P and A53T mutants upon destabilization of the long-range hydrophobic cluster, we sought to determine the affinities of these proteins for the polycation spermine. The rationale

was that if electrostatic contacts are modulated, one should perceive a change in the affinity of the protein for the polycations.

When we titrated  $\alpha$ S A30P and A53T mutants with spermine we observed a general effect of the polycation on the amide resonances of the protein. Both the chemical shift perturbations and the changes in the intensity of the signals observed for *wt*  $\alpha$ S (Fernandez et al., 2004) were reproduced for the A30P and A53T mutants (Figure 5.12). The chemical shifts perturbations were also localized at the C-terminus of the protein, with the principal changes centered on the stretch comprising residues 124 to 135, similar to the *wt* protein, and thus permitting a comparison of the binding affinities for the three proteins.

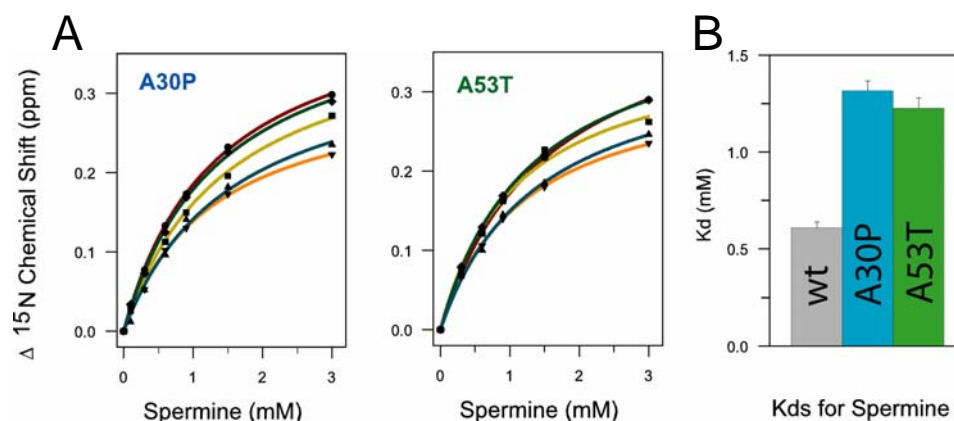

**Figure 5.12. Binding of spermine to mutant  $\alpha$ S is similar as to the *wt* protein.** Comparison between polyamine binding to *wt* and mutant  $\alpha$ S. Upon spermine binding (3mM) to  $\alpha$ S, changes in  $^{15}\text{N}$  chemical shifts (bold black line) and in peak intensities (colored bars) are visible, reflecting formation of a complex between the negatively charged C-terminus of the protein and the polycation. **A.**  $\alpha$ S-*wt*. **B.**  $\alpha$ S-A30P. **C.**  $\alpha$ S-A53T.

If the protein is in fast exchange with the ligand, due to the conformational average sampled by the timescale of the NMR measurement, the chemical shifts of those residues directly implicated in the binding event should gradually change from 0 until a maximum

upon saturation. Thus one may employ the HSQC-based titration experiments to evaluate the dissociation constants ( $K_d$ ) of the formation of the protein-ligand complex.

The determinations of the  $K_d$  for the A30P and the A53T proteins is shown in figure 5.13. A global analysis, assuming a single  $K_d$  but independent maximal chemical shifts perturbations for each residue evaluated, determined that both mutant variants have  $\sim$  half the affinity for spermine than the *wt* protein (1.3 mM and 1.23 mM for A30P and A53T, respectively, vs. 0.61 mM for  $\alpha$ S *wt*).

**Figure 5.13. Determination of dissociation constants for spermine-mutant  $\alpha$ S complexes.**  $K_d$  for the binding of the polycation spermine (+4) to both A30P and A53T  $\alpha$ S proteins were determined by titration experiments based on  $^1\text{H}$ - $^{15}\text{N}$ -HSQC NMR spectra. **A.**  $^{15}\text{N}$  chemical shifts difference as a function of total concentration of ligand for  $\alpha$ S-A30P (left) and  $\alpha$ S-A53T (right). Residues are as follows: Ala<sup>124</sup> (dark red), Glu<sup>126</sup> (orange), Met<sup>127</sup> (light green), Ser<sup>129</sup> (dark green), Asp<sup>135</sup> (cyan). **B.** Comparison of  $K_d$ s for spermine- $\alpha$ S complexes determined by this procedure. The values are  $0.61 \pm 0.03$  mM for  $\alpha$ S-*wt*,  $1.31 \pm 0.05$  mM for  $\alpha$ S-A30P, and  $1.23 \pm 0.06$  mM for  $\alpha$ S-A53T. Protein concentration was 100  $\mu\text{M}$  in all the cases.

This result would suggest that the N-terminal and the polycation compete for the negatively charged C-terminal, and that the composite influence of the electrostatic interactions reduce the affinity of the protein for the polycation. The net charge of the N-terminal domain is + 4, equivalent to a single molecule of spermine. The 100  $\mu\text{M}$  of N-terminus in solution was considerable lower than the high excess of polycation present in the sample in great excess. Thus if competition were the sole cause of the affinity change, the  $K_d$  of the N-terminus/C-terminus complex would have to be  $\sim$  10 times lower than for the polyamine/C-terminus complex. This could be explained in terms of the high local concentration effect that the charges at the N-terminus are expected to exert since they are directly attached to the C-terminus through the polypeptide chain and are not subject to diffusion or exchange as the polyamine molecules do.

In the previous we must consider that there is a second effect that may additionally regulate the affinity of the C-terminus to the polycation, namely the residual structure of the C-terminus, which is indeed perturbed in the mutants, as revealed by the RDCs.

In order to explore the possibility that residual structure at the C-terminus regulates binding to polyamines, we studied the spermine binding characteristics of a peptide comprising residues 105 to 136 derived from the C-terminus of  $\alpha$ S. As probed by RDCs this peptide populates unfolded conformations with diminished residual structure when compared with the full length protein (Chapter 1), and thus is an excellent probe for evaluating polyamine binding in the absence of both long range interactions.

Upon titration with spermine the peptide displayed essentially a similar dose-dependent shift of the resonances, although the saturating chemical shifts perturbations for the evaluated residues were 50% to 80% higher than the values displayed by the full length protein. The stronger chemical shift perturbation in the peptide could be due to the absence of conformational restrictions imposed by the full length polypeptide chain.

However, the resulting  $K_d$  for the peptide/spermine complex was  $\sim 1$  mM, approximately 80% higher than the 0.6 mM determined for the *wt* protein. These findings support the notion that the lost of residual structure at the C-terminus is able to modulate binding to ligands, which may also have consequences for other protein-protein interactions.

**Figure 5.11. Determination of dissociation constants for spermine-  $\alpha$ S C-terminal peptide complex.** A titration experiment for spermine binding to the C-terminal peptide of  $\alpha$ S ( $\alpha$ S<sub>105-136</sub>) was carried out to determine the  $K_d$  for the formation of the complex.  $^1\text{H}$ - $^{15}\text{N}$ -HSQC NMR spectra were acquired at a constant concentration of peptide (1 mM) and different concentration of polycation. **A.**  $^{15}\text{N}$  chemical shifts difference as a function of total concentration of ligand for  $\alpha$ S-C-terminal peptide. Residues are as follows: Ala<sup>124</sup> (dark red), Glu<sup>126</sup> (orange), Met<sup>127</sup> (light green), Ser<sup>129</sup> (dark green), Asp<sup>135</sup> (cyan). **B.** Comparison of  $K_d$ s for complexes of spermine- $\alpha$ S (0.61  $\pm$  0.03 mM) and for spermine- $\alpha$ S-C-terminal peptide (1.0  $\pm$  0.2 mM).

If we now compare the whole picture, the doubling in  $Kd$  of the mutant protein/spermine complex can be attributed to the loss of residual structure and from the strengthen of electrostatic long range interactions. Assuming a linear combination of both effects we can estimate that the competition between the N-terminus and the polyamine for the negative charges at the C-terminus would account for  $\sim 20\%$  increase in the  $Kd$ . Thus there is an increment in the effectiveness of the N-terminal/C-terminal interaction upon reduction of the long range hydrophobic interaction.

**Figure 5.12. Synergistic long range interactions in  $\alpha$ S.** Proposed scheme for the occurrence of long-range interactions in  $\alpha$ S. The ensemble of conformations populated by native  $\alpha$ S (center) accounts for long-range interactions involving the N-terminus (blue), the NAC region (yellow) and the C-terminus (red) of the protein. The presence of genetic mutations (right) abolishes the hydrophobic NAC/C-terminus interaction, while charge shielding (right) as the presence of salt or low pH cause reduction of the electrostatic N-/C-terminus interaction.

In conclusion, dipolar couplings demonstrate that the intricate network of long-range interactions is perturbed in PD-linked mutant  $\alpha$ S, such that the protein is more flexible and able to sample conformations somewhat more collapsed than the *wt* protein. Due to the preferential interaction with the N-terminus, the C-terminus would not be favored to interact with the NAC region, and the hydrophobic residues of this latter domain would be exposed to the solvent, increasing the free energy of the ensemble of conformations. Thus the A30P and A53T mutant  $\alpha$ S may overcome more easily the energetic barrier for self-association, leading to an increased tendency to oligomerize (Conway et al., 2000).

## 6. Results. Chapter III: “Structural characterization of the PD-associated protein $\beta$ -Synuclein.”

The protein  $\beta$ -synuclein ( $\beta$ S) is, together with  $\gamma$ S, the second and third discovered members of the synuclein family of proteins.  $\beta$ S is highly homologous to  $\alpha$ S, co-localizing in presynaptic nerve terminals (Buchman et al., 1998). However, in pathological conditions such as Parkinson’s disease (PD) or dementia with Lewy bodies (DLB),  $\beta$ S has a protective role, impeding  $\alpha$ S aggregation, both *in vitro* and *in vivo* (Hashimoto et al., 2001; Uversky et al., 2002). It has been suggested that a disruption of a critical balance between  $\alpha$ S and  $\beta$ S abundance may be required for neurodegeneration to occur (Rockenstein et al., 2001; Hashimoto et al., 2004), and indeed it has been proposed that a direct interaction between  $\alpha$ S and  $\beta$ S is responsible for the inhibitory effect to take place, albeit such a phenomenon has not been documented (Park and Lansbury, 2003).

As determined by CD spectroscopy  $\beta$ S populate unfolded states in aqueous solution (Uversky et al., 2002), and adopt alpha helical conformations upon binding to lipid vesicles (Park and Lansbury, 2003), identically to  $\alpha$ S. Conversely,  $\beta$ S and  $\alpha$ S differ in their ability to assemble into amyloid-like fibrils, given that  $\beta$ S does not readily aggregate as  $\alpha$ S under physiological conditions (Uversky et al., 2002). These differences can be reconciled by consideration of the absence in  $\beta$ S of a hydrophobic 11 amino acid stretch important for  $\alpha$ S fibrillation (Figure 6.1) (Giasson et al., 2001).

**Figure 6.1. Alignment of  $\alpha$ S and  $\beta$ S amino acid sequence.** Comparison of the amino acid sequences of  $\alpha$ S and  $\beta$ S. Alignment privileged amino acid conservation on  $\alpha$ S RDCs domains (Chapter 1), so no gap penalty was imposed. Shaded in grey are amino acids that differ between both proteins.

Interestingly, it was recently reported that  $\beta$ S can also assemble into  $\beta$ -sheet rich oligomers or adopt fibrillar structures under extreme conditions (Yamin et al., 2005). The capacity of  $\beta$ S to fibrillate appears to be determined by the presence of imperfect KTKEGV

repeats in the N-terminal domain of the protein, which is more than 90% homolog to  $\alpha$ S (Yamin et al., 2005).

In order to shed more light into the mechanisms regulating  $\alpha$ S fibrillation is thus mandatory to inspect  $\beta$ S for sequence determinants of such behavior, similarly to what we determined for  $\alpha$ S in chapter 1. No high resolution spectroscopic study had been previously performed on  $\beta$ S, such that nothing was known about the characteristics of the conformations populated by this protein. Such information would be very valuable for a comparative assessment of the hierarchy of tertiary interactions impeding  $\alpha$ S oligomerization, or as a prelude for identifying structural determinants able to reverse  $\alpha$ S aggregation.

In this chapter we describe the first characterization of  $\beta$ S by means of high resolution NMR spectroscopy. First we applied a set of triple resonance experiments in order to assign the resonances of the protein, and to determine its secondary structure propensities and backbone dynamics. We further studied the protein by techniques optimized for the evaluation of unfolded states of polypeptides, namely RDCs and PRE, and compared those determinations with the measurement of  $^3J_{\text{HNH}\alpha}$  couplings, reporters of  $\phi$  torsion angles. A thorough comparison with its neurotoxic homolog  $\alpha$ S provides clues for the understanding of the aggregation behavior of the latter protein.

### 6.1 Backbone assignment of $\beta$ S.

As a first step towards the characterization of the structure and dynamics of  $\beta$ S, we had to assign the NMR resonances corresponding to the backbone of the protein, since there were no previous reports on NMR experiments on this particular protein. Conventional three-dimensional HNCO, HN(CA)CO, HNCACB and CBCA(CO)NH spectra (Ikura et al., 1990) were successfully recorded on a  $^{13}\text{C}$ - $^{15}\text{N}$  labeled  $\beta$ S sample, but assignment was difficult just relying on this experiments. Due to the unfolded nature of  $\beta$ S a limited dispersion of resonances was observed, demanding the use of non-standard three-dimensional experiments, as the HNN pulse-sequence (Panchal et al., 2001) in order to unequivocally assign the resonances. Further obstacles arose from the presence of imperfect KTKEGV repeats but could be circumvent with the strategy applied (table 6.1).

As observed in the  $^1\text{H}$ - $^{15}\text{N}$  HSQC spectrum shown on figure 6.2, amide cross-peaks of  $\beta$ S are localized into regions according to the residue nature. Together with the narrow chemical shift dispersion in the  $^1\text{H}$  dimension, resembling the one of  $\alpha$ S (chapter 1) and

denatured ubiquitin (Peti et al., 2001), these observations demonstrate the unfolded nature of  $\beta$ S in solution.

**Figure 6.2.** Assignment of the  $^1\text{H}$ - $^{15}\text{N}$  HSQC spectrum of  $\beta$ S. Employing a combinations of triple resonance experiments it was feasible the assignment of the backbone resonances corresponding to  $\beta$ S. Shown is here an assigned  $^1\text{H}$ - $^{15}\text{N}$  HSQC spectrum where the resonances corresponding to the amide N-H bond are detected. Conditions were pH 6.5, NaCl 100 mM.

Despite signal overlap we were able to assign 126 from 128 non proline residues, failing only to observe resonances corresponding to the very first and second amino acids, due to rapid exchange. Thus 98% of the chemical shifts corresponding to  $^1\text{H}$ ,  $^{15}\text{N}$ ,  $^{13}\text{C}\alpha$ ,  $^{13}\text{C}\beta$  and  $^{13}\text{C}'$  atoms from the backbone of  $\beta$ S were determined.

Interestingly all the amide cross-peaks occurring in the HSQC spectrum display closely similar intensities, suggesting that conformational exchange does not occur under this condition of pH and temperature. The conditions employed to study  $\beta$ S were pH 6.5 and 100 mM NaCl, and when compared with the spectrum of  $\alpha$ S measured at the same conditions, some differences are evident. As observed in figure 6.3, the pattern of intensity for amide resonances corresponding to  $\beta$ S is nearly flat (red line), except for short stretches of residues centered on amino acids 8 and 44. Differences with  $\alpha$ S (blue line) were observed at Thr, Ser and Val residues.

**Figure 6.3. Intensity ratios for amide resonances in  $\beta$ S compared with  $\alpha$ S.** Profile for the normalized intensity ratio (respect to average signal), corresponding to  $\beta$ S (red line) and  $\alpha$ S (blue line) at pH 6.5.

In order to further compare the intensity profiles of  $\beta$ S with  $\alpha$ S, we measure an HSQC spectrum of  $\beta$ S at pH 7.4 (Figure 6.4A). As shown on figure 6.4B, under these conditions  $\beta$ S appears to behave similarly to  $\alpha$ S, and features a reduced intensity of several resonances at the N-terminus of the protein. Thus amide exchange rates are also defining the intensity of peaks at the N-terminal region of  $\beta$ S.

**Figure 6.4. Amide resonances of  $\beta\text{S}$  at pH 7.4.** **A.**  $^1\text{H}$ - $^{15}\text{N}$  HSQC spectrum of  $\beta\text{S}$  measured at pH 7.4 and 100 mM NaCl (blue), overlapped with a spectrum measured at pH 6.5 and 100 mM NaCl (red). The spectrum in blue was acquired at 600 MHz while the spectrum in red at 900 MHz (cryoprobe), and thus the differences in line widths. **B.** Intensity plots of the spectrums shown on A for  $\beta\text{S}$  at pH 7.4 (blue bars, A) and pH 6.5 (red line, B), scaled to the peak intensity of the residue A<sup>134</sup>. **C.** Normalized peak intensity for  $\beta\text{S}$  (blue line) and  $\alpha\text{S}$  (green line) at pH 7.4, relative to average peak height.

In order to obtain a general characterization on the ensemble of conformations populated by the protein, we measured the hydrodynamic properties of  $\beta$ S. Employing PFG NMR we found that, although being 6 residues shorter,  $\beta$ S possess an Rh almost 0.5 Å longer than  $\alpha$ S (Figure 6.4).

**Figure 6.4. Hydrodynamic properties of  $\beta$ S.** **A.** Measurement of Rh by PFG-NMR for  $\alpha$ S and  $\beta$ S under different solution conditions. The expected Rh for length are calculated based on empirical determinations on native and unfolded proteins (Wilkins, 1999, Biochemistry), and as described in the methods section. **B.** Plot of compaction factors derived in A.

The degree of unfolding of the two proteins can be compared through calculation of their compaction factors, which relates the measured Rh with empirical estimations of the minimum and maximum values expected for the length of the polypeptide chain (Wilkins et al., 1999). Thus, at the studied conditions,  $\alpha$ S possess a compaction factor of 0.3, higher than the 0.22 value determined for  $\beta$ S. This predicts that  $\beta$ S is considerably more extended than  $\alpha$ S, which has been already observed by SAXS (Uversky et al., 2002). Furthermore, by measuring the Rh at strong denaturing conditions, we determined that at 8 M urea  $\beta$ S adopts a completely unfolded conformation (compaction factor of 0.04), while  $\alpha$ S still is still slightly collapsed (compaction factor of 0.12). This supports the findings of small persistence of residual long range interactions between the N- and C-terminus of  $\alpha$ S at 8 M urea, as probed by PRE (Chapter 1), and suggests that  $\beta$ S may not feature such stabilizing interactions, adopting readily random coil conformations.

