# *Chapter 1*

## Introduction

## **Introduction**

### **1.1. Scope**

The present Thesis is devoted to a detailed analysis of sedimentary provenance indicators from Late Mesozoic to Tertiary synorogenic, mixed siliciclastic-carbonate deposits in the Dinarides. Generally, such sedimentary sequences retain a wealth of information about the past geologic buildup, tectonothermal events and palaeogeographic connections of the orogen, furthermore about the pathways of sediment dispersal and their tectonic control.

Section 1.3 below outlines in more detail the approaches adopted or developed in this study, and Section 1.4. presents the structuration of the Thesis. These are preceded by an overview on the tectonic setting of the Dinarides and the geological framework of the investigated areas in Section 1.2.

I have prepared the Thesis under the supervision of Prof. Dr. Hilmar von Eynatten and Dr. István Dunkl at the Department of Sedimentology/Environmental Geology of the Geoscience Center Göttingen, in the period from October 2004 to November 2008. I most sincerely thank them for their guidance and the ever-stimulating, friendly working atmosphere at the Department. The research was funded by the Deutsche Forschungsgemeinschaft, with additional support coming from the Synthesys Programme.

### **1.2. The Dinarides**

#### *1.2.1. Introduction*

The Dinaride-Hellenide system of the Alpine orogen consists of a highly impressive edifice of orogen-parallel tectonostratigraphic units, extending for over 1500 km from the Southern Alps in the NW to the Aegean region in the SE (Fig. 1, see also Fig.1 of Chapter 2). Its development has been governed by the convergence of the African and European plates since the Jurassic.

The Dinaride-Hellenide tectonic units are currently divided among ten countries speaking six major languages. Some of the political borders run parallel to the orogenic strike infavourably separating internal and external orogenic domains; currently, the level of knowledge on the geodynamic significance of the tectonic units varies from region to region.

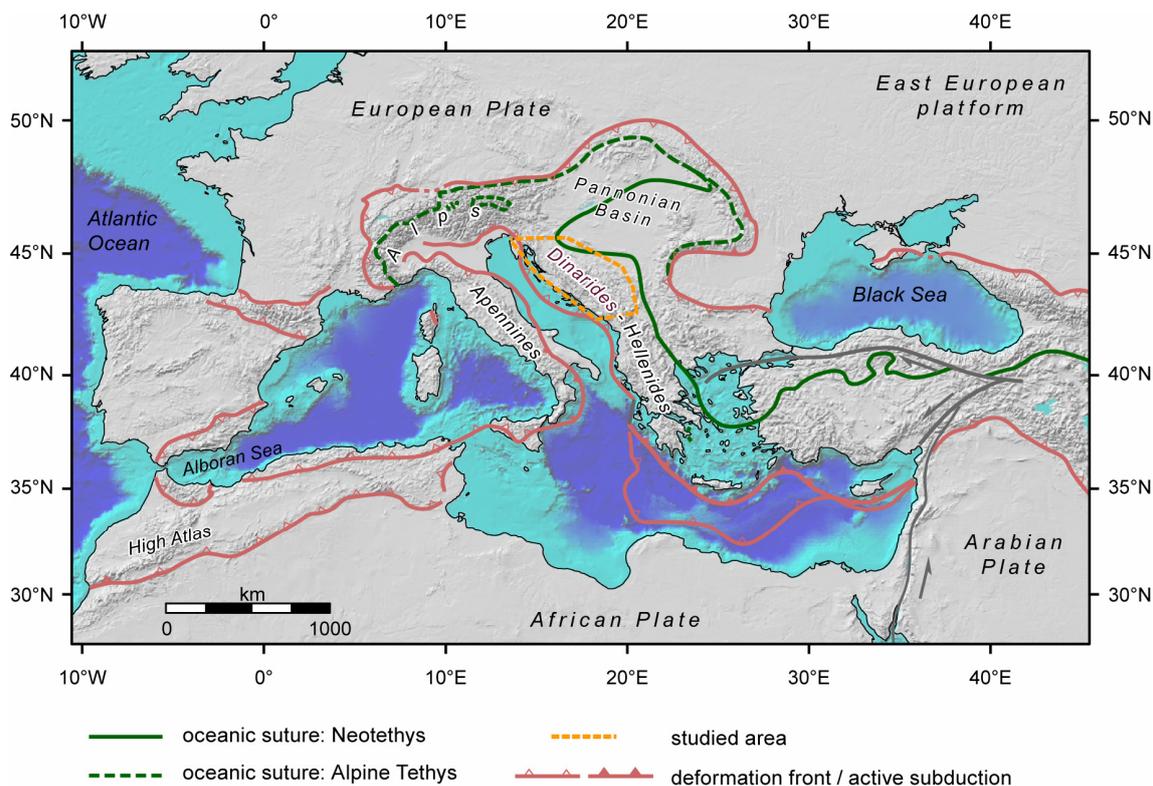

*"Namentlich infolge der unermüdlichen Studien von C. Renz, dann aber auch infolge jener der deutschen, österreichischen und ungarischen Geologen, die den Balkan [...] untersuchten, hat sich unsere Kenntnis des Baues der Dinariden wieder wesentlich erweitert und so kann denn eine Synthese der Dinariden versucht werden."*

– begins Franz Baron Nopcsa in 1921 with his lucid synthesis of the Dinaride-Hellenide tectonostratigraphy. Understanding the architecture and evolution of the Dinarides reached further landmark stages owing to the work of, among others, Cvijić (1924), Kossmat (1924), Petković (1961), Aubouin (1973), Dimitrijević (1982, 1997), Pamić *et al.* (1998, 2002) and Karamata (2006). The latest tectonic map and interpretation of the units have been elaborated by Schmid *et al.* (2006, 2008) and we have mostly followed the tectonic subdivision proposed by these authors.

### *1.2.2. Overall tectonic architecture*

As an integral part of the European Alpine chain, the Dinarides are located between the Southern Alps and the Hellenides, forming a SW-vergent pile of Alpine tectonostratigraphic units. They essentially consist of Jurassic ophiolites thrust onto the distal passive margin of the Adriatic plate (Dimitrijević, 1982; Pamić *et al.*, 2002; Karamata, 2006; Schmid *et al.*, 2008). The latter is built up of sedimentary to low-grade metamorphic Lower Palaeozoic basement and its Permo-Mesozoic cover. Large-scale Early Cretaceous thrusting involved several Adria-derived units passively carrying the ophiolites previously thrust onto them, and gave rise to the formation of a vast clastic wedge in front of the continental-ophiolite thrust sheet complex (Aubouin, 1973; Schmid *et al.*, 2008; Chapters 2 and 3 of this Thesis). The Outer Dinaride structural units are dominated by the elements of the large Mesozoic Adriatic Carbonate Platform (Vlahović *et al.*, 2005). Individual tectonic units of the platform are often separated by imbricated slices of Tertiary flysch which shows mixed carbonate–siliciclastic composition (Chorowicz, 1977; Chapter 5 of this Thesis), hinting at a major sediment

source outside the platform. Thrusting in the Outer Dinarides was accompanied by the formation of a retrowedge at the NE margin of the Dinarides – the Sava Zone – that formed the collisional zone of the Dinarides with the Tisza Unit in the Tertiary (e.g. Pamić 1993, Tari, 2002; Schmid *et al.*, 2008).