## 6.2. Propensity to form secondary structure in $\beta$ S is suggested by chemical shift analysis.

In the preceding section we have found differences and similarities between  $\alpha$ S and  $\beta$ S, but still both proteins are considerably unfolded as judge by  $^1\text{H}$  and  $^{15}\text{N}$  resonance dispersion. Triple resonance NMR experiments are well suited to provide information about the backbone of an unfolded protein on a residue-specific basis. Thus, local propensities for

structures that are preferentially sampled by the backbone of such highly dynamic systems may be derived from the determination of the NMR chemical shifts for backbone  $H\alpha$ ,  $C\alpha$  and  $C'$  atoms, as well as side-chain  $C\beta$  atoms (Dyson and Wright, 2004). In particular  $H\alpha$ ,  $C\alpha$  and  $C'$  chemical shifts are suitable for determining secondary structure propensities by subtracting the values corresponding to the empirically determined random coil shifts (Wishart and Sykes, 1994).

As shown in figure 6.5, significant deviations in chemical shifts occur for backbone regions in  $\beta$ S. Consistent negative deviations for  $H\alpha$  shifts suggest that the whole polypeptide chain populates conformations with slight helical nature (Figure 6.5A). Positive deviations in  $C\alpha$  and  $C'$  shifts, indicative of  $\alpha$ -helical propensities, were exclusively observed at the N-terminus of the protein, where the stretch comprising residues 56 to 66 showed the strongest propensity to adopt such conformations.

Negative deviations from random coil shifts are indicative of  $\beta$ -sheet or extended structures, and were evidenced at the whole C-terminus of  $\beta$ S, surprising result in view of the occurrence of 8 proline residues on this region. The restrictions imposed by these amino acids, known to impede  $\beta$ -sheet formation, would then favor adoption of extended polyproline II conformations in  $\beta$ S, consistently with the helical preference determined by  $H\alpha$  deviations (McCarney et al., 2005). Backbone chemical shift analysis fail to differentiate polyproline II from  $\beta$ -sheet, which largely overlap in the Ramachandran space.

**Figure 6.5. Chemical shifts deviations for the backbone of  $\beta$ S.** Measured chemical shift values for backbone atoms of  $\beta$ S were subtracted from random coil values and the result differences are plotted. **A.**  $\text{H}\alpha$  proton. **B.** Carbonyl carbon. **C.**  $\text{C}\alpha$  carbon. **D.**  $\text{C}\beta$  carbon.

Mean weighted chemical shift differences taking in account  $C\alpha$  and  $C'$  deviations from random coil values showed a strong dependence between residual secondary structure in  $\beta$ S and interactions with the solvent. As depicted in figure 6.6, hydrophilic regions on the N-terminus of the protein displayed propensity to adopt  $\alpha$ -helical conformation, while hydrophobic regions reflected a tendency to populate conformations with residual  $\beta$ -sheet character, likely providing a minimized interaction with the polar solvent.

**Figure 6.6. Mean weighted chemical shifts correlate with hydrophilicity in  $\beta$ S.** Correlation between combined and weighted carbonyl and  $C\alpha$  carbon chemical shifts differences (grey bars), and hydrophilicity by Kite-Doolittle method (red line, 9 residue window).

The correlation with the solvent is lost for the C-terminus of the protein, starting on residue 80. Due to the high net charge of this region (-16), a strong hydrophilicity was predicted, but the chemical shift analysis indicates an overall tendency to populate restricted conformations with  $\beta$ -sheet propensity. As stated before, the occurrence of 8 proline residues discourages such residual structure on this region and we interpret this observation as a tendency to adopt polyproline II conformations. The helical nature of this particular structure would thus be in accordance with the hydrophilic properties of the C-terminus and with a strong protein-solvent interaction.

For  $\alpha$ S, only  $C\alpha$  chemical shift differences with random coil values have been reported (Bussell and Eliezer, 2001). When compared with those that we measured in  $\beta$ S, a strong correlation at the N-terminus is observed (Figure 6.7), due to the high homology of both domains. However, almost the whole stretch of residues between amino acids 8 to 50 displays in  $\beta$ S (blue line) a reduced propensity to adopt secondary helical structure compared with  $\alpha$ S (red line). The opposite is seen around position 60, where  $\beta$ S shows high propensity to form helical structures which are small in  $\alpha$ S. This is likely to be due to the absence of

hydrophobic residues in the beginning of the central domain of  $\beta$ S, favoring solvent-side chains interactions.

**Figure 6.7. Comparison of secondary chemical shift deviations for  $\alpha$ S and  $\beta$ S.** Deviations of measured chemical shifts from the expected random coil values provide hints on the nature of the secondary structure sampled by the backbone of a protein. For  $\text{C}\alpha$  (B), CO (C) and mean weighted carbon chemical shift (D) positive deviations are indicative of  $\alpha$ -helices, while negative deviations suggest  $\beta$ -sheet or extended conformations. In the case of Ha (A), an inverse relationship is valid. In red is

shown  $\beta$ S and in blue  $\alpha$ S, both measured at pH 6.5 and 100 mM NaCl. Protein sequences are aligned according to the lack of NAC region in  $\beta$ S and the shorter C-terminus in  $\alpha$ S (top scheme).

The correlation is lost at the C-terminus of the protein, with  $\beta$ S showing an overall propensity towards extended conformations, while in  $\alpha$ S few scattered residues show such characteristic. Although both proteins possess a highly negatively charged C-terminus,  $\beta$ S possess 3 more negative residues featuring an increased number of aspartic residues instead of the glutamic ones found in  $\alpha$ S. In addition,  $\beta$ S has 8 Pro residues on this domain, 3 more than  $\alpha$ S, which could sustain extended conformations as polyproline II.

### 6.3. NMR relaxation evidences fast dynamics in $\beta$ S.

In order to provide more insights into the unfolded nature of the protein we characterized the dynamics of the polypeptide chain by measuring  $T_1$ ,  $T_2$  and heteronuclear NOEs for backbone resonances in  $\beta$ S. These standard determinations are very useful for determining order parameters in folded proteins, which are related to the motional restrictions associated with domains with defined secondary structure.

As observed in figure 6.8, measurement of  $R_1$  and  $R_2$  rates for  $\beta$ S amide cross-peaks displayed a bell-shaped profile characteristic of unstructured polypeptides. For  $R_1$  a mean value of  $1.4 \text{ s}^{-1}$  was observed (Figure 6.8A), while the average  $R_2$  value was  $3.0 \text{ s}^{-1}$  (Figure 6.8B), rates very similar to the ones reported for other native unfolded polypeptides as the HIV-1 Tat protein or the histone mRNA binding protein SLBP (Thapar et al., 2004; Shojania and O'Neil, 2006a). Minor deviations centered on residues 42, 60 and 110 were evidenced, suggesting slower dynamics for these regions in the ns-ps timescale. These determined values clearly indicated that rapid internal motion exists for most amides, consistent with the protein being mostly unfolded.

In addition, steady-state heteronuclear NOEs were measured for  $\beta$ S and ranged in the region  $\pm 0.2$ , indicative of the absence of restricted dynamics in the ns-ps timescales (Figure 6.7C). Nevertheless two stretches of residues with high NOEs were evidenced centered on positions 60 and 90, likely reflecting minor degrees of dynamic restrictions in such timescale.

When compared with  $\alpha$ S, some particular differences can be noted. The average  $R_1$  for  $\alpha$ S ranges on  $\sim 2 \text{ s}^{-1}$ , significantly higher than the mean value in  $\beta$ S ( $1.4 \text{ s}^{-1}$ ) (Bussell and Eliezer, 2001). Similarly, the  $R_2$  mean value for  $\alpha$ S is higher than for  $\beta$ S ( $3.8 \text{ s}^{-1}$  vs  $3.0 \text{ s}^{-1}$ ), and only displays a cluster with high  $R_2$  at position 44. What is preserved between both

proteins is the NOE pattern which for  $\alpha$ S ranges also on the  $\pm 0.2$  region. The lower  $R_1$  and  $R_2$  values are in line with the higher unfolded nature of  $\beta$ S respect  $\alpha$ S.

**Figure 6.8. NMR-relaxation profiles for  $\beta$ S.** **A.** Longitudinal relaxation rates ( $R_1$ ). **B.** Transverse relaxation rates ( $R_2$ ). **C.** Heteronuclear NOEs with a 5 residue average window.

#### 6.4. Residual structure in $\beta$ S probed by dipolar couplings.

It has been shown throughout the previous chapters how residual dipolar couplings were a very powerful NMR parameter to study the unfolded state of  $\alpha$ S. However, interpretation of RDCs in random coil polypeptides has been a subject of debate, but now it is widely accepted that they report on the degree of residual structure and the persistent length of segments in the chain (Louhivuori et al., 2003; Louhivuori et al., 2004). Thus small couplings would be indicative of a poor degree of preferred orientations by the segment, while high RDCs values

would arise from conformational restrictions and residual structure. We have previously applied this technique to study the native unfolded state of  $\alpha$ S and found long range interactions and residual structure at the C-terminus of the protein important for impeding protein aggregation (Chapter 1).

When  $^1D_{NH}$  dipolar couplings were measured in  $\beta$ S aligned in Pfl phages as anisotropic media, we observed predominantly positive couplings similar to what was described for  $\alpha$ S (Figure 6.10A). A particular feature of  $\beta$ S is that the whole C-terminus of the protein shows RDC values that on average are 2 times higher than the N-terminus. These small couplings in the N-terminal domain are indicative of the flexible nature of this region, in line with the relaxation rates that we determined. On the other hand, the high couplings measured for the entire stretch of 30 residues at the C-terminus suggest a significant amount of residual structure, not detected by measurement of relaxation but inferred from the chemical shift analysis, and supporting the occurrence of polyproline II conformations.

**Figure 6.10. Residual dipolar coupling in  $\beta$ S.** **A.** RDCs profile for  $\beta$ S aligned in Pfl (5mg/ml). **B.** Pattern of RDCs for  $\beta$ S aligned in 5%  $C_8E_5$ /octanol.

Importantly, the main features of the RDCs pattern were reproduced in a second alignment media, a PEG/alcohol mixture (Figure 6.10B).

The high values of RDCs at the C-terminus of the protein are reminiscent of the profile obtained for  $\alpha$ S. In  $\alpha$ S the RDCs reported long range-induced residual structure as

two clusters with particularly high values of  $^1D_{NH}$  correlating with couplings in the NAC region. When compared with  $\beta$ S (Figure 6.11), it is noteworthy the sole presence of high couplings at the C-terminus, which are not restricted but rather extended to the whole domain.

**Figure 6.11. Comparison of RDCs between  $\alpha$ S and  $\beta$ S.** Overlay of RDCs profiles for  $\alpha$ S (blue) and  $\beta$ S (red) measured in C8E5/octanol as alignment media. Sample condition was pH 6.5 and 100 mM NaCl in both cases.

The question underlying these findings is whether  $\beta$ S, although being highly unfolded, still has long range interactions, or whether in this case the RDCs are probing a locally-encoded residual structure. Due to the absence of the NAC region, feasible long-range contacts to occur in  $\beta$ S would involve the positively charged N-terminus and the negatively charged C-terminus, as seen in the case of  $\alpha$ S.

### 6.5. Residual structure in $\beta$ S is locally encoded.

In order to dissect local and non-local contributions to the conformational restrictions observed at the C-terminus of  $\beta$ S, we sought to evaluate the occurrence of long range interactions in this protein. In a similar fashion as used to reveal long range contacts in  $\alpha$ S (Chapter 1), we employed paramagnetic resonance enhancement by nitroxide spin labels to study the conformations populated by  $\beta$ S in solution.

When we placed the paramagnetic reporter at the N-terminus of the protein (position 18<sup>th</sup>) the broadening effect was only local but more pronounced than the one expected for a

random coil polypeptide, suggesting a minor degree of compactness of this region (Figure 6.12). Similarly, when the spin label was placed at the center of the protein (position 79<sup>th</sup>), a strong paramagnetic effect extended towards the N-terminus of the protein but not towards the C-terminus, reflecting the occurrence of local compaction but the absence of long-range contacts.

**Figure 6.12. Paramagnetic relaxation enhancement in  $\beta$ S.** Two Cys-containing mutants of  $\beta$ S (A18C and A79C) were constructed in order to provide attachment sites for the paramagnetic tag MTSL. **A.** Overlay of the HSQC spectra measured in the presence (red) and absence (blue) of MTSL attached to position 18.

Note how affected resonances are broadened beyond detection. **B.** Same as A, but for the MTSL tag placed on position 79. **C.** Profile of intensity ratios for resonance peaks between the paramagnetic (MTSL) and diamagnetic (no MTSL) states for  $\beta$ S-A18C protein (black bars). In red, the intensity ratios for the mirrored mutant in  $\alpha$ S ( $\alpha$ S-18C) are overlaid for comparison. The expected profile for a random coil polypeptide, with the paramagnetic tag placed at the same position, is depicted in grey dashed line. **D.** The same as C, but for  $\beta$ S-A19C (black bars) and  $\alpha$ S-A90C (red line).

The paramagnetic labeling at 18<sup>th</sup> and 79<sup>th</sup> positions in  $\beta$ S mirror the 18<sup>th</sup> and 90<sup>th</sup> positions employed in the study of  $\alpha$ S, which allowed us to perceive long range contacts between the N- and C-terminus of the protein and a compaction at the C-terminus aid by an interaction with the central hydrophobic stretch, respectively (Chapter 1). In  $\beta$ S neither long range interactions nor C-terminal compaction was observed, which may be due to the lack of the hydrophobic region in the middle of the protein. Thus residual structure at the C-terminus of  $\beta$ S is exclusively the result of local conformational restrictions. In addition, these results in  $\beta$ S provide additional confirmation to the key role that the central hydrophobic region of  $\alpha$ S plays on the formation of the long range interactions with the C-terminus.

### **6.6. Polyproline II structure is evidenced at the C-terminus of $\beta$ S.**

Local structure in unfolded polypeptides has been attributed to the presence of a significant amount of polyproline II (PII) helical extended conformations, even for sequences of low proline content (McCarney et al., 2005). This observed tendency to adopt PII helix is attributed to the tendency of the backbone to preferentially populate  $\phi$ ,  $\psi$  angles in the lowest, broadest energy levels, situated in the upper left quadrant of the Ramachandran space, where  $\beta$ -sheet and PII helices occur (Dyson and Wright, 2002).

To further search for factors that could explain the chemical shift patterns and the RDCs profile obtained for  $\beta$ S, we measured  $^3J_{\text{HNHA}}$  scalar couplings which report on the  $\phi$  torsion angle of a given residue. Thus small  $^3J_{\text{HNHA}}$  couplings (3 to 5 Hz) correspond to helical conformations, where high couplings are indicative of sheet conformations (8 to 11 Hz) (Dyson and Wright, 2002). As shown on figure 6.13, the  $^3J_{\text{HNHA}}$  scalar coupling profile for  $\beta$ S demonstrates that the whole polypeptide backbone is preferentially sampling coil and helical conformations, with no single residue displaying coupling values higher than 8. The average coupling value of  $\sim 5.5$  is reduced in comparison with the value of  $\sim 7$  found for other unfolded polypeptides (Smith et al., 1996; Shojania and O'Neil, 2006a).

**Figure 6.13.**  $^3J_{\text{HNH}\alpha}$  profile for  $\beta\text{S}$ . The measurement of three-bond scalar coupling between the amide proton and the  $\text{C}\alpha$  proton is indicative of the  $\phi$  torsion angle that the amino acid is preferentially sampling. The secondary  $^3J_{\text{HNH}\alpha}$  profile (coil values subtracted from experimental values) for  $\beta\text{S}$  (red) is compared with the weighted deviation between carbonyl and  $\text{C}\alpha$  carbons (blue), indicative of secondary structure propensities for the polypeptide backbone.

The low  $^3J_{\text{HNH}\alpha}$  scalar couplings are easily rationalized for the N-terminal half of the protein (up to residue 80), by correlating with the determined chemical shift deviation, suggesting a sampling of conformations with a slight preference for  $\alpha$ -helices. The correlation is lost in the C-terminus, where  $\text{C}\alpha$  and  $\text{C}'$  deviations suggest populations of extended,  $\beta$ -sheet like, conformations, while  $\text{H}\alpha$  and  $^3J_{\text{HNH}\alpha}$  couplings demonstrate that these residues preferentially sample helical conformations. The backbone conformation reconciling such features is the PII structure, which preserves helical-like features sampling an extended space (Dyson and Wright, 2002). The PII residual structure at the C-terminus of  $\beta\text{S}$  is also suggested by the presence of 8 Pro residues, 2 of them consecutive, which do not particularly favor sampling  $\beta$ -sheet conformations, but may easily adopt PII structure.

Additional support for claiming the finding of PII instead of  $\alpha$ -helices, could be inferred from the RDCs pattern. While  $\beta$ -sheet and PII conformations align the NH bond vector perpendicular to the principal axis to the chain direction,  $\alpha$ -helices align it parallel (Mohana-Borges et al., 2004). This effect will provoke, in the manner that we determined the RDCs, dipolar couplings to be positive for  $\beta$ -sheets and PII structures, and negative for  $\alpha$ -helices. We did observe strong positive coupling for the whole C-terminus, supporting the preferential sampling of residual PII conformations. In line with these findings we detected negative RDCs for the first 10 residues of the protein (aligned in C8E5, Figure 6.12B), but failed to detect such conformational restriction in the rest of the N-terminus, where couplings were very small, similar to what is expected for a random coil ensemble (Louhivuori et al.,

2004). These data do not support the existence of a population of conformers with a consistent  $\alpha$ -helical content at the N-terminus, suggesting rather a highly dynamic conformational sampling, likely modulated by solvent-side chains interactions.

The  $^3J_{\text{HNH}\alpha}$  scalar couplings measured for  $\alpha\text{S}$  (Figure 6.14) were also consistent with the unfolded nature of the protein, with a mean value of  $\sim 8$  Hz, slightly higher than the average value of  $\sim 7$  Hz, found in unfolded polypeptides. When compared with the previous result, the overall smaller couplings on  $\beta\text{S}$  are readily evident. Interestingly, the C-terminus of  $\alpha\text{S}$ , despite having 5 Pro residues and a similarly high negative net charge as  $\beta\text{S}$ , does not populate PII structure, as suggested by the higher  $^3J_{\text{HNH}\alpha}$  couplings.

**Figure 6.14. Comparison of  $^3J_{\text{HNH}\alpha}$  couplings for  $\alpha\text{S}$  and  $\beta\text{S}$ .** **A.** Overlay plot of three-bond scalar coupling between amide proton and  $\text{C}\alpha$  proton for  $\alpha\text{S}$  (blue) and  $\beta\text{S}$  (red). **B.** Comparison of secondary  $^3J_{\text{HNH}\alpha}$  profile (coil values subtracted from experimental values) for  $\alpha\text{S}$  (blue) and  $\beta\text{S}$  (red), over a 5 residue window, indicative of the differences in the conformations sampled by both polypeptide chains. Sample condition was pH 6.5 and 100 mM NaCl in both cases.

The  $^3J_{\text{HNHA}}$  values reported here for  $\alpha\text{S}$  were measured at pH 7.4 while the ones in  $\beta\text{S}$  were measured at pH 6.5. This could be a reason why some differences for the couplings at the N-terminus of both homologous proteins were observed for this highly conserved domain. However, as RDCs probed in  $\alpha\text{S}$ , only minor changes were determined on the protein upon a slight reduction in the pH, which are centered on the very N-terminus. The structural features of the C-terminus domain of  $\alpha\text{S}$  remained unperturbed, and thus a comparison with  $\beta\text{S}$  is possible.

In summary we have demonstrated in this chapter that  $\beta\text{S}$  is a natively unfolded protein that populates an ensemble of extended conformations. The N-terminal half of the protein does not possess significant amount of residual structure, and interacts strongly with the aqueous solvent. Conversely, the C-terminal half populates conformations with significant residual PII extended structure. Furthermore, these studies also helped us to understand the role of residual structure and long range interactions in the native state of  $\alpha\text{S}$ .

## 7. Results. Chapter IV: “Structural basis of metal binding to $\alpha$ -synuclein”.

An increasing number of studies indicate that transition metals, in their di- and trivalent ionic form, are capable of accelerating the aggregation process of various pathologic proteins, as  $A\beta$ , prion proteins,  $\beta$ 2-microglobulin and  $\alpha$ S (Sayre et al., 1999). In the case of  $\alpha$ S, it was shown that Cu(II) was the most effective ion in promoting  $\alpha$ S oligomerization (Paik et al., 1999). Later on, a systematic analysis of the effect of various metal ions revealed that Al(III), Fe(III) and Cu(II) efficiently accelerate  $\alpha$ S fibrillation *in vitro*, whereas Fe(II) and Mn(II) presumably form stable complexes with the protein as they quench tyrosine fluorescence (Uversky et al., 2001c; Golts et al., 2002).

Neither the structural characterization of the binding sites for metal ions, nor the identification of the amino acids involved in the interaction have been reported up to date. We thus sought to employ high-resolution spectroscopic techniques to establish the role of metal ions in  $\alpha$ S fibrillation at the molecular resolution currently available for other amyloid diseases.

We chose Cu(II) as the first metal ion to characterize, since it was reported to effectively accelerate  $\alpha$ S aggregation (Paik et al., 1999), and because it seems to be a common denominator under many amyloid diseases as AD and Prion diseases, among others (Sayre et al., 1999). In addition, the paramagnetic nature of the metal ion allowed us to employ high resolution techniques, as NMR to map the binding interfaces, and electron paramagnetic resonance (EPR) spectroscopy to study the ligand contribution to the complex. After assessing the structural determinants of Cu(II) binding to  $\alpha$ S we performed a comparative study of other divalent paramagnetic ions in order to determine the hierarchy of metal-protein complex formation.

### 7.1. Cu(II) binding to $\alpha$ S promotes protein aggregation

The above-mentioned reports on the effects of transition metal ions on  $\alpha$ S fibrillation were performed at mM concentrations, far greater than those normally occurring in tissues, which are  $\sim 20 \mu\text{M}$  (Brown et al., 1997), such that the physiological relevance of these effects is still open to question. Performing experiments under more physiological conditions provide more relevant indications as to whether metal binding may or may not be a relevant event in the aggregation of  $\alpha$ S *in vivo*.

We monitored the time course of  $\alpha$ S aggregation in the presence of  $\text{CuCl}_2$  at  $37^\circ\text{C}$  by the Thioflavin-T fluorescence assay. Addition of 40 to  $200 \mu\text{M}$  Cu(II) decreased the

characteristic lag time for aggregation of the unliganded protein in a manner dependent on Cu(II) concentration (Figure 7.1A). An inverse relationship was found between  $t_{1/2}$  and Cu(II) concentration, but no major changes were observed in the rate of monomer addition ( $k_{app}$ ).

**Figure 7.1. Aggregation kinetics  $\alpha$ S aggregation in the presence of copper.**

**A.** 0 (dark red), 40 (orange), 100 (dark yellow) and 200  $\mu$ M of Cu(II) (green) were added to 100  $\mu$ M  $\alpha$ S, and the protein was incubated at 37  $^{\circ}$ C with continuous stirring. Solid lines represent fits according to the  $\alpha$ S aggregation model. The fits yielded the following parameters:  $k_{app}$  ( $h^{-1}$ ) =  $0.19 \pm 0.03$ ,  $0.15 \pm 0.05$ ,  $0.14 \pm 0.05$ ,  $0.14 \pm 0.01$  and  $t_{1/2}$  (h) =  $47 \pm 5$ ,  $31 \pm 4$ ,  $25 \pm 3$ ,  $11 \pm 3$  (in order of increasing Cu(II) concentration). **B.** PAR assay of Cu(II) content in  $\alpha$ S fibrils obtained in the aggregation assay shown in A.

We determined whether Cu(II) was incorporated into the fibrils to any significant degree, and we found that 70-90% of the Cu(II) added to the aggregation assay was incorporated into the protein aggregates (Figure 7.1B). Notably, even when 5 equivalents of Cu(II) were added, more than 4 equivalent were found in the fibrils, suggesting the presence of several binding sites for the metal.

Since solution conditions strongly perturb the morphology of the resulting  $\alpha$ S fibrils (Hoyer et al., 2002), it was necessary to assess whether the metal incorporation had any particular influence on the aggregated protein. A morphological analysis by electron microscopy of the fibrils formed upon incubation with 40 to 200  $\mu$ M Cu(II) revealed fibrillar structures qualitatively similar to those obtained in the absence of the metal ion (Figure 7.2). This suggests that the Cu(II)-bound aggregating-prone protein populates misfolded conformations that are on-pathway intermediates of fibrillation.

**Figure 7.2. Morphology of  $\alpha$ S fibrils grew in the presence of copper.** Electron microscopy images of  $\alpha$ S aggregates obtained without Cu(II) (**A**) or in the presence of 100  $\mu$ M Cu(II) (**B**). Scale bars, 100 nm.

### 7.2. Quantitative assessment of Cu(II) binding to $\alpha$ S.

Besides the notorious effect of Cu(II) on the aggregation of  $\alpha$ S, it was of interest to determine the affinity of the protein for the metal, in order to assess the possibility that the complex occurs *in vivo*. We obtained initial estimates of the dissociation constant for Cu(II) binding to  $\alpha$ S by equilibrium dialysis. By equilibrating a metal-free  $\alpha$ S solution against buffer containing 1  $\mu$ M or 10  $\mu$ M Cu(II), and measuring the increment of metal inside the protein compartment, we estimated Cu(II):protein ratios of 0.9 and 1.4 after dialysis. Thus,  $\alpha$ S is able to bind more than one equivalent of Cu(II) with dissociation constants  $<1$   $\mu$ M and  $>10$   $\mu$ M.

**Figure 7.3. Equilibrium dialysis of the complex  $\alpha$ S-Cu(II).** **A.**  $\alpha$ S was subjected to equilibrium dialysis experiments. Free (orange) or Cu(II) preloaded (dark yellow) protein was extensively dialyzed against buffer free of metal, and  $\sim 0.3$  eq of metal were found attached to the protein. Similarly, free protein was dialyzed against buffer containing 0.1  $\mu$ M (green), 1  $\mu$ M (cyan) or 10  $\mu$ M (blue) of Cu(II) and the amount of metal liganded by the protein was measured. In all the cases protein concentration was 300  $\mu$ M. **B.** Cu(II) binding to  $\alpha$ S estimated by equilibrium dialysis suggest two sites of binding one with high affinity ( $K_{d1} < 1$   $\mu$ M and  $K_{d2} > 10$   $\mu$ M).

When a solution of  $\alpha$ S containing one equivalent of Cu(II) was dialyzed against a metal-free buffer, a Cu(II):protein ratio of 0.26 was obtained, demonstrating both the reversibility and high affinity of the Cu(II)- $\alpha$ S complexes.

Formation of Cu(II) complexes often leads to energetic transitions in the metal that can be efficiently studied spectroscopically. We monitored Cu(II) binding by visible electronic absorption and CD spectroscopy, performing titrations of  $\alpha$ S with increasing concentrations of metal. At sub-stoichiometric Cu(II): $\alpha$ S ratios, a single visible absorption band appeared in the electronic spectra at  $\sim 620$  nm, saturating at one equivalent with  $\epsilon = 70$  M<sup>-1</sup> cm<sup>-1</sup>, typical of a Cu(II) d-d transition (Figure 7.4.A).

The absorption maximum ( $\lambda_{\max}$ ) is sensitive to the identity of the metal ligands and can be used as an indication of the number of nitrogen ligands bound to the Cu(II) ion (Bryce and Gurd, 1966). The visible absorption spectrum of the Cu(II)- $\alpha$ S complex is characteristic of two or three nitrogen coordination in a type (II) square-planar or distorted tetragonal arrangement. Beyond one equivalent of Cu(II), the visible absorption band increased in intensity and shifted toward lower energy. Subtraction of the spectrum recorded with one equivalent of Cu(II) revealed an absorption band with a maximum at 720 nm, likely reflecting the incorporation of a second Cu(II) ion into a different coordination environment.

**Figure 7.4. Absorption spectroscopy of Cu(II)- $\alpha$ S complexes.** **A.** Ligand field region of the spectra. Bold lines highlight the spectra at 1, 2, 3 and 4 equivalents of Cu(II). **B.** Direct titration of  $\alpha$ S with Cu(II). Concentration dependence of the second derivative absorbance at 620 nm (dark red) and 660 nm (orange). Solid lines show the result of the simultaneous fit of both sets of data points as described in the text.

Analysis of the second derivatives ( $\partial^2 E / \partial \lambda^2$ ) of the spectra yielded quantitative information. The plot of this quantity at 620 nm showed discontinuities in the binding curve at one and two molar equivalents of Cu(II) (Figure 7.4B). However, the absorbance curves

recorded up to four equivalents of Cu(II) did not saturate. Thus, we fit the data according to a model incorporating complexes of Cu(II) in three classes of independent, non-interactive binding sites per  $\alpha$ S molecule: (1) a high affinity site ( $K_{d1}$ ); (2) a lower affinity site ( $K_{d2}$ ); and (3) a class of non-specific  $n$  sites with very low affinity ( $K_{d3/n}$ ).

The molar derivative absorbance signal  $[(\partial^2 E/\partial \lambda^2)]$  corresponding to the above scheme is given by

$$\Delta \left( \frac{\partial^2 E}{\partial \lambda^2} \right) = \sum_{k=1}^3 \alpha_k \delta_k \quad [1]$$

where  $\alpha_k$  and  $\delta_k$  are the relative fractional concentration and the molar difference absorbance second-derivative, respectively, associated with formation of the Cu(II) complex(es) at site  $k$ .

Analysis according to these models yielded the following dissociation constants:  $K_{d1} = 120 \pm 160$  nM,  $K_{d2} = 36 \pm 36$   $\mu$ M and  $K_{d3/n} = 470 \pm 80$   $\mu$ M. Despite the large numerical uncertainties associated with these quantities, due to the high concentration of the protein required to achieve accurately measurable signals ( $[\alpha S]_{tot} \gg K_{d1,2}$ ), their relative order of magnitude was well established.

The CD spectra of  $\alpha$ S complexed with Cu(II) showed a positive band in the d-d region ( $\sim 600$  nm) and a negative band at 300 nm (Figure 7.5A). The latter can be assigned to a charge transfer transition (c.t.) between the metal center and an imidazole group ( $\pi_1 N_{im}-Cu$  c.t., 280-345 nm) or a deprotonated peptide nitrogen (N-Cu c.t., 295-315 nm) (Daniele et al., 1996).

**Figure 7.5. Absorption spectroscopy of Cu(II)- $\alpha$ S complexes.** **A.** CD spectra of wild type  $\alpha$ S corresponding to 0 (black), 0.5 (red), 1 (green), 2 (blue) and 3 (yellow) equivalents of Cu(II) added to the protein. **B.**  $\Delta \epsilon$  values at 300 nm (dark red) and at 599 nm (orange) vs. Cu(II) concentration. Protein concentration was 300  $\mu$ M.

The CD band at 300 nm saturated with one equivalent of added Cu(II) (Figure 7.5B). In contrast, the intensity of the CD band at 600 nm increased up to one equivalent of Cu(II), decreased upon further addition up to two equivalents of Cu(II), and remained constant at higher Cu(II) concentrations. We conclude that the c.t. band is associated with the highest affinity Cu(II) binding site. The decrease in ellipticity at 600 nm observed with more than one equivalent of Cu(II) probably reflects the development of a negative band associated with formation of the second Cu(II) complex.

### 7.3. Dissecting domain contributors to Cu (II) binding to $\alpha$ S.

In order to evaluate the contributions of different regions of the protein to Cu(II) binding we divided the  $\alpha$ S molecule in two, constructing an  $\alpha$ S C-terminal deletion mutant ( $\alpha$ S<sub>1-108</sub>) and an N-terminal deletion mutant ( $\alpha$ S<sub>95-137</sub>). We studied the association of Cu(II) to both mutants by UV-Vis and CD spectrophotometric titrations.

As observed in figure 7.6, both polypeptides bind Cu(II) in a different manner. While the absorption spectrum of the Cu(II)- $\alpha$ S<sub>1-108</sub> complex was similar to that of the wild-type protein, the ligand field absorption band in the spectra of  $\alpha$ S<sub>95-137</sub> was considerably red-shifted. These results suggest that the high affinity Cu(II) binding site is located at the N-terminus of the protein.

**Figure 7.6. UV-Vis spectroscopy of Cu(II) binding to  $\alpha$ S<sub>1-108</sub> and  $\alpha$ S<sub>95-137</sub>.** The contributions to different regions of the protein to the binding of Cu(II) was studied

on deletions mutants of the protein. **A, B.**  $\alpha S_{1-108}$  titration with Cu(II) shows the evolution of a peak at 630 nm which saturates at 1 equivalent of metal added. **C, D.** Conversely, titration of  $\alpha S_{95-137}$  shows a band evolving at 680 nm and saturating at 2 equivalents of metal added. In all the cases protein concentration was 300  $\mu M$ .

The CD spectra of both truncated species displayed even stronger differences. The Cu(II)- $\alpha S_{1-108}$  complex closely matched that of the full length  $\alpha S$ , from which we conclude that the geometry and position of the ligand set observed in the whole protein is highly conserved in the  $\alpha S_{1-108}$  fragment (Figure 7.7A).

Conversely, the truncated form  $\alpha S_{95-137}$  showed an intense negative band in the visible region at  $\sim 700$  nm ( $\Delta\epsilon_{700} = -0.5 M^{-1} cm^{-1}$ ) and a positive band centered at 324 nm, assigned to a N-Cu c.t (Figure 7.7B). Indeed, a negative band was foreseen upon titration of full length  $\alpha S$  by an excess of metal, suggesting that the second affinity binding site in the protein may be located at the C-terminus.

**Figure 7.7. CD spectroscopy of Cu(II) binding to  $\alpha S_{1-108}$  and  $\alpha S_{95-137}$ .** Domain contributions to copper binding in  $\alpha S$  could be determined by the CD spectrum of the deletion mutant-Cu(II) complexes. The CD spectra of  $\alpha S_{1-108}$  (**A**) and  $\alpha S_{95-137}$  (**B**) are shown. Spectra correspond to 0.5 (black), 1 (red), 2 (green) and 3 (yellow) equivalents of Cu(II) added to the proteins. Protein concentrations were 200  $\mu M$  ( $\alpha S_{1-108}$ ) and 150  $\mu M$  ( $\alpha S_{95-137}$ ).

These results establish the hierarchical contributions of regions in the polypeptide to metal binding. While Cu(II) binding to the N-terminal fragment mirrors the CD spectra of the Cu(II): $\alpha S$  complex, the metal complex with the C-terminal fragment is not able to recreate any of the Cu(II) binding sites of  $\alpha S$ .

#### 7.4. Mapping Cu(II) binding interfaces in $\alpha S$ by heteronuclear NMR.

Due to the paramagnetic nature of Cu(II), we could explore the details of Cu(II) binding to  $\alpha S$  by NMR spectroscopy. Similarly to the paramagnetic effect that we exploited with

nitroxide spin labels in the previous chapters, the electron spin relaxation from the Cu(II) ion provokes differential broadening of the amide resonances linked to the paramagnetic center. Thus, through-bond or through-space interactions (up to  $\sim 10\text{\AA}$ ) will cause a reduction in the intensity of the peaks in the NMR spectrum, providing means for mapping the metal binding interfaces in the protein.

We first recorded a series of  $^1\text{H}$ - $^{15}\text{N}$  HSQC spectra of  $100\ \mu\text{M}$   $\alpha\text{S}$  at pH 6.5 in the presence of increasing concentrations of Cu(II) (0-60  $\mu\text{M}$ ) and determined the extent of paramagnetic broadening by evaluating the ratio of peak intensities in the presence ( $I_{\text{para}}$ ) and absence ( $I_{\text{diam}}$ ) of the metal ion. As shown on figure 7.8, significant changes in cross-peak intensities occurred in well-defined regions of  $\alpha\text{S}$ .