### 1.2.3. Tectonic significance of the ophiolites and the Adriatic continental basement

#### 1.2.3.1. Dinaride ophiolite thrust sheets

The Dinaride ophiolites appear in two distinct belts which gave rise to a vigorous debate on their relation. Several models were proposed; the existence of two oceanic basins, either separated by an intraoceanic "microcontinent" (Robertson and Karamata, 1994; Karamata *et al.*, 2006), or opened consecutively in an arc/back-arc system (Pamić *et al.*, 2002). Alternatively, the ophiolites originated from a single

oceanic basin the fragments of which were emplaced to different distances onto the overridden continental plate (Kober, 1912; Bernoulli and Laubscher, 1972; Schmid *et al.*, 2008). Although there is a consensus in earlier models that oceanic convergence was not associated with a significant island arc igneous activity (Ivanov *et al.*, 1987; Pamić *et al.*, 2002; Dimitrijević *et al.*, 2003), an increasing number of petrological and geochemical data point to island arc affinity in the Dinaride ophiolites, and also in other equivalent, displaced ophiolite sequences in Albania, in the Hellenides and in the Bükk Mts. in NE Hungary and the Apuseni Mts. in Transylvania. The island arc signatures are explained by the development of an intra-oceanic supra-subduction-zone (e.g. Aigner-Torres and Koller 1999; Robertson, 2004; Beccaluva *et al.*, 2005; Bortolotti and Principi 2005; Bazylev *et al.*, 2006; Lugović *et al.*, 2006, 2007; Rassios and Moores 2006; Smith 2006; Dilek *et al.*, 2008). K/Ar, Ar/Ar and Sm/Nd age data of sub-ophiolitic metamorphic soles from Dinaride and Albanian ophiolites range between 178 and 161 Ma, indicating Middle Jurassic intraoceanic thrusting (e.g. Okrusch *et al.* 1978; Parlak and Delaloye 1999; Dimo-Lahitte *et al.* 2001; Olker *et al.* 2001; Smith 2006 and references therein). Ophiolite obduction onto the Adriatic margin was completed by Late Jurassic and involved HP/LT metamorphism in deep crustal levels of both the oceanic and Adriatic plate margins (see discussion in Chapter 2). Stratigraphic constraints on the timing of obduction are provided by the Tithonian-Berriasian age of the oldest sedimentary deposits sealing the ophiolites, consisting of alluvial coarse-grained siliciclastic strata and shallow marine carbonates interfingering with them (Blanchet *et al.* 1970; Bortolotti *et al.*, 1971; Charvet and Termier 1971; Charvet 1973, 1978; Neubauer *et al.* 2003).

### 1.2.3.2. Inner Dinaride continental thrust sheets

The continental units in the Inner Dinarides represent major, Adria-derived thrust sheets exposed in large, orogen-parallel tectonic windows (Bernoulli and Laubscher, 1972; Schmid *et al.*, 2008), and dominated by Palaeozoic to Triassic siliciclastic and carbonate sediments as well as acid igneous suites (Podubsky, 1970; Rampnoux, 1970; Djoković, 1985; Dimitrijević, 1997; Pamić and Jurković, 2002). They underwent regional thermal overprint ranging up to anchi- to epizonal conditions; a latest Jurassic to Early Cretaceous cooling is widely demonstrated by several Ar/Ar, K/Ar and zircon

FT age data from a number of basement units (Milovanović, 1984; Árkai *et al.*, 1995; Belak *et al.*, 1995; Pamić *et al.*, 2004; Ilić *et al.*, 2005; Judik *et al.*, 2006; Muceku *et al.*, 2006; – see discussion in Chapter 2).

### 1.2.3.3. Sava Zone

The Sava Zone is an elongated, highly complex tectonic zone located at the northern margin of the Inner Dinarides (Fig. 1 of Chapter 6). It separates them from the Tisza Unit further in the north, which is a basement unit in a rather exotic position; it was detached from the European margin in the Jurassic, with its subsequent tectonic evolution involving thrusting and large amounts of strike-slip displacement (e.g. Csontos and Vörös, 2004). The Sava Zone comprises Late Cretaceous ophiolites, representing a remnant basin of the Neotethys Ocean subducting below the Tisza Unit, which are overlain by Late Cretaceous to Eocene mixed siliciclastic–carbonatic flysch-like deposits. Sediments of the Sava Zone and their ophiolitic or continental basement underwent deformation and Alpine regional metamorphism due to the collision of the Tisza Unit with the Inner Dinaride continental margin. The degree of metamorphism exhibits a large regional variation, ranging up to amphibolite facies, and dated mostly as Late Cretaceous to Early Paleogene. The sedimentary–metamorphic sequence is intruded by Late Cretaceous to Oligocene granitoids and bimodal volcanic series (Pamić and Šparica 1983; Pamić 1993, 1998, 2002; Pamić *et al.*, 2000; Balen *et al.*, 2003; Starijaš *et al.*, 2005, 2006; Krenn *et al.*, 2008; Ustaszewski *et al.*, in press).

Siliciclastic components of the flysch were sourced from a composite source area made up of ophiolites, granitoids and metamorphic units (Jelaska *et al.*, 1970; Mikes *et al.*, 2006b; Ustaszewski *et al.*, in press). Palaeocurrent indicators suggest sediment transport from NE to E relative to the Sava Zone at present directions (Jelaska *et al.*, 1970, Babić and Zupanić 1976; Jelaska 1978), or from E to SE if the Tertiary counter-clockwise rotation in the Sava Zone that exceeds 30° is also taken into account (Márton *et al.*, 2005).