**Figure 7.8. NMR spectra of Cu(II) binding to  $\alpha\text{S}$ .** Overlaid  $^1\text{H}$ - $^{15}\text{N}$ -HSQC spectra of  $\alpha\text{S}$  ( $100\ \mu\text{M}$ ) in the absence (red) and presence of  $40\ \mu\text{M}$  Cu(II) (blue, left) and  $100\ \mu\text{M}$  Cu(II) (blue, right).

The strongest broadening effects at  $20\ \mu\text{M}$  Cu(II) were centered on the amide group of His50 in the N-terminal region, whereas little or no broadening was observed for the amide groups of residues located in the NAC region or belonging to the C-terminal domain (Figure

7.9A). Thus, the N-terminal region was the most affected by Cu(II) binding under this condition.

The broadening was further pronounced at 40-60  $\mu\text{M}$  Cu(II), as reflected in values of  $I_{\text{para}}/I_{\text{diam}} < 0.2$  for the resonances corresponding to residues 3-9 and 49-52 (Figure 7.9B, 7.9C). Residues 15-45 were also involved to a lesser extent, but significant changes were evidenced at the C-terminal region, the strongest effect centered on Asp<sup>121</sup>. Interestingly, the amide resonances assigned to the NAC region remained unaltered, even at higher Cu(II) concentrations. All NMR spectral changes induced by Cu(II) were abolished upon EDTA addition, confirming the reversibility of Cu(II) binding.

**Figure 7.9. Cu(II) binding to  $\alpha\text{S}$  investigated by NMR.**  $I_{\text{para}}/I_{\text{diam}}$  profiles corresponding to 100  $\mu\text{M}$   $\alpha\text{S}$  at pH 6.5. **A.** 20  $\mu\text{M}$  Cu(II). **B.** 40  $\mu\text{M}$  Cu(II). **C.** 60  $\mu\text{M}$  Cu(II).

The NMR titration experiment showed that the residues encompassing His50 were the most perturbed, suggesting that the imidazole ring plays a critical role in anchoring the Cu(II) ion to the N-terminal domain. In order to prove this assertion we tested whether modification of the sole His residue in  $\alpha\text{S}$  by DEPC affects Cu(II) binding to the protein.

Exposure to DEPC shifted the paramagnetic influence of Cu(II) from the N-terminal to the C-terminal domain (Figure 7.10A), manifested by substantial changes in cross-peak intensities at Cu(II) concentrations as low as 20  $\mu\text{M}$ . The strongest effects were centered on the amide group of Asp<sup>121</sup>, whereas resonances in the NAC domain remained unaffected under these conditions. The decrease in intensity of the signals corresponding to residues 49-52 was likely due to residual Cu(II) coordination capability of His50, e.g. through the imidazole N atom unmodified by DEPC. In summary, Cu(II) binding to DEPC-treated  $\alpha\text{S}$  clearly shows the existence of two different copper binding interfaces in the protein, one at the N-terminus and another at the C-terminus.

**Figure 7.10. Modulation of copper binding to  $\alpha$ S studied by NMR.** Peak intensity ratios corresponding to Cu(II) binding to modified and C-terminal truncated  $\alpha$ S. **A** DEPC-modified  $\alpha$ S, 20  $\mu$ M Cu(II). **B**. 20  $\mu$ M Cu(II), pH 5.0. **C**. Wild type ( $\Delta$ ) and 1-108 ( $\bullet$ )  $\alpha$ S, 20  $\mu$ M Cu(II).

Because protonation of His50 should reduce Cu(II) binding, we determined the pH dependence of Cu(II) binding to  $\alpha$ S in the range of 5.0-6.5 (Figure 7.11). The  $I_{\text{para}}/I_{\text{diam}}$  profile measured at pH 5.0 and 20  $\mu$ M Cu(II) is shown in figure 7.10B. The strongest broadening effects corresponded to the C-terminal domain, again centered on Asp121, with a smaller effect evident in the N-terminal domain, located at His50. The cross-peaks of residues in the NAC region remained insensitive to Cu(II) at pH 5.0.

**Figure 7.11. Protonation of His<sup>50</sup> modulates Cu(II) binding to  $\alpha$ S.** pH titration of 100  $\mu$ M  $\alpha$ S in the presence of 40  $\mu$ M Cu(II). Selected regions of the  $^1\text{H}$ - $^{15}\text{N}$  HSQC spectra are shown, and the most affected signals by the binding of Cu(II) are identified.

It is noteworthy that even when the most affected cross-peaks in the N-terminal region were severely broadened under conditions favoring Cu(II) binding (pH 6.5); signals were still detected at 40-60  $\mu$ M Cu(II) (Figure 7.9B, 7.9C). In contrast, upon DEPC modification or protonation of His50, Cu(II) concentrations as low as 20  $\mu$ M were sufficient

to broaden beyond detection the resonances of the most affected residues in the C-terminal region (Figure 7.10A, 7.10B). This behavior presumably reflects differences in the exchange dynamics and residence times of the two Cu(II) binding sites in  $\alpha$ S and supports the assignment of the N-terminal region as the high affinity interface.

The interaction of the C-terminal truncated species of the protein with Cu(II) was studied with the aim of understanding further the structural contribution of the C-terminus to the overall binding process. The  $I_{\text{para}}/I_{\text{diam}}$  profiles for  $\alpha$ S1-108 in the concentration range of 0-60  $\mu$ M of Cu(II) were almost identical to those obtained with wild-type  $\alpha$ S (Figure 7.10C), confirming that the binding of Cu(II) to the N-terminal region of  $\alpha$ S is independent of the presence of the C-terminus.

Conditions that were effective in triggering  $\alpha$ S aggregation were shown previously to induce changes in the general properties of the ensemble populated by the protein (Chapter 1). In addition, mM concentrations of metal ions have shown to cause a reduction in the radio of gyration ( $R_g$ ) of the protein, and effect that was attributed to the formation of a partially folded intermediate (Uversky et al., 2001b; Uversky et al., 2001c). We sought evidence for the formation of metal-induced misfolded intermediates of  $\alpha$ S by determining the hydrodynamic properties of the  $\alpha$ S-Cu(II) complexes employing PFG-NMR. Measurement of  $R_h$  for  $\alpha$ S (100  $\mu$ M) in the absence and presence of Cu(II) (40 to 200  $\mu$ M) did not provide evidences of a partially collapsed intermediate or an extended species. While the values observed for the protein in its native state ( $R_h$  of 32.0  $\text{\AA}$ ) were consistent with previous determinations (Morar et al., 2001; Uversky et al., 2001b) no changes were detected upon addition of Cu(II) ( $R_h$  of 32.1  $\text{\AA}$ ), suggesting that the interaction neither affects the size of native  $\alpha$ S ensemble nor causes a significant collapse to a more compact conformation.

### 7.5. Cu(II) coordination in the complex with $\alpha$ -synuclein studied by EPR.

The 9-GHz-EPR spectrum of the  $\alpha$ S-Cu(II) complex at pH 6.5 was characteristic of Type 2 Cu(II) proteins (Väängård, 1972) (Figure 7.12A). The spectrum of the DEPC-modified  $\alpha$ S-Cu(II) complex presented similar characteristics but some differences were evident (Figure 7.12C). The Cu(II) complexes between the modified and unmodified protein differed qualitatively in that the spectrum of the former extended to a significantly lower field and lacked an over-shoot line in the  $g_{\perp}$  region. The Cu(II) hyperfine splittings and  $g$ -values in the low-field, parallel region were  $A_{\parallel} = 186$  and  $176 \times 10^{-4} \text{ cm}^{-1}$ , and  $g_{\parallel} = 2.223$  and  $2.316$  ( $g_{\perp} \sim 2.05$  and  $2.06$ ), for the unmodified and modified protein, respectively.

**Figure 7.12. EPR spectroscopy of Cu(II) binding to  $\alpha$ S.** 9-GHz EPR spectra of Cu(II) bound to  $\alpha$ S (1:1 molar ratio). **A.** pH 6.5. **B.** pH 5.0. **C.** DEPC-modified at pH 6.5. In all the measurements  $T = 77$  K. Centre field = 0.297 T; scan width = 0.2 T;  $\nu = 9.146$  GHz. Dotted vertical lines correspond to the three lower hyperfine lines in the DEPC-modified sample.

The Cu(II) EPR spectrum of the unmodified protein at pH 5.0 (Figure 7.12B) resembled that of the unmodified protein at pH 6.5, but also clearly contained a weaker spectral component corresponding to the DEPC-modified protein (Figure 7.12C). The appearance of the latter, lower affinity, component agrees fully with the NMR results at pH 5.0.

Figure 7.13 provides a plot of  $A_{//}$  vs.  $g_{//}$  for various small-molecule Cu(II)-complexes, using data from the literature showing the dependence of these parameters on the type of ligands in the complexes (Peisach and Blumberg, 1974; Sakaguchi and Addison, 1979). The EPR data from Cu(II) bound to unmodified  $\alpha$ S at pH 6.5 correlated rather well with those for Cu(II)-complexes with 2 nitrogen and 2 oxygen ligands ( $N_2O_2$ ), whereas in the case of  $\alpha$ S with modified histidine, the EPR parameters were indicative of four oxygen ligands ( $O_4$ ).

**Figure 7.13. Correlation diagram between  $A_{||}$  and  $g_{||}$  in the EPR spectra of Cu(II) complexes with different ligands.** The labels correspond to ■ four nitrogen ligands ( $N_4$ ), ● four oxygen ligands ( $O_4$ ), ▲ four sulphur ligands ( $S_4$ ), ○ two nitrogen and two oxygen ligands ( $N_2O_2$ ), □ imidazyl-type  $N_4$  ligands. References to original data are in (Peisach and Blumberg, 1974; Sakaguchi and Addison, 1979). Dashed horizontal and vertical lines indicate the parameters for Cu(II) bound to native (A) and chemically modified (B)  $\alpha$ S at pH 6.5.

### 7.6. Paramagnetic metal ions bind to $\alpha$ S with different affinities.

In the previous sections we have assessed the structural features of Cu(II) binding to  $\alpha$ S, given that this metal is strongly bound by the protein, causing an increase on its fibrillation rate. In order to establish the hierarchy of metal- $\alpha$ S interaction, we comparatively studied the role of other paramagnetic metal ions on  $\alpha$ S aggregation.

We have previously shown that 40  $\mu$ M of Cu(II) were effective in accelerating the aggregation of  $\alpha$ S (100  $\mu$ M). To determine whether other divalent cations as Mn(II), Fe(II), Co(II) or Ni(II) could directly affect fibril formation of  $\alpha$ S under similar conditions, we monitored the kinetics of aggregation of  $\alpha$ S in the presence of 100  $\mu$ M Mn(II), Co(II), Ni(II) and Fe(II), monitored by the standard Thioflavin-T fluorescence assay (Figure 7.14). We additionally employed Cu(II) as a control for the assay. The characteristic  $t_{1/2}$  for aggregation of  $\alpha$ S was reduced from  $\sim 65$  h to  $\sim 30$  h in the presence of 100  $\mu$ M Cu(II) (Figure 7.14). Instead, no fibrils were observed in the presence of the other divalent metal ions during the

firsts 30 h, indicating that these cations have a minimal or no stimulatory effect on  $\alpha$ S fibrillation under these conditions.

**Figure 7.14. Aggregation kinetics of  $\alpha$ S in the presence of divalent metal cations.** **A.** 100  $\mu$ M  $\alpha$ S in Buffer A ( $\blacktriangle$ ), 100  $\mu$ M Cu(II) ( $\blacklozenge$ ), 100  $\mu$ M Co(II) ( $\bullet$ ), 100  $\mu$ M Mn(II) ( $\blacktriangledown$ ), 100  $\mu$ M Ni(II) ( $\blacksquare$ ), 100  $\mu$ M Fe(II) ( $\blacklozenge$ ). Solid lines represent fits to the Equation 1 as described in the methods section. **B.** Plot of  $t_{1/2}$  (h) values obtained for each metal ion from the fitting procedure in **A**. Control ( $64 \pm 7$ ), Cu(II) ( $30 \pm 2$ ), Ni(II) ( $64 \pm 6$ ), Co(II) ( $53 \pm 4$ ), Mn(II) ( $57 \pm 6$ ) and Fe(II) ( $67 \pm 5$ ). Error bars correspond to standard errors of five independent experiments. Line corresponds to the value obtained for wt  $\alpha$ S.

In order to assess whether the absence of fibrillation enhancement by the other divalent metal ions might be linked to a reduced affinity for the protein, we estimated the dissociation constants of the various  $\alpha$ S-metal(II) complexes by equilibrium dialysis (Figure 7.14). In contrast to the  $K_d$  evidenced for Cu(II) using this technique ( $K_d < 1 \mu$ M), the dissociation constants estimated for Mn(II), Fe(II), Co(II), and Ni(II) were all in the 1-2 mM range.

**Figure 7.15. Equilibrium dialysis for metal(II)- $\alpha$ S complexes.** Equilibrium dialysis plots characterizing the binding of divalent metal ions to  $\alpha$ S. Mn(II) ( $\blacksquare$ ), Co(II)

(●), Fe(II) (◆), Ni(II) (▲). The  $K_d$  values estimated for Fe(II), Mn(II), Co(II), and Ni(II) are all in the 1-2 mM range.

These results demonstrate that under the low concentrations of metal ions used in the aggregation experiments, the degree of occupancy of the metal binding sites in  $\alpha$ S was significant only for Cu(II).

### 7.7. NMR characterization of the interaction between divalent metal ions and $\alpha$ S.

Although scarcely populated under the conditions assayed, the  $\alpha$ S-metal(II) complexes could be extensively characterized by NMR due to the paramagnetic nature of the metal ions studied. The range of  $\alpha$ S-metal(II) affinities estimated indicates that the metal complexes determined here must have lifetimes substantially shorter than that with Cu(II) at the N-terminus of  $\alpha$ S. This implies that the resonances of the nuclei close to the paramagnetic ions can be more dramatically affected than those in a tight complex (*e.g.*,  $\alpha$ S-Cu(II)) due to paramagnetic exchange broadening (Bertini et al., 2003). This effect serves as a sensitive indicator of the location of the metal ions in the protein structure, and has been successfully applied in the characterization of transient metal-protein interactions by NMR (Bertini et al., 2003).

Changes in the  $^1\text{H}$  NMR spectra of the side chains of a protein are sensitive probes for detecting metal binding and defining the binding interface. (Viles et al., 1999; Belosi et al., 2004; Jones et al., 2004; Syme et al., 2004; Valensin et al., 2004; Gaggelli et al., 2005) The  $^1\text{H}$  NMR spectra of  $\alpha$ S in  $\text{D}_2\text{O}$  showed well-resolved clusters of resonances in the 7.0-8.0 ppm range, comprising the side chains of different aromatic residues: His (aa50), Phe (aa4, aa94) and Tyr (aa39, aa125, aa133, aa136) (Figure 7.16A). The distribution of these residues throughout the  $\alpha$ S sequence provides excellent probes for exploring the binding features of metal ions to  $\alpha$ S.

Addition of 50  $\mu\text{M}$  Cu(II) to  $\alpha$ S caused the selective disappearance of the His<sup>50</sup> peak (Figure 7.16B), whereas further addition of Cu(II) (100  $\mu\text{M}$ ) revealed the disruption of the fine scalar-coupling structure of Tyr signals and the disappearance of resonances in the Phe region (Figure 7.16C). This pattern fully agrees with our previous finding, showing the preferential binding of Cu(II) at the N-terminus (indicated here by the disappearance of His<sup>50</sup> and resonances attributed to Phe<sup>4</sup>) and the low affinity effects on the C-terminus due to exchange broadening (showed by the broadening of Tyr resonances).

**Figure 7.16.  $^1\text{H}$  NMR spectra of aromatic side-chains of  $\alpha\text{S}$  in the presence of divalent metal ions.** Spectra were registered at  $15^\circ\text{C}$  in  $\text{D}_2\text{O}$  of samples containing  $100\ \mu\text{M}$   $\alpha\text{S}$  (A),  $50\ \mu\text{M}$   $\text{Cu(II)}$  (B),  $100\ \mu\text{M}$   $\text{Cu(II)}$  (C),  $100\ \mu\text{M}$   $\text{Mn(II)}$  (D),  $100\ \mu\text{M}$   $\text{Fe(II)}$  (E). The asterisk (\*) indicates peaks broadened beyond detection.

As shown in Figure 7.14D, the presence of  $100\ \mu\text{M}$   $\text{Mn(II)}$  caused the selective line broadening of Tyr signals, likely reflecting the preference of this metal ion for the C-terminus. The remaining sharp signals in the cluster centered at  $6.6\ \text{ppm}$  belong to Tyr<sup>39</sup>, as revealed by the 1D spectrum of the C-truncated species ( $\alpha\text{S}$  1-108) (data not shown). The spectral features of the 1D  $^1\text{H}$  NMR of  $\alpha\text{S}$  in the presence of  $100\ \mu\text{M}$   $\text{Fe(II)}$  remained almost unperturbed (Figure 7.16E), as was also the case with  $100\ \mu\text{M}$   $\text{Co(II)}$  and  $\text{Ni(II)}$ .

To shed light on the structural basis determining the affinity of  $\alpha\text{S}$  by metal ions, the specific regions for metal binding to  $\alpha\text{S}$  were mapped by two-dimensional heteronuclear NMR spectroscopy. We first recorded a series of  $^1\text{H}$ - $^{15}\text{N}$  HSQC spectra of  $\alpha\text{S}$  ( $100\ \mu\text{M}$ ) in the presence of increasing levels of  $\text{Mn(II)}$ . Sub-stoichiometric concentrations of  $\text{Mn(II)}$  were necessary to avoid an excessive broadening of the signals and to minimize chemical exchange effects. Significant changes in cross-peaks intensities were observed under these conditions, being restricted to residues located in the C-terminal region of  $\alpha\text{S}$  (Figure 7.17).

**Figure 7.17.  $^1\text{H}$ - $^{15}\text{N}$  HSQC spectra of  $\alpha\text{S}$  in the presence of Mn (II).** Overlaid contour plots of the  $^1\text{H}$ - $^{15}\text{N}$  HSQC spectra of 100  $\mu\text{M}$   $\alpha\text{S}$  in buffer B, at 15°C, in the absence (red) and presence (blue) of 100  $\mu\text{M}$  Mn(II). Amino acid residues broadened beyond detection are identified.

The strongest broadening effects at 10-20  $\mu\text{M}$  Mn(II) corresponded to amide groups of residues Asp<sup>121</sup>, Asn<sup>122</sup> and Glu<sup>123</sup>, indicating that this site is the most populated under these conditions (Figure 7.18A). The paramagnetic effect was further pronounced and generalized at 40-100  $\mu\text{M}$  Mn(II) (Figure 7.18B, 7.18C), possibly reflecting the transient population of secondary sites. Interestingly, the amide resonances assigned to residues located in the N-terminus or belonging to the NAC region remained unaltered even at high Mn(II) concentrations.

**Figure 7.18. Paramagnetic broadening caused by binding of Mn(II) to  $\alpha$ S.**  $I/I_0$  profiles of the backbone amide groups of  $\alpha$ S in the presence of divalent metal ions.  $^1\text{H}$ - $^{15}\text{N}$  HSQC spectra of 100  $\mu\text{M}$   $\alpha$ S in Buffer B, at 15°C were registered upon addition of 15  $\mu\text{M}$  Mn(II) (A), 40  $\mu\text{M}$  Mn(II) (B), 100  $\mu\text{M}$  Mn(II) (C). N-terminal region (residues 1-60), NAC region (residues 61-95), C-terminal region (residues 96-140) are highlighted.

Titration of  $\alpha$ S with Fe(II), Co(II) and Ni(II) showed effects qualitatively similar to those caused by low levels of Mn(II), in that resonances of residues Asp121, Asn122 and Glu123 in the C-terminus were severely affected (Figure 7.19A, 7.19B). However, no generalized line broadening was induced at the C-terminus by added 100  $\mu\text{M}$  metal ion; overall the spectra remained sharper and the effects were well localized in the 121-123 region. Since the affinities estimated for the  $\alpha$ S-metal(II) complexes are similar, the different degree of broadening must be reflecting the magnitude of the electron spin relaxation times ( $\tau_s$ ) of each paramagnetic metal ion (Mn(II)  $\sim 10^{-8}$  s, whereas Fe(II), Co(II) and Ni(II)  $\sim 10^{-$

$^{11}\text{-}10^{-13}\text{s}$ ) (Bertini and Luchinat, 1996) The cross-peaks of residues located in the NAC region remained insensitive to Fe(II), Co(II) and Ni(II) even at metal: $\alpha\text{S}$  ratios of 10:1, whereas a paramagnetic effect centered on His50 was clearly observed for [Fe(II)], [Co(II)]  $\geq$  500  $\mu\text{M}$  (Figure 7.19D-7.19F).

**Figure 7.19. Binding of Fe(II), Co(II) and Ni(II) to  $\alpha\text{S}$ .**  $I/I_0$  profiles of the backbone amide groups of  $\alpha\text{S}$  in the presence of divalent metal ions.  $^1\text{H}$ - $^{15}\text{N}$  HSQC spectra of 100  $\mu\text{M}$  AS in Buffer B, at 15°C were registered upon addition of (A) 100  $\mu\text{M}$  Co(II), (B) 1000  $\mu\text{M}$  Co(II), (C) 100  $\mu\text{M}$  Ni(II), (D) 1000  $\mu\text{M}$  Ni(II), (E) 100  $\mu\text{M}$  Fe(II), (F) 1000  $\mu\text{M}$  Fe(II). N-terminal region (residues 1-60), NAC region (residues 61-95), C-terminal region (residues 96-140) are highlighted.

An estimation of the binding affinity of Mn(II) to  $\alpha\text{S}$  was independently obtained by NMR. Determining the paramagnetic relaxation enhancement,  $R_{1p}$ , induced by low stoichiometric levels of metal at different concentrations of protein provides a valuable tool to assess the dissociation constant of the complex (Bertini and Luchinat, 1996). A plot of  $1/R_{1p}$  against  $C_{\alpha\text{S}}$  for Asp<sup>121</sup>, Asn<sup>122</sup> and Glu<sup>123</sup> resonances gives a straight line (Figure 7.20),

from which a dissociation constant of  $\sim 1$  mM was obtained. This determination confirms the findings from equilibrium dialysis experiments.

**Figure 7.20. Paramagnetic relaxation enhancement induced by Mn.** An independent estimation of the affinity constant of the complex  $\alpha$ S-Mn(II) was obtained by measurement of the paramagnetic relaxation enhancement cause by the metal at different protein concentrations. Residues at the C-terminal are Asp<sup>115</sup> (red), Asp<sup>119</sup> (orange), Asp<sup>121</sup> (dark yellow), Asn<sup>122</sup> (green), Glu<sup>123</sup> (light blue), Ala<sup>124</sup> (dark blue), Asp<sup>135</sup> (violet).

*Discussion*

---

## 8. Discussion

### 8.1. Auto-inhibitory long range interactions in the native state of $\alpha$ S.

The protein  $\alpha$ -synuclein ( $\alpha$ S) is implicated in the deposition of pertinacious aggregates in many neurodegenerative disorders, including Parkinson's disease.  $\alpha$ S is expressed in high levels in the *substantia nigra* of healthy individuals, and locus triplication, point mutations, or as yet elusive environmental conditions are able to cause the self-association of the protein in the form of toxic oligomers and amyloid like fibrillar structures (Cookson, 2005). What is intriguing from the biophysical point of view, is that  $\alpha$ S belongs to the class of natively unfolded proteins with no apparent ordered secondary structure detectable by far-UV CD, FTIR or NMR spectroscopy (Uversky, 2003). Thus, it is not evident how this protein is able to avoid self-association and amyloid deposition in the neuronal cytoplasm.

The challenge of this thesis work has been to rationalize in structural terms the inactive state of the soluble, unstructured protein, searching how the enhancement of aggregation is achieved by point mutations, ligand binding or changes in solution conditions. However, the conformational flexibility inherent to natively unfolded proteins places them beyond the reach of classical structural biology, and a special set of NMR-based experiments had to be implemented in order to study the native soluble state of  $\alpha$ S, namely paramagnetic relaxation enhancement and residual dipolar couplings.

When we employed paramagnetic relaxation enhancement from site-directed spin-labeling, we were able to detect a complex network of long range interactions involving an N- to C-terminal contact plus a shielding of the hydrophobic central NAC region by the C-terminus. Experiments conducted under chemical denaturation suggest that the contacts between the NAC region and the C-terminus are of hydrophobic nature. On the contrary, the interaction between the positively charged N-terminus and the acidic C-terminus are electrostatic in origin. Furthermore, distance restraints were obtained from the paramagnetic experiments and an ensemble of conformations was obtained for the native state of  $\alpha$ S (Figure 8.1.).

The model that we present here can be interpreted as either an ensemble of unfolded structures, where each structure is satisfying the experimental data, or as an ensemble of unfolded structures where as an average the ensemble satisfy the experimental data (Teilum et al., 2002). Despite these uncertainties, it is evident from our experiments and structure calculations that  $\alpha$ S is not a random coil as was described before, but rather populates a

defined set of conformations that, despite lacking secondary structure, are stabilized by long range tertiary contacts.

**Figure 8.1. Summary of structural features in the ensemble of  $\alpha$ S conformations derived by PRE.** The native state of  $\alpha$ S, although deprived of persistent secondary structure, should not be viewed as a random coil, rather specific long range (tertiary) contacts promote population of compact conformations, which aid the protein to remain soluble.

We attempted to determine the importance of these long range contacts in maintaining the protein in its soluble state by assaying different conditions known to enhance self-association and aggregation of the protein. We observed a significant impairment of long range interactions upon addition of a natural polycation, spermine, which specifically bind to the C-terminus of the protein. This effect was evidenced as a retirement of the C-terminus from the NAC region, causing a solvent exposure of the central hydrophobic domain. Similarly, raising the temperature to 47 °C caused a release of this protective effect. In the case of the polyamine-bound  $\alpha$ S we further obtained evidenced that the hydrodynamic shape of the ensemble was increased, supporting the achievement of a more extended conformation.

Furthermore, when we studied the A30P or A53T familial mutants of  $\alpha$ S, known to cause early on-set PD, likely due to an increased oligomerization propensity, we also observed a slight perturbation of the key long range interaction between the C-terminus and the NAC region. However, strong N-terminal and C-terminal compactions remain unaltered in these proteins, and a slight increase of the electrostatic interaction is suggested. Thus, the general shape of the ensemble of conformations populated by the mutants is somewhat collapsed respect the *wt* protein.

Interestingly, this mechanism of losing key tertiary contacts rendering a more unfolded state is proposed as the trigger mechanism for the misfolding of proteins that account for defined secondary structure (Jahn and Radford, 2005). The similar situation that

is found in our studies for  $\alpha$ S would imply that even for natively unfolded proteins, the general mechanisms proposed for amyloid formation are still applicable.

Examination of the homologous protein  $\beta$ S, which lacks the central NAC region and consequently does not readily oligomerize, did not evidence long range interactions. Neither electrostatic N- to C-terminal contacts nor C-terminal compaction occur in  $\beta$ S, as probed by the PRE strategy. This is in line with the determination of the size of the ensemble, which showed to be considerably more expanded than  $\alpha$ S. While the positively charged N-terminus of  $\alpha$ S and  $\beta$ S is almost identical, the very acidic C-terminus is highly divergent and more negatively charged in  $\beta$ S, thus electrostatic long-range interactions would be favored. The absence of such contacts could be then rationalized either by the requirement of the flip-back of the C-terminus on the NAC region for the electrostatic interaction to occur or by particular conformational states adopted by the domains imply in the interaction which disfavors such contacts. Since in the genetic mutants we evidenced persistent electrostatic interactions in the absence of the hydrophobic core, it is very likely that conformational restrictions at the C-terminus of  $\beta$ S are responsible for inhibiting the formation of such interactions. As discussed afterwards, we found at the C-terminus of  $\beta$ S a strong amount of polyproline II (PII) extended conformations which opposes to the compact and flexible nature of the C-terminus in  $\alpha$ S.

At the same time our studies were reported, a similar work on  $\alpha$ S was published by the Dobson laboratory (Dedmon et al., 2005). The authors employed the same PRE-based strategy to investigate the nature of the ensemble of conformations populated by  $\alpha$ S, arriving to the same conclusions as the one presented in this work. They investigated 5 different Cys-containing mutants and obtained by restrained molecular dynamic simulations an ensemble of conformations which reproduces the compact dimensions experimentally observed in the protein. A close comparison of their contact map with ours shows a striking correlation, validating our studies, and supporting the occurrence of tertiary interactions in  $\alpha$ S.

Spin-labeling techniques have been previously employed in the study of the unfolded states of otherwise normally folded proteins, but have never been used in natively unfolded proteins. From the methodological point of view, this study represents the first of such application of long range restraints to determine a low resolution model of a natively unfolded protein. The number of intrinsically unstructured proteins is growing rapidly (Uversky et al., 2000), and it is becoming clear that these proteins participate in a vast range of biochemical processes (Dyson and Wright, 2005). We thus believe that our results will

encourage future high resolution structural studies of dynamic ensembles of interconverting conformers.

## 8.2. Residual structure in the ensemble of conformers populated by $\alpha$ S.

Residual dipolar couplings measured in a weakly aligned protein are excellent reporters of residual structure and conformational restrictions in the unfolded states of proteins (Shortle and Ackerman, 2001; Fieber et al., 2004; Mohana-Borges et al., 2004). In contrast to the bell-like smooth distribution of dipolar couplings that is expected for a random coil polypeptide chain (Louhivuori et al., 2003), a particular distribution of predominantly positive RDCs was observed for  $\alpha$ S. Five different domains could be identified in the protein, consistently with previous biophysical studies, and linker regions with couplings close to zero could be rationalized by the occurrence of residues with small side chains (Ala-Gly linkers) (Mohana-Borges et al., 2004). This local higher flexibility of the polypeptide backbone effectively decouples the five domains, and they would exhibit concerted motions, suggesting that they may also align independently (Figure 8.2.).

**Figure 8.2. RDCs probe residual structure and long range interactions in  $\alpha$ S.** The N-terminus is subdivided into two regions with similar RDCs (domain I: residues 1-28; domain II: residues 33-65) with a linker sequence showing couplings close to zero (residues 28-32). The NAC domain (residues 61-95) exhibits large couplings about its central core, is flanked by two regions with reduced RDCs (residues 66-70 and 88-92) and is followed by a fourth domain (IV) comprising residues 95-101.

The C-terminus (domain V) displays exceptionally large couplings with two major peaks for residues 115 to 119 and 125 to 129.

Steric hindrance between residues, limiting the conformational space that the torsion angle is allowed to sample, was probed by RDCs, suggesting that this parameter is sensitive to conformational restrictions (Louhivuori et al., 2004). The model suggests that high RDCs in unfolded polypeptides would be displayed by regions with residual structure, since they adopt a defined alignment, which does not average out in the ensemble of conformations. In our measurements, the highly acidic C-terminus of  $\alpha$ S exhibited very large dipolar couplings, which in principle could be associated with side-chain-side-chain repulsion and to the occurrence of proline residues. However, chemical denaturation of the protein decreased the RDC values in this region, and studies of a C-terminal peptide showed couplings of a magnitude similar to the rest of the protein. Suggesting that the residual structure is not locally encoded rather is a consequence of long range contacts. This fully agrees with the results obtained employing spin labels, showing that the C-terminus is involved in tertiary contacts.

RDCs also probed the impairment of long range interactions in  $\alpha$ S upon conditions that trigger protein oligomerization. Polyamine binding and increased of temperature were shown to cause reduction of couplings at the C-terminus of the protein, demonstrating that the residual structure in the C-terminus is key to ensure the population of native conformations.

Notably, RDCs resulted to be excellent reporters of the differences between the conformations populated by the  $\alpha$ S genetic mutants, respect the *wt* protein. The measurement of RDCs in the A30P and A53T mutants of  $\alpha$ S shows that these point mutations cause a great perturbation of the long range interactions that are responsible of maintaining the protein in an auto-inhibited soluble state. Higher couplings at the C-terminus, distant from the site of the mutation, are consistently reduced, which supports the absence of the NAC-C-terminus interaction, already observed in by PREs. A similar effect for key point mutations has been recently observed by RDCs on the denaturated state of acyl-coenzyme A binding protein (ACBP) at pH 2.3. Fieber and colleagues (Fieber et al., 2004) showed that a reduction in RDCs for certain residues in the Ile<sup>27</sup>Ala mutant of ACBP is correlated with the abolishment of long range interaction between two distant domains, already evidenced by other means. Further evidence for single point mutations affecting long range hydrophobic interactions in non-native states was obtained in a study of denaturated lysozyme at pH 2 (Klein-

Seetharaman et al., 2002). The Trp62Gly substitution breaks up a long range hydrophobic core that stabilizes the unfolded state of lysozyme, as was evaluated by NMR transverse relaxation rates.

Therefore valuable residue-specific information on the composition of the ensemble of conformations that are populated by the natively unfolded  $\alpha$ S can be obtained easily analyzing the variations of RDCs profiles of the protein. This methodology is, up to now, the only experimental set up where slight changes at the level of the  $\alpha$ S monomer are able to be detected, and may constitute an essential tool for screening during the development of therapeutic drugs for PD.

### **8.3. Dissecting the nature of long range interactions probed by RDCs in $\alpha$ S**

As mentioned before, in folded proteins RDCs report on the orientation of internuclear vectors relative to a global molecular alignment tensor (Bax, 2003). In unfolded states of polypeptides they are believed to provide information about the degree of orientation that the internuclear vector adopts, with respect to the orientation of the persistence length fragment in which the residue is immersed (Dyson and Wright, 2004). Thus, RDCs are suggested to be valuable reporters of both local and long-range conformational propensities, and indeed they have proved to be exquisitely sensitive in the study of  $\alpha$ S conformations. However, the true nature of what RDCs are able to detect is somehow still unclear, and thus it is instructive to comment on how the studies of the  $\alpha$ S system may help to shed more light on this issue.

At the starting of this thesis work, the application of RDCs for unfolded proteins had just been introduced. Almost 5 years ago, much of a debate was started when Shortle explained the unexpected observation of RDCs in chemically denatured staphylococcal nuclease as evidence of the persistence of secondary structure, contrary to the expectation of vanishingly weak couplings due to conformational averaging (Shortle and Ackerman, 2001). Theoretical studies by Annala refuted that explanation stating that conformational restrictions on the backbone of the polypeptide chain were sufficient to give non-vanishing RDCs (Louhivuori et al., 2003; Louhivuori et al., 2004), and later, experimental data from the Poulsen and Wright laboratories conclusively demonstrated the ability of RDCs to probe conformational propensities in chemically denatured proteins (Mohana-Borges et al., 2004). However, it has not been until very recently that ensemble-averaged computer simulations provided conclusive evidence on the nature of RDCs in unfolded states of proteins.

In order to understand the origin of conformational restrictions probed by RDCs, Sosnick and colleagues (Jha et al., 2005a) generated an unfolded state ensemble by using a self-avoiding statistical coil model that was based on backbone conformational frequencies in a coil library, a subset of the Protein Data Bank (Jha et al., 2005b). This ensemble of unfolded chains is shown to predict the experimental RDCs in chemically denatured apomyoglobin, ubiquitin, staphylococcal nuclease and eglin C, while retaining the global conformation of the unfolded state ( $R_g$ ). The authors found that local structural propensities, in particular extended  $\beta$  and PII conformations, contributed strongly to the RDC signal (Jha et al., 2005a).

Blackledge and colleagues (Bernado et al., 2005b), independently generated a statistical ensemble of coil conformations and calculated averaged RDCs over the entire population. Each conformer from the ensemble was built sequentially using randomly selected  $\phi/\psi$  pairs drawn from a database of amino acid specific conformations present in loop regions of high-resolution X-ray structures, and a simple volume-exclusion model was added to avoid steric overlap. RDCs were calculated for each NH vector of the conformer and  $D_{NH}$  from each site were then averaged over 50000 conformers to ensure convergence. The authors successfully reproduced RDCs from the native unfolded domain of protein PX and the chemically unfolded states of apomyoglobin and staphylococcal nuclease. The outcome of this study is that non-vanishing RDCs will be expected for polypeptides sampling randomly the Ramachandran space, and suggest that RDCs are an interpretable structural signature of the unfolded state (Bernado et al., 2005b).