#### 1.2.3.4. Outer Dinarides

The Outer Dinaride thrust sheets are dominated by Mesozoic carbonate sequences of several km thickness, constituting the vast Adriatic Carbonate Platform (AdCP; Vlahović *et al.*, 2005). The thrust fronts are associated by flysch-like sediments, deposited in a large foreland basin system on top of the SW-directed Dinaride thrust wedge (Fig. 1 of Chapter 5). Basin remnants can be traced along the orogenic strike from the Southern Alps to the Hellenides, occurring mostly as thin imbricate slices (OGK – Basic Geologic Map of former Yugoslavia, 1:100.000 sheets). Stratigraphic position of the flysch has traditionally been described in terms of a Palaeogene marine sequence overstepping the Mesozoic AdCP. The flysch is underlain by well-dated Lower to Upper Eocene Globigerina marls; their contact is conformable at places, but angular or erosional unconformities have been often reported (e.g. Marinčić, 1981; Marjanac, *et al.*, 1998; Marjanac, 2000). Due to imbricate thrusting, the flysch slices are tilted, truncated, and less than 100-400 m thick. Turbidite beds are dominantly composed of siliciclastics, with a highly variable amount of carbonate admixture. Based mostly on paleocurrent indicators and heavy mineral analyses, two different hypotheses exist for the provenance of the siliciclastic material in the NW part of the basin system; a dual, Alpine-Dinaride source (Magdalenić, 1972) and an exclusive sediment supply from Dinaride units in the NE (Marinčić, 1981; Marinčić *et al.*, 1996) were both proposed. In the central and SE parts of the basin, the use of palaeocurrent indicators for deciphering the ultimate source location of siliciclastic input is limited, due to complex basin floor topography and flow reflection (e.g. Marjanac, 1990; 1996), and the origin of the siliciclastic detritus is not well understood.

The flysch sandstones are lithic wackes to calcilithites, with their main framework components averaging at  $Q_{60-85}F_{5-15}L_{10-25}$ , corresponding to a recycled orogenic provenance (Mikes *et al.*, 2006a). Major and trace element geochemistry and heavy mineral analysis indicate provenance mixing of mature, quartzose sedimentary rocks and ophiolitic units. Cr-spinel, garnet, rutile, zircon, tourmaline and apatite as well as minor amounts of staurolite and glaucophane characterize most of the heavy mineral assemblages in the entire basin system (Woletz, 1962; Pavičić *et al.*, 2003; Mikes, 2003; Mikes *et al.*, 2005). Locally however, especially in the central and SE part of the basin, the heavy mineral spectra comprise higher amounts of unstable metamorphic species (hornblende, tremolite, epidote, chloritoid). Regional distribution of new

calcareous nannofossil depositional ages reveals an increasing preservation for the Neogene part of the sequence towards the SE (Chapter 5). This pattern is well in line with a recent kinematic reconstruction by Ustaszewski *et al.* (2008), proposing that the amount of post-Early Miocene shortening increases in this direction. The above data suggest increased relief and exhumation in the SE Dinarides in the Late Tertiary, and westerly-directed drainage into the foreland basin system.

### **1.3. Recent advances in sedimentary provenance analysis**

The composition of siliciclastic sediments yields crucial information for deciphering the lithology, thermal history, kinematic evolution and several other aspects of the rock associations in the sedimentary source area. However, a number of other processes do also operate during the evolution of sediments, which exert a fundamental control on their composition and will modify the original source area signal to varying degrees. The most important processes include chemical weathering, grain breakage and abrasion, provenance mixing, sediment recycling, hydraulic sorting, authigenesis and intrastratal solution. Several techniques are available to describe a particular aspect of sediment composition, the most powerful being petrography, heavy mineral analysis and whole-rock geochemical analysis. In all cases, data interpretation must take the above processes into account in order to reasonably assess source area composition (e.g. Zuffa *et al.*, 1984; Pettijohn *et al.*, 1987; Ibbeken and Schleyer, 1991; Morton *et al.*, 1991; Johnsson and Basu, 1993; Morton and Hallsworth, 1999; von Eynatten and Weltje, 2004).

Heavy minerals – accessory constituents of arenites, with their densities typically higher than that of quartz – are particularly useful indicators of sedimentary provenance. They are rock-forming to accessory minerals of metamorphic and igneous source rocks liberated and released by source area weathering, and they can be introduced to the sedimentary cycle by reworking from older sediments, as well. More than 50 heavy mineral species have been described (Parfenoff *et al.*, 1970; Boenigk, 1983; Mange and Maurer, 1992). Many of them have very specific and restricted paragenesis, providing source rock information which cannot be acquired by other techniques. Principles and procedures of heavy mineral analyses were extensively

discussed by Morton (1985a), Mange and Maurer (1992) and Mange and Wright (2007).

Conventional heavy mineral data can usually not directly mirror the source rock mineralogy for the reasons noted above, and a reliable comparison of samples in terms of source area signatures becomes difficult. However, data directly connected to the sediment source, essentially unbiased by weathering, hydraulic sorting and intrastratal solution can be obtained. Examination of the optical (e.g. Lihou and Mange-Rajetzky, 1996), chemical (e.g. Mange and Morton, 2007), geochronological (e.g. Fedo *et al.*, 2003) and thermochronological (e.g. Carter, 1999) signatures of single grains for a given heavy mineral species are probably the most powerful. In principle, many techniques already well established in igneous and metamorphic petrology can be adopted for the study of heavy minerals whenever a textural context (such as in garnet-biotite Fe-Mg exchange thermometry, for instance) is not required for the target mineral. Source area characterization can be made with an even higher confidence if two or more of the single-grain attributes are combined (Basu *et al.*, 1998; Dunkl *et al.*, 2001). In the following we briefly review the most important single-grain techniques, many of which have been extensively applied in the present Thesis.

*External zircon morphology:* there is a relationship between the external morphology (relative arrangement of prism and pyramid faces) of zircon crystals and the principal chemical magma type in which they were formed (Pupin, 1980; Benisek and Finger, 1993). Recently, the method has been successfully applied to detrital zircon crystals (Caironi *et al.*, 1996; Schäfer and Dörr, 1997; Dunkl *et al.*, 2001).