A collaboration with the Blackledge laboratory allowed us to apply this strategy on the RDCs studies of  $\alpha S$  (Bernado et al., 2005a). An ensemble of conformers was generated for  $\alpha S$  and RDCs were calculated for the protein aligned in C8E5/octanol anisotropic media (Figure 8.3.A). The range and fine structure of RDCs in  $\alpha S$  were reproduced for the central part of the protein (residues 30 to 110) suggesting local conformational restrictions caused by random sampling of residue-specific  $\phi/\psi$  distributions (Bernado et al., 2005b). However, the ensemble failed to reproduce the high couplings at the N- and C-terminus of the protein. When a long-range interaction constraint between the N- and C-terminus was imposed to the creation of the ensemble, a remarkably close agreement with the experimental value was obtained in the RDCs calculations (Figure 8.3.B). Variations in long-range contacts were assayed, but the closest match remained to be in the N- to C-terminal contact. The results indicate that the proposed contact is present in the native ensemble of conformations

---

populated by  $\alpha$ S in solution, although they do not exclude the presence of other contacts within the same conformer. Indeed, imposing as constraints simultaneous contacts between the C-terminal domain and N-terminal and NAC regions provides an ensemble that fits the data almost as closely ( $\chi^2=59$ ).

**Figure 8.3. Long range order in  $\alpha$ S probed by ensemble-averaged simulations of RDCs. A , B.** Ensemble-averaged RDCs simulated (red) without long-range contacts (red, A) and when long range contacts between the N-terminus and C-terminus are set as restraints (red, B). In blue the experimental RDCs measure in Pf1 phages as alignment media are shown. Simulated data are scaled to maximize fit in the region 22-112. **C.** Effect of long-range contacts on capacity of conformational ensembles to reproduce experimental RDCs from  $\alpha$ S. Figures denote  $\chi^2 = \sum (D_{ij,calc} - D_{ij,meas})^2$  that compares experimental RDCs measured in  $\alpha$ S aligned in Pf1 phage with calculated averages over 50000 conformers having long-range contacts ( $<15$  Å)

between C $\beta$  in the specified ranges. Adjacent domains are equivalent to ensembles with no specified contact shown in A ( $\chi^2=129$ ) and are not shown.

This theoretical approach is therefore complementary to the PRE-based detection of long-range contacts in  $\alpha$ S, and unequivocally shows that tertiary interactions are present in the native state of  $\alpha$ S. We are working currently in an atomic resolution complementation to this alignment prediction strategy, which may deliver more precise detail on the conformations populated by  $\alpha$ S, and comparison with the ensemble of conformers that we previously generated by PRE will further provide valuable insights.

Intriguingly, when we measured RDCs in the homologous protein  $\beta$ S, which lacks the central hydrophobic domain and does not evidence tertiary interactions as the one present in  $\alpha$ S, we observed that the C-terminus of this protein also displayed high couplings. However, in contrast to the profile obtained for  $\alpha$ S, high couplings in  $\beta$ S were exclusively located at that region, which has previously displayed a strong tendency to populate extended conformations with the PII signature. The occurrence of 8 Pro residues and the contribution of electrostatic repulsion between negatively charged side chains (net charge of -16) favor the adoption of extended conformations at the C-terminus. Thus, in this particular case, RDCs probe locally encoded conformational restrictions in the ensemble of conformations populated by the natively unfolded protein  $\beta$ S.

Taken together these data supports the novel interpretation of RDCs as simultaneous reporters of long-range structural order and local conformational sampling in an ensemble of rapidly interconverting conformations.

### **8.3. RDCs probe slow conformational dynamics in $\alpha$ S**

NMR spectroscopy is uniquely suited for studying dynamical processes in proteins such as intramolecular motions. Movements in the range of the rotational correlation time of the molecule ( $\sim$  ns) can be efficiently studied employing  $^{15}\text{N}$  spin relaxation. On the other hand, motions in the order of micro to milliseconds require the use of other experimental approaches. Slow time scales are of particular interest because functionally important biological processes, including enzyme catalysis, signal transduction, ligand binding, protein folding and allosteric regulation, among others are expected to occur in this time range (Mittermaier and Kay, 2006). Thus, motions up to millisecond time scales can be detected using CPMG relaxation dispersion methods (Palmer et al., 2001), as recently evidenced for folding intermediates of the Fyn SH3 domain (Korzhnev et al., 2004). However, these

measurements are very time consuming. Another alternative for characterizing slow dynamics are RDCs, which also report on averages over longer time scales (up to the millisecond range) and therefore encode key information for understanding protein motions in the submicro- to millisecond range (Figure 8.4) (Bouvignies et al., 2005; Lakomek et al., 2006).

**Figure 8.4. NMR parameters employed to detect motions in proteins.** Almost all different types of motions that may occur in proteins can be efficiently studied by means of NMR spectroscopy.

RDCs report on time and ensemble-averaged conformations and therefore can be used to characterize both the structure and dynamics of unfolded proteins. When we employed RDCs to characterize the ensemble of rapid interconverting conformations of  $\alpha$ S, we found a high degree of conformational restriction present at the C-terminus of the protein. Measurement of RDC in  $\alpha$ S under the presence of chemical denaturants, on a C-terminal peptide and on A30P and A53T mutants demonstrated that this residual structure was not locally encoded, but rather was caused by a precise contribution of long-range interactions, which were further confirmed by ensemble-averaged computer simulations. Such conformational restrictions were not evidenced by  $^{15}\text{N}$  relaxation time measurements, showing that  $\alpha$ S was indeed very flexible. Furthermore, these measurement did not indicate any major long-range effects upon A30P and A53T replacements (Bussell and Eliezer, 2001). As  $^{15}\text{N}$  relaxation is sensitive to motions in the order of pico- to nanoseconds, we conclude that RDCs probe slow motions ( $\mu\text{s}$ -ms time scale) in the conformations populated by  $\alpha$ S.

Transverse relaxation rates have been also used previously to probe long-range interactions within the unfolded state of proteins (Klein-Seetharaman et al., 2002).  $^{15}\text{N}$  relaxation time measurements of  $\alpha\text{S}$  did not provide evidence for long-range interactions and only a very slight increase in  $R_2$  relaxation rates for residue 20 and 122 was observed, supporting our findings (Bussell and Eliezer, 2001). Thus, it is particularly interesting that the intrinsic structure present in  $\alpha\text{S}$  restricts motions slower than the overall correlation time of the protein, but faster than the millisecond motions probed by  $R_2$  measurements. This timescale is precisely the one in which secondary structures form during protein folding (Kubelka et al., 2004). Moreover, this suggests that the conditions that trigger  $\alpha\text{S}$  oligomerization, in particular the PD-linked mutations, strongly increase structural fluctuations on this time scale, reducing the energetic barrier required for self association (Figure 8.5).

**Figure 8.5. Proposed scheme for the increased neurotoxicity of  $\alpha\text{S}$  genetic mutants.** In this study we demonstrated that the two familial Parkinson's disease associated mutants A30P and A53T perturb the long range interactions essential for the native state of  $\alpha\text{S}$ . Long range interactions characterize the auto-inhibited native state of  $\alpha\text{S}$ , maintaining the protein in a soluble innocuous state. Mutant  $\alpha\text{S}$  can overcome more easily the energetic barrier for self-association, leading to an increased tendency to oligomerize. Polyamine binding and high temperature, conditions that *in vitro* enhance  $\alpha\text{S}$  aggregation, induce a completely unfolded structure. Therefore we propose that redistribution of the ensemble of  $\alpha\text{S}$  conformers, such that the highly amyloidogenic NAC region becomes exposed to the solvent and  $\beta$ -sheet rich conformations are adopted more easily, represents the common mechanism for both genetically linked and environmentally induced  $\alpha\text{S}$  oligomerization in Parkinson's disease.

In the case of  $\beta\text{S}$ , our studies on the backbone dynamics probed by  $^{15}\text{N}$  longitudinal and transverse relaxation rates show the bell-shaped pattern expected for a random coil

polypeptide, and only suggest slight conformational restrictions at residues 40 to 45. However, chemical shift deviations and  $^3J_{\text{HNH}\alpha}$  couplings in the C-terminus are suggestive of a strong propensity for populating extended conformations, likely PII, opposite to the rest of the protein where solvent interactions dictate the conformational propensity. When we measured RDCs for backbone NH in  $\beta\text{S}$  it was evident that residual structure was present at the whole domain, which, as mentioned before, in this case was not due to long range interactions. This suggest a bias in the random sampling of residue-specific  $\phi, \psi$  distributions for the C-terminus of  $\beta\text{S}$ , causing restricted motions occurring in the  $\mu\text{s}$ -ms timescale only detected by RDCs.

#### **8.4. Stabilization of auto inhibitory interactions in $\alpha\text{S}$ may inhibit amyloid protein deposition.**

There is a whole body of biochemical evidence supporting the occurrence of the auto inhibitory long range interactions that we have identified in  $\alpha\text{S}$ . Shielding of the hydrophobic central region of the protein by the C-terminal domain explains why this acidic tail functions as a chaperone-like solubilizing domain (Souza et al., 2000). It also provides a reason for the fact that C-terminally truncated  $\alpha\text{S}$  is more amyloidogenic than the full-length protein (Crowther et al., 1998), an event that has been documented *in vivo*, and has been suggested to trigger disease states (Li et al., 2005).

Posttranslational modifications are also known to occur at specific sites of the C-terminus of  $\alpha\text{S}$ , triggering aggregation of the protein. Influence in fibrillation has been reported to be exerted by methionine oxidation, tyrosine nitration and phosphorylation of Ser<sup>129</sup> (Fujiwara et al., 2002; Norris et al., 2003). The effect of this modifications seems to be related to the formation of stable oligomeric species, in line with the proposed facilitation of  $\alpha\text{S}$  self association upon loss of residual structure. It could be particularly interesting to evaluate modified  $\alpha\text{S}$  with the set of NMR experiments that we have optimized.

Furthermore, the compaction of both the N- and C-termini coupled to a flip-back of the C-terminus over the central region of the protein explains why the hydrodynamic radius of  $\alpha\text{S}$  corresponds to that of a completely unfolded polypeptide chain in the presence of 8 M urea, but, as we determined is considerably smaller in the native state. *In vivo*, the native compaction is likely to be further stabilized by the strong excluded volume effects associated with macromolecular crowding. Indeed,  $\alpha\text{S}$  has recently been shown to remain natively unfolded in the bacteria cytoplasm, by *in-vivo* NMR measurements (McNulty et al., 2006a).

It is thus very likely that these long-range interactions that we identified *in vitro* play a central role *in vivo*.

We conclude that the release of intrinsic structure in the  $\alpha$ S monomer is *a* or *the* key step that triggers oligomerization and aggregation. That is, the achievement of the fully unfolded state renders the hydrophobic patches of the NAC region accessible, and the N-terminus fully extended, such that the protein is able to adopt  $\beta$ -sheet conformations conducive to aggregation. The high free energy of the extended conformation, in which the hydrophobic NAC region is exposed to the solvent, would favor the association of monomers, thereby increasing the extent of both the nucleation and propagation steps of aggregation. It follows that alterations in the energetic barriers to achieve this conformational transition would affect the deposition rate of  $\alpha$ S aggregates *in vivo* and thus the evolution of disease. From the therapeutic point of view, it could be foreseen that the reinforcement of these native, auto-inhibitory, long-range interactions in  $\alpha$ S may constitute a logical functional target for new pharmacological agents designed to impede or even reverse aggregate formation in Parkinson's disease.

### **8.5. Redistribution of the ensemble of $\alpha$ S conformers may underlie toxic gain-of-function in A30P and A53T genetic mutants.**

Similarly to the posttranslational modifications evidenced for the *wt* protein, several biological and biochemical properties underlying the toxic gain-of-function of the familial mutants A30P and A53T of  $\alpha$ S can now be rationalized in terms of the different intrinsic structural features of these proteins (Table 8.2). Recently, it was proposed that the generation and accumulation of C-terminal truncated  $\alpha$ S may involve cleavage between residues 119 to 123, phenomenon that was enhanced in mice models upon expression of mutant  $\alpha$ S (Li et al., 2005). These findings may be explained by the results of the present study. Although the truncation site is far from the A30P and A53T missense mutations, the destabilization of  $\alpha$ S tertiary structure may allow proteases to degrade the  $\alpha$ S C-terminus more efficiently.

This destabilization may also be the source for the increased affinity of lysosomal chaperone-mediated autophagy (CMA) receptors for mutant  $\alpha$ S, recognizing the sequence  $_{95}\text{VKKDQ}_{99}$  present in the C-terminus of  $\alpha$ S, and thereby causing an impairment in protein catabolism (Cuervo et al., 2004). Regarding self-association, an increased tendency to form dimers, oligomers and annular protofibrils has been evidenced for both PD-linked mutants (Conway et al., 2000; Lashuel et al., 2002a; Krishnan et al., 2003), which may as well be

explained in terms of our findings. The decreased shielding of the highly hydrophobic NAC region due to the reduction of long-range interactions, would allow A30P and A53T mutant  $\alpha$ S to preferentially expose this region to the solvent, facilitating self-association.

Characteristics associated with the increased neurotoxicity of A30P and A53T	
Biological features	Reduced cell viability in cell culture models (1) Increased inhibition of proteasomal activity (2) Impaired protein degradation via CMA (3) Enhanced in vivo C-terminal truncation (4)
Biochemical features	Facilitated formation of dimers (5) Acceleration of oligomerization (6) Presence of annular protofibrils (7) Rapid fibrillation (only A53T) (8) Higher vesicle permeabilization activity (9)
Structural features	Perturbed autoinhibitory long range interactions Increased backbone flexibility in the nano to microsecond time scale Increased exposure of NAC region

**Table 8.1. Distinctive features of  $\alpha$ S-mediated pathogenesis correlate with the properties of A30P and A53T mutants.** References are as follows: (1) (Dev et al., 2003), (2) (Stefanis et al., 2001; Tanaka et al., 2001), (3) (Cuervo et al., 2004), (4) (Li et al., 2005), (5) (Krishnan et al., 2003), (6) (Conway et al., 2000), (7) (Lashuel et al., 2002a), (8) (Conway et al., 2000), (9) (Volles and Lansbury, 2002).

Thus, the redistribution of the structural ensemble of the A30P and A53T  $\alpha$ S mutants potentiates oligomerization and modulates binding to ligands, proteases and receptors. This effect may account for the toxic gain-of-function of familial Parkinsonism-linked mutant  $\alpha$ S. Conformationally altered  $\alpha$ S may constitute a general molecular mechanism underlying the induction of PD by environmental and genetic conditions. Thus, agents specifically designed to stabilize the native state of  $\alpha$ S may also prove useful in impeding or reversing its pathologic aggregation in familial forms of Parkinson's disease.

### 8.6. Characterization of the structural basis of metal- $\alpha$ S complexes.

The neurobiology of metal ions has attracted growing interest by virtue of their link to major neurological syndromes. Divalent metal ions, especially Cu(II), Fe(II) and Mn(II), are considered as risk factors for PD based on clinical and epidemiological studies (Sayre et al., 1999). The simplest mechanism proposed involves a direct effect of the metal ions on the aggregation of  $\alpha$ S (Uversky et al., 2001c). In this study, we found that Cu(II), but not Mn(II),

Co(II), Ni(II) or Fe(II), are effective in accelerating the aggregation of  $\alpha$ S at low  $\mu$ M concentrations, likely found *in vivo*. Differences between Cu(II) and the other divalent ions studied relate to the primary site of binding and to the different ranges of affinities estimated for the formation of metal- $\alpha$ S complexes (Table 8.2). These findings lead to a new conceptual scheme defining the hierarchy of metal- $\alpha$ S interactions which reflects both biological and structural effects, the latter resulting from the nature of the coordinating moieties of the protein, as discussed below.

Complex	Aggregation and affinity		Primary binding sites	
	t1/2 (h)	Kd(mM)	Motifs	Domain
Free	64 $\pm$ 7	-	-	-
Cu(II)	30 $\pm$ 2	$\sim$ 0.1 <sup>a</sup>	<sup>1</sup> MDVFMKGLS <sup>9</sup> <sup>48</sup> VAHGV <sup>52</sup>	N-terminal
Other metals	61 $\pm$ 7	$\sim$ 1000 <sup>b</sup>	<sup>119</sup> DPDNEA <sup>124</sup>	C-terminal

**Table 8.2. Effects of binding of divalent metal ions to  $\alpha$ S.** Synopsis of results derived from aggregation assays and affinity determinations for binding of Cu(II) and other divalent metal ions (Fe(II), Mn(II), Ni(II) and Co(II)) to  $\alpha$ S.

According to the analysis of Thio-T traces of metal-induced  $\alpha$ S fibrillation, Cu(II) promotes nucleation of  $\alpha$ S but does not affect the growth phase, suggesting that the Cu(II)-bound form of  $\alpha$ S is more prone to nucleate than the unliganded protein, a feature observed previously for polyamine complexes (Fernandez et al., 2004). The presence of Cu(II) in the fibrils indicates that the protein aggregates in its copper-bound form. Interestingly, Cu(II) does not affect the structural features inherent to the spontaneous aggregation of  $\alpha$ S, inasmuch as copper-induced fibrils exhibit the same morphology as those formed in the absence of the cation.

Previous studies suggested that  $\alpha$ S was able to bind between five to ten copper ions with a  $K_d$  of  $\sim$  50  $\mu$ M (Paik et al., 1999; Lee et al., 2003). We showed here that the protein tightly binds only two Cu(II) ions per monomer with dissociation constants in the 0.1-50  $\mu$ M range. More Cu(II) ions can be ligated by the protein, but with significantly lower affinity and probably via non-specific electrostatic interactions with charged amino acid side groups located at the C-terminus. We found that at sub-stoichiometric levels Cu(II) mainly interacts with residues located in the N-terminal region of  $\alpha$ S, contrary to previous results suggesting

that Cu(II) was exclusively bound to the negatively charged C-terminal region (Paik et al., 1999; Uversky et al., 2001c). In the light of our findings, we believe that the observation of the N-terminal binding site for Cu(II) was masked in the previous studies due to a bias in the experimental setup designed to observe rapid oligomerization of  $\alpha$ S. The high metal:protein ratios employed (5 to 10 molar excess, 0.5 mM Cu(II) concentration), and the SDS-PAGE methodology chosen to evidence  $\alpha$ S self-interaction, requiring the addition of a coupling reagent for stabilizing the oligomers, could have impaired the observation of the high affinity binding site, in favor of the more numerous lower affinity bindings sites.