*Single-grain geochemistry:* numerous heavy mineral species exhibit a wide range of chemical composition, representing end-member solid solutions. The actual composition and chemical zoning patterns of a detrital grain can depend on the metamorphic grade and/or bulk geochemical composition of the parent rock (e.g. Morton, 1991). Measurements performed with an electron microprobe allow rapid and highly reproducible geochemical analyses and a large throughput of detrital grains. The most rewarding detrital minerals are *garnet* (Morton, 1985b; Haughton and Farrow, 1989), *tourmaline* (Henry and Dutrow, 1992; von Eynatten and Gaupp, 1999), *pyroxene* (Cawood, 1983; Krawinkel *et al.*, 1999) and *blue sodic amphibole* (Mange-Rajetzky and Oberhänsli, 1982; Faupl *et al.*, 2002). Of special importance is *chrome spinel*, the composition of which sensitively indicates parental melt or host peridotite compositions (Irvine, 1965 *et* 1967; Dick and Bullen, 1984; Arai, 1992; Barnes and

Roeder, 2001; Kamenetsky *et al.*, 2001). It provides a clue to the plate tectonic setting of mafic-ultramafic source rocks and can in turn give rise to paleogeographic reconstructions (Poher and Faupl, 1988; Arai and Okada, 1991; Hisada and Arai, 1993; Cookenboo *et al.*, 1997). Trace element data of *rutile*, its growth generally restricted to medium-to-high-grade metamorphic rocks (Force, 1980), have been recently shown to be useful in constraining protolith chemistry and metamorphic grade (Zack *et al.*, 2004a,b; Triebold *et al.*, 2007).

*Zircon fission track thermochronology*: determination of single crystal ages of zircon by fission track (FT) dating (e.g. Naeser, 1979) reflects the cooling ages of the source rocks. The obtained zircon age spectra thus provide a guide to possible source areas, by revealing their different thermal evolution (Hurford *et al.*, 1984; Hurford and Carter, 1991; Brandon and Vance, 1992; Dunkl, 1992; Carter, 1999; Dunkl *et al.*, 2001; Trautwein *et al.*, 2001). Combined with morphological analyses, episodes of volcanic activity can also be identified, in addition to the refinement of the petrology of inferred plutonic rocks (Dunkl, 1992; Dunkl and Nagymarosy, 1992; Trautwein *et al.*, 2001; Dunkl *et al.*, 2001).

*White mica  $^{40}\text{Ar}/^{39}\text{Ar}$  chronology*: Ar/Ar single-grain geochronology of detrital white mica is a potential tool for deciphering orogenic processes in both modern and ancient orogens (e.g., Copeland and Harrison, 1990; Stuart *et al.*, 2001). In combination with FT thermochronology of zircon and apatite, the cooling of source rocks in the temperature interval of approx. 400°C down to ~100°C can be precisely traced. Geochemical analysis of the dated minerals provide further petrogenetic information on the source rocks (von Eynatten and Wijbrans, 2003; Grimmer *et al.*, 2003).

*Zircon U/Pb geochronology*: U/Pb single-grain geochronology of detrital zircon reveals the magmatic and/or high-grade metamorphic age structure of the source units and, with expanding instrument capacities and improving precision, its application has been rapidly increasing in the past years (e.g. Košler *et al.*, 2002; Fedo *et al.*, 2003, Jeffries *et al.*, 2003, Frei and Gerdes, 2008).

*Monazite (Th-U)/Pb geochronology*: Since its advent ca. 20 years ago (Suzuki *et al.*, 1991 and references therein), analytical progress made in the electron microprobe (Th-U)/Pb total chemical dating methodology (Montel *et al.* 1996; Williams *et al.*, 2006, Jercinovic *et al.*, 2008) enables it to become a routine procedure also in sedimentary provenance analysis (e.g. Kusiak *et al.*, 2006). Limitations include the

thermal instability of the epoxy resin used for embedding the detrital grains; this requires using a lower beam current than for polished thin-sections, potentially reducing the precision of the Pb concentration determination.

#### **1.4. Structure of the Thesis**

In the following Chapters 2 to 6, we present the results of a detailed sedimentary provenance study undertaken in Cretaceous to Tertiary basins of the Dinarides. The major objective will be to put new constraints on the orogenic evolution of this integral segment of the European Alpine chain. We follow the approach of in-depth characterizing the detritus derived from major tectonostratigraphic units, focusing on information extracted via the geochemistry, geochronology and fission-track thermochronology of single detrital grains. We will use these results to describe the paleogeology and understand sediment dispersal patterns which are all dependent on the large-scale crustal and surface processes involved in the Alpine orogeny.

Chapter 2 deals with the Latest Jurassic to Cretaceous evolution of the distal continental margin of the Adriatic plate, through the provenance analysis of the Bosnian Flysch. We trace the palaeogeology of obducted ophiolite sequences and their continental basement units which were exhumed and eroded, shedding detritus into a foredeep developed in front of the thrust complex. We address the problem by petrography, whole-rock geochemistry, clay mineralogy, single-grain geochemistry of detrital tourmaline, garnet, rutile and Cr-spinel as well as U/Pb geochronology and FT thermochronology of detrital zircon. New constraints on the depositional age come from carbonate microfacies analysis and calcareous nannoplankton determination.

Chapter 3 focuses on the geochemistry of detrital Cr-spinel from Early Cretaceous clastic basins in the NW Dinarides, characterized by a rather comparable tectonic setting to that of the Bosnian Flysch. The results are discussed together with previous data on heavy mineral assemblages and a model is proposed for the evolution of the basins.

Chapter 4 presents the results from three different geochronometers in detrital minerals, from sediments genetically related to the convergent Neotethyan margin in the Dinarides. Apatite FT, monazite electron microprobe (Th-U)/Pb and zircon LA-

ICPMS U/Pb single-grain ages are consistent and provide evidence for Late Jurassic acid magmatism and explosive volcanism at the Neotethyan supra-subduction zone.

In Chapter 5, we provide new constraints on the Miocene depositional age of flysch deposits in the Outer Dinaride foreland basin, based on calcareous nannofossil age determinations. Non-overlapping taxon ranges suggest extensive sediment reworking in the Outer Dinaride wedge-top basins from Late Cretaceous to Neogene times. Discovery of Neogene nannofossil species suggest that the Middle Eocene planktonic foraminifera, on which the earlier age assignment was based, are most probably in an allochthonous position. The results are in agreement with tectonic data from the region and with previous nannofossil age results, and are hoped to provide a new framework for interpreting heavy mineral data from the dated flysch units.

Chapter 6 is devoted to U/Pb–FT double-dating experiments performed on detrital zircon from the Dinarides. We extract a high-temperature geochronological and a low-temperature thermochronological datum from the same detrital grains. They are integrated using a two-dimensional statistical approach which accounts for the contrasting amounts of single-grain age uncertainties yielded by the both techniques, in order to identify geologically meaningful age clusters. Double dating of zircon yields valuable insights into the underlying U/Pb age structure of the sedimentary source area of the Dinaride sediments and into their subsequent thermal evolution. Source identification is possible with a confidence that can not be achieved by using the two dating techniques separately.

Finally, Chapter 7 summarizes the most important conclusions drawn in the Thesis.