Different clusters of residues at the N-terminus are clearly simultaneously affected by Cu(II) binding, with aa3-9 and aa49-52 showing the strongest effect, whereas aa20-24 and aa39-44 were less affected. The broadening effect of a type II Cu(II) site on the amide resonances reaches  $\sim 11$  Å from the Cu(II) location (Bermel et al., 2003). Thus, a decrease in intensity of a resonance does not necessarily indicate the direct participation of the corresponding residue in the coordination of the metal ion. Nevertheless, upon modification of His<sup>50</sup> by DEPC, the entire N-terminus of the protein loses the ability to interact with the metal, demonstrating the role of this residue as the anchor for Cu(II) binding and suggesting the involvement of the affected regions in the formation of a single Cu(II) binding interface. This finding also correlates with the Cu(II) coordination environment described by EPR, characterized by two N and two O ligand atoms. His<sup>50</sup> provides one nitrogen ligand, implying that the source of the other nitrogen comes either from the amide backbone or the N-terminal NH<sub>2</sub> group. The oxygen ligands could be provided by water molecules or/and backbone carbonyls from the peptide.

Our results ascribed the second, lower affinity, binding motif for Cu(II) in  $\alpha$ S to the C-terminus. The affected region comprises residues 110-140, which also constitute the primary binding site for the polycationic polyamines (Fernandez et al., 2004). However, as demonstrated upon modification or protonation of the His<sup>50</sup>, the Cu(II)- $\alpha$ S interaction within this interface is initially highly localized around residues 119-123, the spectral features of which are most affected. Thus, we conclude that Asp<sup>119</sup>, Asp<sup>121</sup>, Asn<sup>122</sup> and Glu<sup>123</sup> likely represent the ligand set for the second metal ion. Correspondingly, EPR spectroscopy indicates that the Cu(II) atom bound to DEPC-modified AS has four oxygen donors, suggesting the involvement of carboxylates as major contributors for metal binding.

After this study was published, two reports have provided complementary evidence showing that the first ten N-terminal residues of  $\alpha$ S are able to bind Cu(II) (Kowalik

(Kowalik-Jankowska et al., 2005) in the absence of the His<sup>50</sup> residue, and suggesting that this amino acid may be involved on a second high affinity site also located at the N-terminus (Sung et al., 2006). It is possible that in our experiments unspecific DEPC modification of the N-terminus at pH 6.5, or its protonation at pH 5, may have occurred simultaneously to His<sup>50</sup> modifications, masking the distinction of two binding sites. However, DEPC is highly specific to His residues, and the N-terminus should be fully protonated at pH lower than 7 (pKa > 8.0). We do not disfavor the ability of the sole N-terminus to bind Cu(II), but it is possible, due to the highly flexible nature of the polypeptide backbone, that binding of Cu(II) to the N-terminus of  $\alpha$ S does not involve a single binding interface, rather is dynamic and may accommodate different ligand sets. In the absence of the His residue, another side chain may provide the N contribution (a Lys for example) preserving the ability of the protein to bind the metal. EPR and affinity determinations on a His50 mutant  $\alpha$ S protein are going to provide more insights into the mechanism of Cu(II) binding .

Since elucidation of the residue specific effects might be central to an understanding of the mechanism of metal induced fibrilogenesis of  $\alpha$ S, we also performed experiments aimed at correlating Cu(II) binding and destabilization of the  $\alpha$ S monomer structure. The invariance of the chemical shifts of the backbone amide groups and of the hydrodynamic properties of  $\alpha$ S indicate the absence of significant conformational changes or the induction of a partially misfolded species. Thus, in the presence of Cu(II), the formation of a complex between Cu(II) and  $\alpha$ S, rather than the induction of a partially folded structure, would represent the critical step in the early stage of fibrillation of the protein. However, the central question as of what constitutes the basis for the enhancement of aggregation by Cu(II) binding could still be related to a perturbation of N-terminal long range interactions, similarly to what occurs upon protonation of the N-terminus and His<sup>50</sup> upon reducing the pH in  $\alpha$ S.

Another possibility, similar to what has been reported for the amyloid  $\beta$ -peptide and prion protein, is that  $\alpha$ S is also highly susceptible to metal-catalyzed oxidation, a reaction that induces extensive oligomerization and precipitation of these proteins (Paik et al., 1999; Requena et al., 2001). Since metal catalyzed oxidation of proteins is a highly selective, site-specific process that occurs primarily at protein sites with transition metal-binding capacity (Stadtman and Oliver, 1991), one can hypothesize that copper binding to the N-terminus of  $\alpha$ S renders the protein a relatively easy target (*e.g.* for oxidative damage) and that the ensuing damage might lead *in vivo* to a cascade of structural alterations promoting the generation of a pool of  $\alpha$ S molecules more prone to aggregate.

The NMR analysis of the rest of  $\alpha$ S-metal(II) complexes indicated that the divalent metal ions studied bind preferentially to the C-terminal domain of  $\alpha$ S in its native state. We conclude that a common, multiple binding site for metal ions exists in the region comprising residues 110-140, which also constitutes the binding interface for polycationic polyamines (Fernandez et al., 2004). Exploiting the different degree of paramagnetism of the metal ions or using substoichiometric metal to protein ratios we identified the primary site for metal ion coordination. The metal interaction was localized on residues Asp<sup>121</sup>, Asn<sup>122</sup> and Glu<sup>123</sup>, the spectral features of the former being the most affected. This picture is very similar to that determined for the  $\alpha$ S-Cu(II) complexes formed at low pH, a condition favoring Cu(II) binding to the C-terminus

A coordination site formed mostly by carboxylate moieties is in agreement with the modest affinity constants observed for metal binding to the C-terminus of  $\alpha$ S, and thus the high levels of metal ions, except Cu(II), required to induce the aggregation of  $\alpha$ S (Uversky et al., 2001c). Some studies propose that the mechanism for metal  $\alpha$ S induced aggregation could involve exclusively binding to the negatively charged carboxylates in the C-terminal region, leading to masking of the electrostatic repulsion and the collapse to a partially-folded conformation (Paik et al., 1999; Uversky et al., 2001c). Although the NMR experiments performed at up to 1 mM concentrations of metal ions did not reveal the formation of such an intermediate, our results support a mechanism of metal-induced aggregation *in vitro* sharing common features for the divalent metal ions Mn(II), Fe(II), Co(II) and Ni(II); yet indicating that this process differs significantly from that induced by Cu(II).

It is also instructive to relate the metal binding to  $\alpha$ S with other structural features characterizing the  $\alpha$ S system. The identification of a similar binding interface for divalent metal ions in the C-terminus of  $\alpha$ S suggest a common mode of binding dictated largely by electrostatic interactions. Under these circumstances, the metal ions would more likely interact with carboxylate groups clustered in the protein sequence. This might be the case with the Asp<sup>121</sup> binding site, which is surrounded by the aspartic and glutamic acids Asp<sup>119</sup>, Glu<sup>123</sup> and Glu<sup>126</sup>. A qualitatively similar effect would be expected for the cluster of residues around Asp<sup>135</sup>, comprising Glu<sup>130</sup>, Glu<sup>131</sup>, Glu<sup>137</sup> and Glu<sup>139</sup>. Instead, a noticeable difference was observed in the metal binding capabilities of the two regions. These discrepancies can be reconciled by comparing the RDC profiles for  $\alpha$ S with the  $I_{\text{para}}/I_{\text{diam}}$  profiles obtained in the presence of low sub-stoichiometric levels of metal ions. As shown in figure 8.4, a clear

correlation is observed between the selective broadening induced by the binding of divalent metal ions to the C-terminus and the intrinsic residual structure identified in that region.

**Figure 8.4. Binding of divalent metals to the C-terminus of  $\alpha$ S correlates with the residual structure of that domain.** A. Ipara/Idiam profiles for 100  $\mu$ M  $\alpha$ S, pH 6.5, in the presence of 15  $\mu$ M Mn(II) (red circle) and 40  $\mu$ M Co(II) (green triangle). At pH 5.0, Cu(II) binding is also located preferentially at the C-terminus (15 mM Cu(II), blue). B. RDCs profile for the C-terminus of  $\alpha$ S at pH 6.5 aligned in C8E5/octanol.

The strong correlation between the location of the primary metal binding site and the dynamic and structural properties inherent to the C-terminal domain suggest that the presence of a specific spatial organization about residues 121-123 might result in a particular orientation of the coordination moieties favoring metal binding to this region. Thus, we propose that binding of metal ions to the C-terminus of  $\alpha$ S is not driven exclusively by electrostatic interactions but is mostly determined by the intrinsic conformation of this domain. Complementary experiments on  $\alpha$ S-metal complexes under conditions where long-range interactions and residual structure are impaired, i.e. under 8 M urea or with A30P or A53T mutations, will be needed to prove this hypothesis.

This view is consistent with recent biochemical and structural studies revealing a role for dynamic and conformational restrictions at the C-terminus in controlling abnormal  $\alpha$ S cleavage and degradation *in vivo*. It was recently shown that the generation and accumulation of C-terminal truncated AS might be involved in the initiation and progression of  $\alpha$ S aggregation *in vivo* (Li et al., 2005). *In vitro* studies have shown endoproteolytic cleavage of

$\alpha$ S by proteasomes at Asp<sup>119</sup>-Pro<sup>120</sup> and cleavage of  $\alpha$ S by calpain I at Asn<sup>122</sup>-Glu<sup>123</sup> (Liu et al., 2003; Mishizen-Eberz et al., 2003; Li et al., 2005). In particular, the Asp-Pro peptide bonds are known to be very labile, (Segalas et al., 1995) and thus the presence of a specific spatial organization in this region might act to protect the sole Asp-Pro bond in  $\alpha$ S from cleavage. We observe substantial differences in the degree of broadening induced by metal ions on the amide backbone cross peaks of residues Asp<sup>119</sup> and Asp<sup>121</sup>, located within the <sup>119</sup>DPDNEA<sup>124</sup> fragment, which could reveal a certain degree of hindrance necessary to maintain the <sup>119</sup>Asp-Pro<sup>120</sup> bond in a non-cleavable conformation.

### **8.7. Cu(II) binding is a biological link among amyloid diseases.**

The fact that Cu(II) can promote  $\alpha$ S aggregation efficiently at physiologically relevant concentrations, and the identification of a binding interface in the N-terminus where Cu(II) binds with the highest affinity, constitute important findings of this work and support the notion of PD as a metal-associated neurodegenerative disorder. At this juncture a tighter link with other amyloid-related disorders such as Alzheimer's disease and prion disease can be sought, based on these new insights into the structural basis of copper interactions with  $\alpha$ S. The key factors of AD and prion diseases are the amyloid precursor protein (APP) and prion protein (PrP), respectively.

As shown in table 8.3, the principal feature of Cu(II) binding to APP, PrP and  $\alpha$ S is the presence of His residues acting as anchoring sites and allowing coordination with other nitrogen, oxygen or sulfur donors in 2N1O1S, 2N2O or 3N1O arrangements. In all cases, the proteins bind one copper atom per site. Interestingly, the affinity of Cu(II) for these proteins is in the low or sub-micromolar range, a fact that may have important biological implications. Even if the intracellular Cu(II) pools are regulated by binding to ligands (i.e., metallothioneins) of various affinities, the coordination of Cu(II) by these ligands is labile and subject to fluctuations.

**Table 8.3. Structural and binding properties of high affinity Cu(II) sites in amyloidogenic proteins involved in Alzheimer's disease, Prion disease and Parkinson's disease.** \* A $\beta$ <sub>1-40</sub>, A $\beta$ <sub>1-42</sub>, † Reported data correspond to the octarepeat binding motif. ‡ Coordination geometry: T (tetrahedral); S (square-planar); DT (distorted tetragonal). References are as follows: 1, (Hesse et al., 1994); 2, (Barnham et al., 2003); 3, (Atwood et al., 1998); 4, (Garzon-Rodriguez et al., 1999); 5, (Huang et al., 1999); 6, (Karr et al., 2004); 7, (Hornshaw et al., 1995); 8, (Brown et al., 1997); 9, (Viles et al., 1999); 10, (Aronoff-Spencer et al., 2000); 11, (Garnett and Viles, 2003).

It is likely that the concentrations of Cu(II) in neurons and glia are sufficient to contribute to potential abnormal interaction with proteins such as  $\alpha$ S, under certain stress circumstances. Furthermore, although the metabolic pathways of extracellular Cu(II) are poorly understood, Cu(II) levels as high as 15  $\mu$ M can be envisioned (Hartter and Barnea, 1988), sufficiently high to form complexes with extracellular targets implicated in disease such as amyloid- $\beta$  peptide (A $\beta$ ). Although more studies are needed to explore other biological aspects of Cu(II)- $\alpha$ S interactions, the structural features emerging from this work indicate that perturbations in copper metabolism may constitute a more widespread element in neurodegenerative disorders than has been recognized previously.

---

## 9. Conclusions

The major outcome of this thesis work concerns the description of the ensemble of conformers populated by the Parkinson's disease associated protein  $\alpha$ S, and the study of the destabilizing effect caused by genetic and environmental factors promoting self-oligomerization and amyloid-like protein deposition. The following conclusions have been derived from the results presented here:

- The protein  $\alpha$ S, although deprived of defined secondary structure, is not a random coil, but rather populates compact conformations stabilized by long range interactions.
- Two types of long-range tertiary contacts are found in  $\alpha$ S, a hydrophobic core between the central NAC region and the C-terminus, and electrostatic interactions between the N- and C-terminus.
- Genetically-linked and environmentally-induced pathological states of  $\alpha$ S are characterized by the impairment of long-range interactions rendering exposure of the central hydrophobic NAC region and facilitating self oligomerization.
- The homologous protein  $\beta$ S, which lacks the central NAC region, does not display long range interaction and populates more extended unfolded conformations, yet with a high content of residual structure at the C-terminus.
- $\alpha$ S possesses a high affinity Cu(II) binding site at the N-terminus of the protein, and interactions with the metal cation at low micromolar concentrations cause aggregation of the protein, suggesting that impairment of Cu(II) homeostasis is a common feature of amyloid disorders such as Alzheimer's or Prion diseases.
- From the methodological point of view, our data represent the first study of a natively unstructured protein by means of PREs, suggesting that this approach may also be valid for the study of such highly dynamic systems.
- In addition, the measurement of RDCs in  $\alpha$ S and  $\beta$ S was shown to be sensitive both to restricted slow motions ( $\mu$ s timescale) and long-range interactions, as complementary probed by ensemble averaged computer-derived structures. This result categorizes RDCs as highly suitable for studying the complex conformational states of natively unfolded polypeptides.

## 11. Appendix

### 11.1 Fluorescence spectroscopy and microscopy to study $\alpha$ -synuclein fibrillation

Fluorescence spectroscopic methods offer a very suitable alternative for studying fast protein dynamics of both small and big size macromolecular complexes, many of which NMR fails to detect. Fluorescence methodologies are usually based on the alteration of the fluorescent properties of a fluorophore upon changes in the chemical constitution and/or physical properties of the solution. Thus phenomena such as fluorescence quenching, spectral shift, changes in lifetime or anisotropy are evidenced upon perturbation of the fluorophore, caused by changes in polarity of the solvent, presence of another fluorophore or increase in the molecular size of the complex. In addition, intramolecular distances can be efficiently studied by FRET, which exploits the distance dependence of near-field dipole-dipole interactions between a pair of chromophores (Lakowicz, 1999). Another method of choice is fluorescence correlation spectroscopy (FCS), which allows the determination of diffusion rates of single particles, providing insights into whether a protein is alone or part of a macromolecular complex.

Fluorescent methods with various degrees of sophistication have proven very useful in unraveling the structural characteristics of amyloid fibrils. The early use of fluorescent dyes may be tracked back to the establishment of ThioT or ANS as amyloid dyes (Nilsson, 2004). However these dyes are not specific, and provide a reduced amount of data, derivable solely from changes in fluorescence intensity, and which do not reveal what is occurring to the protein during the early stages of amyloid conversion. More information can be obtained by the use of intrinsic fluorescent probes, which report on local properties of the polypeptide chain and can be efficiently followed in time. Such fluorescent approaches are relatively easy to apply to proteins *in vitro*, by exploiting the fluorescent properties of Trp and Tyr amino acids, or by conjugating small fluorescent dyes specifically to engineered Cys residues.

Indeed, fluorescent-based methods have been employed to study protein folding and aggregation. Measurement of intramolecular distance between two fluorophores in solution by time-resolved FRET has provided data on the overall shape of the ensemble of structures populated from microseconds to milliseconds time-scale (Ratner et al., 2000). Steady-state fluorescent anisotropy methods have been of use in the case of the islet amyloid peptide (Padrick and Miranker, 2002; Koo and Miranker, 2005). More recently, residue-specific steady-state fluorescence intensity was used to characterize the amyloid core of a yeast prion

protein (Krishnan and Lindquist, 2005). However, time-resolved fluorescence methods, which have resulted very useful in providing global and residue-specific structural information in folding mechanisms (Sridevi et al., 2000; Lakshmikanth et al., 2001; Sridevi et al., 2004), have not been exploited in the study of protein aggregation. Few studies, notably one on the early oligomeric species formed by the A $\beta$  peptide are found in the literature (Allsop et al., 2001), and the formation of amyloid protofibrils by the protein barstar has been recently studied by mapping residue-specific fluorescent dynamics (Mukhopadhyay et al., 2006).

The use of time resolved fluorescent measurements has many comparative benefits compared with steady state measurements, since much of the molecular information available from fluorescence is lost during the time average. The lifetime of the dye is modulated by the presence of different conformational states that influence the rate of decay of its fluorescent intensity. Also, the precise shape of the anisotropy decay contains information about the shape of the macromolecule, its apparent size and its flexibility. In addition, FRET can be efficiently followed by changes in the lifetime of the donor dye. Thus, in fluorescence, a great extent of the molecular information content is only available from time resolved measurements (Lakowicz, 1999).

We applied time resolved fluorescent methods to study the early structural transitions conducive to  $\alpha$ S oligomerization, as well as the build up of such oligomeric species during protein aggregation. Placing fluorescent tags with different properties in several locations of the polypeptide chain provide probes for studying protein self-association at quasi residue-specific level. As a first approach we labeled three Cys-containing variants of  $\alpha$ S and two of  $\beta$ S with commercial maleimide derivatives of the fluorescent dyes Alexa488 (Amersham) and Cy3b (Molecular Probes) (Appendix figure 1). These ten fluorescent derivatives were characterized at the soluble native monomer level by measuring of time-resolved fluorescence according to the time domain (Time-Correlated-Single-Photon-Counting, TCSPC) method. The following results and interpretations are preliminary inasmuch as time did not suffice for a complete analysis.