## Provenance of the Bosnian Flysch

*Tamás Mikes, Dominik Christ, Rüdiger Petri, István Dunkl, Dirk Frei, Mária Báldi-Beke, Joachim Reitner, Klaus Wemmer, Hazim Hrvatović and Hilmar von Eynatten*

### Abstract

Sandwiched between the Adriatic Carbonate Platform and the Dinaride Ophiolite Zone, the Bosnian Flysch forms a c. 3000 m thick, intensely folded stack of Upper Jurassic to Cretaceous mixed carbonate and siliciclastic sediments in the Dinarides. New petrographic, heavy mineral, zircon U/Pb and fission-track data as well as biostratigraphic evidence allow us to reconstruct the palaeogeology of the source areas of the Bosnian Flysch basin in late Mesozoic times. Middle Jurassic intraoceanic subduction of the Neotethys was shortly followed by exhumation of the overriding oceanic plate. Trench sedimentation was controlled by a dual sediment supply from the sub-ophiolitic high-grade metamorphic soles and from the distal continental margin of the Adriatic plate. Following obduction onto Adria, from the Jurassic–Cretaceous transition onwards a vast clastic wedge (Vranduk Formation) was developed in front of the leading edge, fed by continental basement units of Adria that experienced Early Cretaceous synsedimentary cooling, by the overlying ophiolitic thrust sheets and by redeposited elements of coeval Urgonian facies reefs grown on the thrust wedge complex. Following mid-Cretaceous deformation and thermal overprint of the Vranduk Formation, the depozone migrated further towards SW and received increasing amounts of redeposited carbonate detritus released from the Adriatic Carbonate Platform margin (Ugar Formation). Subordinate siliciclastic source components indicate changing source rocks on the upper plate, with ophiolites becoming subordinate. The zone of the continental basement previously affected by the Late Jurassic–Early Cretaceous thermal imprint has been removed; instead, the basement mostly supplied detritus with a wide range of pre-Jurassic cooling ages. However, a c. 80 Ma, largely synsedimentary cooling event is also recorded by the Ugar Formation, that contrasts the predominantly Early Cretaceous cooling of the Adriatic basement and suggests, at least locally, a fast exhumation.

## **2.1. Introduction**

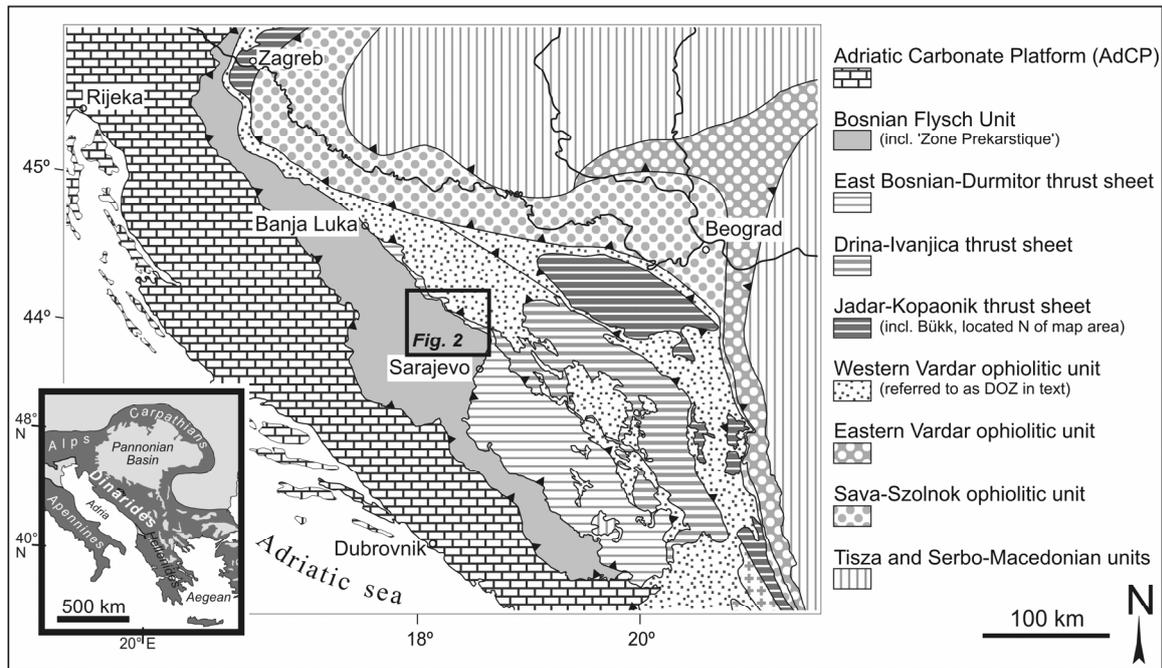

One of the most peculiar tectonostratigraphic units of the Dinaride orogen within the SE European Alpine system is the 'Zone Bosniaque', defined by Aubouin *et al.*, (1970). It is tectonically sandwiched between the most external belt of Dinaride ophiolites in the NE that are floored by continental basement nappes (Aubouin 1973) derived from the Adriatic plate (Schmid *et al.*, 2008), and units of the vast Mesozoic carbonate platform of the Adriatic plate in the SW. The Bosnian Zone mainly comprises thick Late Jurassic to Cretaceous flysch successions and other gravity flow deposits. We will collectively refer to them as Bosnian Flysch hereafter.

The presence of ophiolitic detritus in the Bosnian Flysch had been recognized early on (Blanchet 1966; Blanchet *et al.*, 1969; Charvet 1970; Olujić *et al.*, 1978), yet subsequent tectonic models assessed its importance diversely. Aubouin (1973) suggested that, as a result of Late Jurassic obduction, a foredeep was formed in front of the ophiolite nappes and demonstrated that the lower part of the Bosnian Flysch represents a synorogenic sequence. This view was largely contended by Lawrence *et al.*, (1995), Tari & Pamić (1998), Tari (2002) and Schmid *et al.*, (2008). As a marked contrast, Pamić (1993) and Pamić *et al.*, (1998) interpreted the Bosnian Flysch in terms of a sequence that was deposited on the NE passive margin of Adria; a genetic relationship of the sediments to the Dinaride ophiolites was not part of their models.

In this study a wide range of sedimentary provenance information was acquired to decipher the Late Mesozoic evolution of the source area geology of the Bosnian Flysch. The data were used to assess existing models addressing the geodynamic setting of the flysch. Arenitic samples were analysed for a detailed description of the lithology and age of the source rocks, using heavy mineral signatures and zircon chronology. Clay mineralogical and whole-rock geochemical methods were employed to characterize the provenance of the fine-grained sediments. Our investigations were completed by calcareous nannofossil and carbonate microfacies data, which put additional constraints on the biostratigraphic range.