In time domain measurements, the sample is excited with a pulse of light of short duration, and then the time-dependent intensity is measured following the excitation pulse. Multiple (if they exist) decay times  $\tau$  (tau) are derived by fitting multiple exponential functions to the decay trace. We employed for such measurements an IBH fluorimeter

equipped with Nano-LED pulse laser diode and a TCSPC device, located in the Department of Organic Chemistry, University of Buenos Aires, Argentina.

**Appendix figure 1. Properties of the fluorescent dyes employed for the study of  $\alpha$ S and  $\beta$ S.** **A** and **B**. Structure and fluorescent-associated properties of Alexa488 (**A**) and Cy3b (**B**) on their maleimide-derivative versions. **C**. Normalized fluorescence excitation (dashed lines) and emission (bold lines) spectra for Alexa488 (green) and Cy3b (red).

Preliminary measurement of lifetimes corresponding to  $\alpha$ S and  $\beta$ S labeled proteins are shown in Appendix figures 2 and 3, and the results are summarized on the Appendix table 1. In all the cases, lifetimes were fitted to a two exponential function, one corresponding to a pulse response ( $\sim 0.5$  ns) and the second corresponding to a single population of the dye (2.5 to 4 ns). This suggests that the ensemble of conformations populated by these proteins was highly homogeneous. The lifetime of the dyes attached to the proteins was in all the cases very similar to the ones in free solution (4.1 ns for Alexa 488 and 2.7 ns for Cy3b). However, some features were evident from the slight different lifetimes for the dyes at various positions. In particular the lowest lifetimes were found for the  $\alpha$ S-A140C tagged protein, most likely reflecting the local freedom of the dye attached to the very C-terminal residue. Conversely, the longest lifetimes were observed for the  $\alpha$ S-A90C protein, likely reflecting

the hydrophobic packing caused by long-range interactions probed by NMR-based methodologies.

### Appendix figure 2. Lifetime fluorescent decays for fluorescently labeled $\alpha$ S.

Three different Cys-containing mutants of  $\alpha$ S (A18C, A90C and A140C) were labeled with Alexa488-maleimide and Cy3b-maleimide, and their time dependent fluorescent properties were studied. **A**, **B** and **C**. Each panel shows fluorescent lifetime decays for the corresponding Alexa488 labeled (black, left) and Cy3b labeled protein (red, left), and anisotropy decays for Alexa488 labeled (black, right) and Cy3b labeled protein. **A** is for  $\alpha$ S-A18C, **B** is for  $\alpha$ S-A90C and **C** is for  $\alpha$ S-A140C. **D**. Influence of the solution media on the fluorescent properties for  $\alpha$ S-90C labeled protein. Comparison between buffer and glycerol 50% protein solutions shows the potential of anisotropy measurements for studying changes in diffusion properties of these proteins.

**Appendix figure 3. Lifetime fluorescent decays for fluorescently labeled  $\beta$ S.** The A18C (A) and A79C (B) Cys-containing mutants of  $\beta$ S were labeled with Alexa488-maleimide and Cy3b-maleimide, and their time dependent fluorescent properties were determined. Fluorescent lifetime decays for the corresponding Alexa488 labeled (black, left) and Cy3b labeled protein (red, left), and anisotropy decays for Alexa488 labeled (black, right) and Cy3b labeled protein.

We also performed time-dependent anisotropy measurements on the above mentioned samples. For anisotropy measurements the sample is excited with vertically polarized light and the intensity decay is measured with emission polarizers oriented along either the vertical (parallel) or the horizontal (perpendicular) axis. The anisotropy is derived from the following equation, relating the intensity decays the individual the parallel ( $I_{\text{para}}$ ) and perpendicular ( $I_{\text{perp}}$ ) components (1):

$$r = \frac{I_{\text{para}} - I_{\text{perp}}}{I_{\text{para}} + 2 I_{\text{perp}}} \quad (1)$$

From the time-dependent anisotropy the correlation time of the fluorophore attached to the polypeptide chain can be derived from the Perrin equation (2) for an isotropically rotating sphere, clearly a great simplification of our system:

$$r = \frac{r_0}{1 + \frac{\tau}{\theta}} \quad (2)$$

, where  $r_0$  is the fundamental anisotropy (anisotropy at time 0), and  $\theta$  is the rotational correlation time of the protein. By employing fluorophores with a lifetime  $\tau$  similar to the expected correlation time of the protein,  $\theta$  can be evaluated.

In all assayed protein derivatives, the correlation time of the fluorophore was in the order of  $\sim 1$  ns, much lower than the one expected to  $\alpha$ S based on its molecular weight (5 to 6

ns). However, due to the unfolded nature and high flexibility of the polypeptide chain, one presumes that the correlation time of the fluorophore is not primarily dictated by the tumbling of the whole protein, but rather by local backbone fluctuations of the persistence length segment in which the dye is located. Thus, the very high mobility of the very end segment of  $\alpha$ S was expected, whereas the segments corresponding to the other substitution positions displayed a lower degree of motion. In particular the 90<sup>th</sup> position in  $\alpha$ S, and 79<sup>th</sup> position of  $\beta$ S, were shown to be slightly more dynamically restricted, consistent with the persistent residual structure in the vicinity of the residues revealed by NMR-residual dipolar couplings.

Protein	Lifetime (ns)	R0	Cor. time (ns)
$\alpha$ S-18C-Alexa	3.97	0.236	1.18
$\alpha$ S-90C-Alexa	4.14	0.219	1.24
$\alpha$ S-140C-Alexa	3.80	0.222	0.70
$\beta$ S-18C-Alexa	3.87	0.229	1.22
$\beta$ S-79C-Alexa	3.94	0.240	1.40
$\alpha$ S-18C-Cy3b	2.79	0.288	1.31
$\alpha$ S-90C-Cy3b	2.80	0.276	1.37
$\alpha$ S-140C-Cy3b	2.58	0.295	1.11
$\beta$ S-18C-Cy3b	2.79	0.302	1.28
$\beta$ S-79C-Cy3b	2.69	0.300	1.46

**Appendix table 1. Time-dependent fluorescent properties for fluorescently labeled  $\alpha$ S and  $\beta$ S.** Overview of the determinations of lifetime and anisotropy decays for the different variants of  $\alpha$ S and  $\beta$ S at the monomeric native state.

The rationalization of the fluorescent-derived properties with the NMR-derived structural data was one of many goals of these studies. The preliminary results shown here are promising and suggest that we may be able to detect by lifetime measurement the changes in conformations populated by the unfolded polypeptide chain, and by anisotropy decays the restricted dynamics and oligomerization state of the protein during different stages of the aggregation process. In addition, the use of other fluorescent derivatives is currently under investigation in our laboratories, and will bring a whole new level in the investigation of the

biophysical properties of such protein conversions, particularly during the elusive early stages of association (oligomerization).

The integration of fluorescence spectroscopy in light microscopy adds a new dimension to microscopy, since spatial resolution information about the molecular behavior of proteins can additionally be obtained in living cells. Imaging techniques with spectral resolution in a microscope require that the proteins of interest be fluorescently tagged. This makes such studies in living cells far more complex than *in vitro*. However, it is possible to introduce into the cell an *in vitro* labeled protein, for example by microinjection. Nevertheless this procedure is highly time consuming, since each cell has to be injected individually, and the technique is not suitable for all cell lines. A far more attractive alternative strategy is to add genetically encoded fluorescent tags, as the green fluorescent protein (GFP). Biologically functional GFP fusions have been obtained for a number of proteins, and are the method of choice for studying the fate of proteins inside cells. Amyloid deposition has been studied employing such fusions. Artificial peptides and polyQ constructs have been shown to yield fluorescent aggregates in cell cultures when fused to visible fluorescent proteins (VFP) (Bence et al., 2001; Kim et al., 2002) In some cases, however, the GFP represents an excessively bulky group for the protein to which is added, in particular for small polypeptides such as  $\alpha$ S (Figure Appendix 2A). In particular for  $\alpha$ S, the formation of abnormal non-fluorescent aggregates deprived of fluorescence has been observed in neuronal cultures (McLean et al., 2001). Thus, monitoring  $\alpha$ S amyloid formation in living cells has posed a formidable challenge.

To overcome the problems associated with the use of VFPs the challenge was to search for alternative genetically-encoded tags of reduced size. Such a strategy was developed by the laboratory of Roger Tsien a few years ago in the (most recent form) of a 12-mer peptide tag, containing 4 Cys residues in a defined spatial separation (CysCysXXCysCys). This so-called tetracysteine tag (TC), specifically binds organo-arsenical dyes with high affinity (Griffin et al., 2000). The tag is fused to the gene of interest and transfected cells are stained with the biarsenical dye, which is not fluorescent in solutions and becomes fluorescent upon conjugation to the TC tag. Furthermore, the TC motif is absent from natural genomes and allow specificity of the staining. We thus sought in using the strategy of small, genetically encoded, TC tags to study  $\alpha$ S fibrillation We have succeeded in creating functional fluorescent derivatives of  $\alpha$ S by fusing the TC sequence FLNCCPGCCMEP (Martin et al., 2005) at the C-terminus of the protein (Figure Appendix

5B). This chimera, characterized biophysically to be indistinguishable from the *wt* protein, reacts with the fluorogenic biarsenical compounds known as FIAsh and ReAsH (Figure Appendix 4), yielding fluorescent derivatives that readily aggregate (Figure Appendix 5C and 5D).

**Appendix figure 4. Properties of the FIAsh and ReAsH arsenoxide dyes employed for *in vitro* and *in vivo* studies of  $\alpha$ S fibrillation.** **A.** Structure and fluorescent-associated properties of FIAsh and ReAsH. **B.** Normalized fluorescence excitation (dashed lines) and emission (bold lines) spectra for FIAsh (green) and ReAsH (red).

Monitoring  $\alpha$ S *in vivo* was achieved by either microinjecting pre-labeled  $\alpha$ S-TC-FIAsh protein or by transfecting the cells with an  $\alpha$ S-TC-coding plasmid and staining with the cell permeable FIAsh or ReAsH dyes (Figure Appendix 2E to 2H). The intracellular distribution and aggregation of  $\alpha$ S-TC was assessed in living cells by fluorescence microscopy, exploiting photophysical phenomena such as FRET using singly or doubly stained cells.

**Appendix figure 5. Fusion of a tetracysteine (TC) tag to  $\alpha$ S shields fluorescent amyloid fibrils *in vivo*.** **A.** Structural model for an  $\alpha$ S-VFP chimera. **B.** Structural model for an  $\alpha$ S-TC chimera. **C** and **D.**  $\alpha$ S-TC-FIAsH (**C**) and  $\alpha$ S-TC-ReAsH (**D**) aggregates obtained *in vitro*. **E.** Live SHSY-5Y cell expressing the  $\alpha$ S-TC construct and stained with FIAsH. Perinuclear  $\alpha$ S aggregates are observed. **F, G** and **H.** Fixed SHSY-5Y cell expressing the  $\alpha$ S-TC construct stained with FIAsH (**F**) and immuno-stained with an antibody anti- $\alpha$ S (Alexa633 conjugated secondary antibody, **G**) shows co-localization of aggregates (merged, **H**). Panels C, D, F, G and H were kindly provided by María J. Roberti (MPI-BPC and Universidad de Buenos Aires, Argentina).

Our results validate tetracysteine tags as valuable tools for direct fluorescent studies of  $\alpha$ S fibrillation, and provide the means for investigation of protein misfolding phenomena in general. Furthermore, we foresee the potential use of our fluorescent constructs for screening procedures of therapeutic agents specific for neurodegenerative diseases.

The results shown here on  $\alpha$ S-TC, were obtained in collaboration with María J. Roberti, a PhD student primarily responsible for the research, and a member of the group of Prof. Dr. Elizabeth Jares-Erijman of the Laboratory of Organic Chemistry, University of Buenos Aires. Some of these data have been included in the following paper submitted for publication:

## Acknowledgments

In first place I would like to thank Prof. Dr. Christian Griesinger and Prof. Dr. Thomas Jovin, for giving me such a great project and for their outstanding work as main supervisors of this study. I also gratefully acknowledge supervision, bright ideas, generous support and essential discussions that allowed the accomplishment of this thesis from Dr. Markus Zweckstetter and Dr. Claudio Fernandez.

I am indebted to Prof. Dr. Ralf Ficner and Prof. Dr. Reinhard Jahn for being the *Referent* and *Korreferent* of this thesis work, respectively. In addition, I would like to thank Prof. Dr. Gerhard Braus and Prof. Dr. Michael Kessel for kindly accepting the examiner role at my *Rigorosum* examination.

Many people were involved at different points of my thesis, and the outcome of this work would have not been possible without such contributions. I would like to thank the major contribution to the results presented here from Dr. Rodolfo Rasia, in particular on the study of  $\alpha$ -synuclein-metal interactions and on  $\beta$ -synuclein. In addition, his scientific advises and critical comments have been essential for me and for this project. Many thanks to Dr. Wolfgang Hoyer and Dr. Dmitry Cherny for their support during the early stages of this thesis, and to Andres Binolfi for his outstanding work on  $\alpha$ -synuclein-metal interactions during his stay at the laboratory. Dr. Young-Sang is specially acknowledged for the calculation of the NMR-derived structures, as well as Min-Kyu Cho, Hai-Young Kim and Marco Mukrasch for experimental advices, for sharing data, and for general discussions. Research stays of undergraduate and graduate students in the laboratory have been very helpful in generating and analyzing data, and thus I would like to thank Alexandra-Kloss, Ritika Mahal and Kalina Dimova. Furthermore, skilled assistance from Vinesh Vijayan and Sigrun Rumpel on NMR spectra acquisition and processing is gratefully acknowledged. Special thanks to Reinhard Klement for helpful insights into molecular dynamics simulations and for his continuous support with computers. Technical assistance from Annelies Zechel has been essential at many stages of this work, and is particularly acknowledged.

Collaborations with other laboratories have resulted fundamental in the project, some of them presented on this thesis. I'm indebt to Dr. Derek Marsh and Briggita Angerstein, at the department of Spectroscopy, MPI-BPC, for the EPR spectra acquisition and processing, and to Dr. Pau Bernado and Dr. Martin Blackledge, at the Institute de Biologie Structurale Jean-Pierre Ebel, in Grenoble, France, for the work on simulated RDCs. The work on fluorescent derivatives is part of a research stay at the Department of Organic Chemistry,

University of Buenos Aires, Argentina. I gratefully acknowledge Prof. Elizabeth Jares-Erijman for her scientific expertise and support on this matter. Major contributions to the work on the tetracysteine-tagged  $\alpha$ -synuclein come from Julia Roberti, and are also acknowledged. Many thanks as well to Elizabeth Garfinkel, Sandra Mickowsky and all the members of the Jares laboratory for experimental assistance in Buenos Aires.

At this point I also want to mention the support from other members of the  $\alpha$ -synuclein group, at the MPI-BPC, Shyamala, Yaser, and Soledad, many thanks to all of you!. Also I want to thank the solid-state NMR group, in particular Dr. Henrike Heisse and Dr. Mark Baldus, as well as Dr. Dietmar Riedel, from the Department of Neurobiology, for providing crucial insights into the structure of fibrillated  $\alpha$ -synuclein.

Outstanding scientific environment and expert support for the developing of this project have been provided by members of the DFG Center for Molecular Physiology of the Brain (CMPB), in Göttingen. In particular I would like to thank Prof. Dr. Jörg B. Schulz, Dr. Björn Falkenburger and Felipe Opazo. I also gratefully acknowledge the CMPB for the award of a PhD fellowship and for travel financial support.

I would also like to thank essential scientific support from Dr. Donna Arndt-Jovin, and silent but indispensable help from Renate, Gudrun, Achim, Stephan, Helmut, Monika and Ingrid, as well as the rest of the technical staff at the MPI-BPC.

Many warm thanks to my friends at the Department of Molecular Biology for creating such a comfortable environment inside and outside the lab. From the ones that have left, as Greco, Paula, Vero, Vlad, Claudio and Andres, to the ones that still stay as Fito, Vale, Sole C., Sole G., Julia, Guy, Avishay, Alessandra, Cornelia, Michelle, Shyamala, Yasser and Anthony. Also, special thanks to all the people at the Department of NMR-based Structural Biology, in particular to Peter, Fernando, Vinesh, Sigrun, Monika, Pierre, Min-Kyu, Hai-Young, JJ and Pinar. I will miss you all!

Finally, I want to acknowledge the invaluable “long-range” support from my whole family and friends in Argentina, which I have missed so much during these years. And at last, but not the least, I want to thank the love, kindness and understanding from Marianela, the most marvelous person that I have ever met, and to whom I owe my everlasting happiness. “... beyond comprehension are the reasons that keep you at my side, as beyond reality are those feelings that your love provide...” ... te amo hoy, como ayer, y por siempre...

---

---

**Lebenslauf**

Name: Carlos Walter Bertoncini

Geburtsdatum: 10. April 1977

Geburtsort: Santa Fe, Argentinien

Nationalität: argentinisch

Adresse: Hainbuchenring 1  
37077 Göttingen

**Bildungsweg**

1983 - 1989 Grundschole „Escuela N° 6 Mariano Moreno“, Santa Fe, Argentinien.

1990 - 1996 Gymnasium „Escuela Industrial Superior – Universidad Nacional del Litoral“, Santa Fe, Argentinien, mit einem technischem Abschluss für Chemie verliess.

1997 - 2001 Studium der Biotechnologie an der „Universidad Nacional del Litoral“, Santa Fe, Argentinien, mit einem Diplomabschluss in Biotechnologie.

2002 Wissenschaftlicher am Zelltek, SRL, Santa Fe, Argentinien.

2002 Wissenschaftlicher am Max-Planck-Institut für Biophysikalische Chemie, Göttingen.

seit 2003 Dissertation im Max-Planck-Institut für Biophysikalische Chemie, Göttingen, mit dem Thema „Structure, Dynamics and aggregation mechanism of the Parkinson’s-disease associated protein  $\alpha$ -synuclein“  
bei Prof. Christian Griesinger and Prof. Thomas Jovin.