## 2.2. Tectonic framework

The Bosnian Flysch is a 500 km long belt of Late Jurassic to Cretaceous, mixed siliciclastic-carbonate sequences incorporated into the Dinaride nappe pile (Fig. 1). In the NE, the flysch is tectonically overlain by the East Bosnian–Durmitor thrust sheet

**Fig. 1.** Map showing the major structural units of the Dinarides (after Schmid *et al.*, 2008, slightly modified).

which passively carries Dinaride ophiolite units previously thrust onto it (Schmid *et al.*, 2008; cf. 'Zone Serbe' of Aubouin 1973). The East Bosnian–Durmitor unit wedges out towards the NW, where the Dinaride Ophiolite Zone appears to directly overlie the Bosnian Flysch.

To the SW, the Bosnian Flysch is structurally underlain by the Pre-Karst Subzone and in turn by the Main Karst Zone (Aubouin *et al.*, 1970). The latter largely corresponds to the Adriatic Carbonate Platform (AdCP; defined by Vlahović *et al.*, 2005), the former representing the heteropic, distal slope and basin facies bordering the platform. Overall facies distribution suggests that the AdCP, the largest Mesozoic platform of the Adriatic plate, acted as a palaeotopographic entity during the evolution of the Bosnian Flysch basin (Charvet 1980; Vlahović *et al.*, 2005). It was converted into the tectonic footwall of the Outer Dinaride thrust pile during Tertiary compression (Aubouin *et al.*,

1970; Chorowicz 1977; Charvet 1980; Tari 2002; Mikes *et al.*, 2008a; Schmid *et al.*, 2008).

With respect to the tectonic setting of the ophiolites and other Inner Dinaride structural elements (Fig. 1), we will largely follow the interpretation of a recent kinematic reconstruction made by Schmid *et al.*, (2008). These authors suggest that both belts of Dinaride Triassic-Jurassic oceanic units represent displaced fragments of an initially single zone of Neotethyan ophiolites, which were obducted westwards onto the Adria passive margin in the Late Jurassic. Cretaceous and Tertiary thrusting gave rise to far-travelled thrust sheets composed of continental and ophiolitic series. The orogen-parallel, allochthonous Palaeozoic to Triassic units represent continental basement nappes derived from the distal Adriatic plate, exposed mostly in elongated tectonic windows. This interpretation of Schmid *et al.*, (2008), which is in line with ideas already put forward by, for example, Bernoulli & Laubscher (1972), Charvet (1980), and Gawlick *et al.*, (2008), fundamentally differs from most other models which either propose two Mesozoic oceanic branches separated by a continental microplate (e.g. Dimitrijević & Dimitrijević 1973; Robertson & Karamata 1994; Karamata 2006), or assume that the basement nappes were derived from the European margin by out-of-sequence thrusting (Pamić *et al.*, 1998; Hrvatović & Pamić 2005).

The Jurassic ophiolites structurally above the Bosnian Flysch were described as the Dinaride Ophiolite Zone (DOZ; Dimitrijević & Dimitrijević 1973; Babić *et al.*, 2002; Pamić *et al.*, 2002), Central Dinaride Ophiolite Belt (CDOB; Lugović *et al.*, 1991) or as the zone constituting the most externally transported thrust sheets of the Western Vardar ophiolites (Schmid *et al.*, 2008), or as forming part of the Serb, Golija and Drinjača Zones according to Charvet (1978, 1980). These ophiolites, from now on referred to as Dinaride Ophiolite Zone (DOZ) in this paper, were recently argued to have been formed in an intraoceanic supra-subduction zone setting (Bazylev *et al.*, 2006; Smith 2006; Lugović *et al.*, 2006, 2007). K/Ar, Ar/Ar and Sm/Nd age data of sub-ophiolitic metamorphic soles from Dinaride and Albanian ophiolites range between 178 and 161 Ma, indicating Middle Jurassic intraoceanic thrusting (e.g. Okrusch *et al.*, 1978; Parlak & Delaloye 1999; Dimo-Lahitte *et al.*, 2001; Olker *et al.*, 2001; Smith 2006 and references therein). Petrology of these soles indicates both basaltic (e.g. Pamić *et al.*, 1973; Majer *et al.*, 2003; Operta *et al.*, 2003; Schuster *et al.*, 2007) and sedimentary protoliths (e.g. Karamata *et al.*, 1970; Schreyer & Abraham 1977; Okrusch *et al.*, 1978; Carosi *et al.*, 1996).

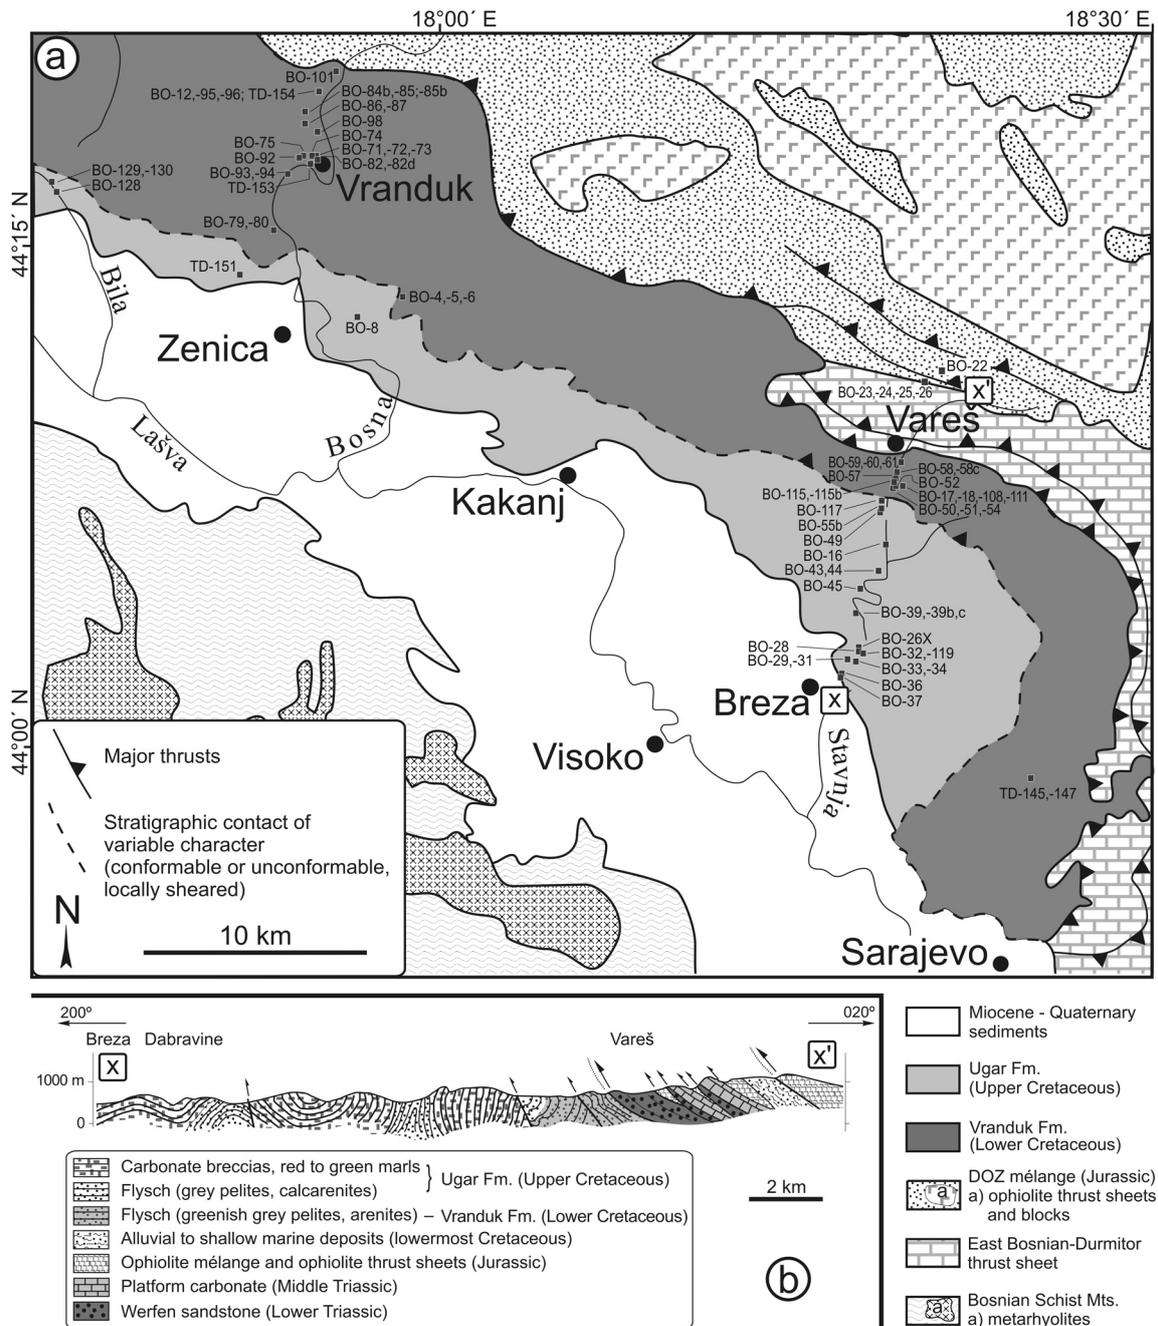

Ophiolite obduction onto the Adriatic margin was completed by Late Jurassic. Deep crustal levels of both the oceanic plate and the Adriatic margin suffered largely coeval (Okrusch *et al.*, 1978; Majer & Lugović 1991; Milovanović *et al.*, 1995; Most 2003) HP/LT metamorphic overprint as is indicated by blueschist facies rocks occasionally found among the metapelitic to metabasic rocks on both the upper and lower plates (Majer 1956; Charvet 1978; Djoković 1985; Majer & Lugović 1991; Mutić & Dmitrović 1991; Milovanović *et al.*, 1995; Belak & Tibljaš 1998; Most 2003). Stratigraphic constraints on the timing of obduction are provided by the Tithonian-Berriasian age of the oldest sedimentary deposits sealing the ophiolites, consisting of alluvial coarse-grained siliciclastic strata and shallow marine carbonates interfingering with them (Blanchet *et al.*, 1970; Charvet & Termier 1971; Charvet 1973, 1978; Neubauer *et al.*, 2003). This unconformity is, however, a diachronous surface; the overlying sediments become progressively younger towards the more internal domains of the DOZ, attaining Cenomanian age at the NE border of the DOZ. These observations indicate an overall transgressive trend from the Tithonian/Berriasian to the Cenomanian, perpendicular to the strike of the orogen (Charvet 1978, 1980).

The continental units in the Dinarides are considered to represent major, Adriatic-derived thrust sheets (see discussion in Schmid *et al.*, 2008). The East Bosnian–Durmitor Unit, together with the Drina–Ivanjica, Jadar, Kopaonik, Medvednica and the displaced Bükk units, are dominated by Palaeozoic to Triassic (meta-) sediments (Podubsky 1970; Rampoux 1970; Djoković 1985; Dimitrijević 1997; Pamić & Jurković 2002), which underwent regional thermal overprint ranging up to anchi- to epizonal conditions. Early Cretaceous cooling is widely demonstrated by K/Ar age data yielding  $135 \pm 11$  Ma in the Drina–Ivanjica Unit (Milovanović 1984),  $118 \pm 4$  Ma (Belak *et al.*, 1995) as well as  $107 \pm 8$  Ma (Judik *et al.*, 2006) in the metapelites of the Medvednica Unit, as well as various ages from 133 to 98 Ma in the Bükk Unit, in agreement with zircon FT age data in this latter tectonic unit (see details in Árkai *et al.*, 1995). Ar/Ar age spectra of detrital white mica from the Ljig Flysch (in the External Vardar Subzone *sensu* Dimitrijević 1997; covering the Jadar–Kopaonik thrust sheet according to Schmid *et al.*, 2008) contain a 110 Ma age component (Ilić *et al.*, 2005). Finally, the Palaeozoic of the Bosnian Schist Mts., considered to represent the basement of the Pre-Karst Subzone (Aubouin *et al.*, 1970; Schmid *et al.*, 2008) also records this thermal event (K/Ar ages from 121 to 92 Ma) prior to its main phase of Paleogene cooling (Pamić *et al.*, 2004).

### **2.3. Geological setting of the Bosnian Flysch**

The Bosnian Flysch forms a rather uniform belt (Figs. 1 & 2): formations comparable to those investigated by this study crop out to the NW of Central Bosnia, in the Zrinska Gora and in the Slovenian Trough (Aubouin *et al.*, 1970; Cousin 1972; Babić & upanič 1976; Bušer 1987; Hrvatović 1999; Rožič 2005), and in form of the so-called Durmitor Flysch in the SE (Dimitrijević & Dimitrijević 1968; Blanchet *et al.*, 1969; Rampnoux 1969; Aubouin *et al.*, 1970). Two distinct lithostratigraphic units characterize the Bosnian Flysch (Olujić 1978; Hrvatović 1999). The lower, turbiditic to monotonous pelagic series is more than 1000 m thick, and is dominantly composed of siliciclastic sandstones, marls, shales, cherty micritic limestones, and grey radiolarites (Vranduk Formation). It stretches along the NE side of the flysch zone (Fig. 2), i.e. nearer to the overriding nappes and hence more proximal to the source.

The upper succession (Ugar Formation; Fig. 2) occurs SW of the Vranduk Formation and is carbonate-dominated, comprising thin-bedded marly to micritic limestones and red or grey shales, intercalated with calcareous turbidites, and finally, coarse catastrophic carbonate mass flow deposits, several tens of metres thick, in the upper part of the sequence. These carbonate debrites contain large Scaglia Rossa clasts up to several metres across, exhibiting internal slump folds. Stratigraphic thickness of the Ugar Formation exceeds 2000 m (Hrvatović 1999). Palaeotransport indicators suggest S- to SE-directed shedding for the Vranduk Formation and SE to NE-directed transport for the Ugar Formation (Dimitrijević & Dimitrijević 1968; Hrvatović 1999). The described formations largely correspond to the sediments of the 'flysch bosniaque interne' of Charvet (1978). Calpionellids and foraminifera suggest that the age of the Vranduk Formation in Central Bosnia ranges mostly from the Tithonian to the Berriasian-Valanginian, whereas that of the Ugar Formation ranges from Late Albian to Maastichtian, and locally, into the Paleocene (Cadet 1968; Dimitrijević & Dimitrijević 1968; Charvet 1978; Olujić *et al.*, 1978). To the N (near Banja Luka), and to the S of Central Bosnia (in the Durmitor Flysch), more complete profiles have been observed in the Vranduk Formation, ranging from the Berriasian up to the Cenomanian (Cadet 1968; Cadet & Sigal 1969; Rampnoux 1969; Blanchet 1970; Charvet 1978). It was suggested that the two formations are separated by an angular unconformity (Dimitrijević 1982 p.14; Csontos *et al.*, 2003; Schmid *et al.*, 2008 p.25); however continuous Cretaceous successions are also preserved in parts of the basin (Dimitrijević 1982 p.14; Barremian

**Fig. 2.** (a) Geological sketch map of Central Bosnia showing sampling locations in the Stavnja Valley (x-x'), in the Bosna Valley and other localities. Map compiled using the 1:100,000 sheets of the Basic Geological Map of Yugoslavia and after Charvet (1978). Refer to Appendix 2-1 for sampling locations off the map. (b) Schematic profile across the Bosnian Unit and the East Bosnian-Durmitor thrust sheet in the Stavnja Valley (after Charvet 1978) illustrating the major tectonostratigraphy of the studied area.

to Campanian succession of Blanchet 1970). The onset of flysch deposition is usually not well constrained because the Vranduk Formation may be either sheared off its basement, or may consist of debrites at its base, lacking direct evidence regarding their sedimentation age. However, most such fragments are Tithonian to lowermost Cretaceous carbonate lithoclasts, and Blanchet *et al.*, (1969) described a profile in which a clastic succession overlies a condensed Upper Triassic to Jurassic sequence. In this profile, red radiolarites are capped by a debrite horizon containing clasts of radiolarite, mafic volcanics and Upper Jurassic marl, in turn overlain by pelagic calcareous marl with Berriasian calpionellids. Recently, Djerić *et al.*, (2007) reported an Oxfordian radiolarite intercalation from the Vranduk Formation. In summary, a transition from pelagic to clastic-dominated deposition in the internal domains of the 'Zone Bosniaque' most likely occurred during the latest Jurassic.

The style of tectonic deformation is different in both units. The Vranduk Formation exhibits tight to isoclinal, metre- to map-scale SW-vergent folds, whereas overprinting box-, mushroom- and kink folds are often observed at outcrop scale. The Ugar Formation, in contrast, is only gently folded. These strata typically exhibit open, map-scale SW-vergent folds. Observed differences in deformation style between the two units may result from the combination of a polyphase folding history (L. Csontos and S. M. Schmid, pers. comm.) and the high competence contrast between the massive Ugar carbonate debrite beds and the siliciclastic-dominated, thinner-bedded Vranduk strata.

#### **2.4. Sampling procedure and analytical methods**

Sampling of the flysch lithologies was performed in two sections cutting perpendicularly across the strike of the nappe pile along the Bosna and Stavnja river valleys (Fig. 2). Additional samples were taken from other parts of the basin (Appendix T2-1). Sampling was completed by sandstone blocks included in the DOZ mélange in the Stavnja Valley profile and further to the NW in the Borja Mountains. For the purpose of this provenance study, the first of its kind performed in the Bosnian Flysch basin, single outcrops were chosen with suitable and representative lithologies. We are aware that this does not replace future detailed sectionwise work.

For petrography, whole-rock geochemistry and accessory mineral separation, fine- to medium-grained sandstones were selected. Coarse-grained sandstones and breccias

were selected for microfacies analysis. For clay mineral analysis and calcareous nannofossil biostratigraphy, pelitic sediments (shale, marl) were sampled, and their aliquots were also used for whole-rock geochemistry. Weathered parts were removed prior to further sample preparation.

#### *2.4.1. Calcareous nannofossils*

Standard smear slides were prepared from 4 suitable pelite samples in the Vranduk Formation and 12 in the Ugar Formation, without chemical treatment or centrifugation. Slides were examined under the microscope in normal and cross-polarized lights at  $\times 1250$  magnification. Stratigraphic evaluation was performed individually for each sample, without using any additional geological information. Cretaceous species ranges were taken from Perch-Nielsen (1985) and Burnett (1998). Taxonomic work followed Bown & Young (1997), Burnett (1998) and Bown *et al.*, (1998). For the list of identified taxa, along with their stratigraphic ranges, refer to Appendix 2-2.

#### *2.4.2. Accessory mineral separation*

About 4-5 kg of fine- to medium-grained sandstone were crushed, dry sieved (0.250 mm), then both fractions were treated individually. For single-crystal geochemistry and chronology, the heavy mineral fraction in the  $<0.250$  mm share was pre-concentrated using a Wilfley-table. Carbonate was removed using a 5% cold acetic acid treatment. Heavy minerals were separated with a hot LST Fastfloat<sup>®</sup> heavy liquid ( $\rho=2.85$  gcm<sup>-3</sup>), then embedded in epoxy, polished and carbon-coated for microprobe analysis. For light microscopy and quantitative heavy mineral analysis, the  $>0.250$  mm share was first disintegrated using 5% acetic acid until carbonate was removed, and then wet sieved to 0.063-0.125 mm. The heavy mineral fraction was separated in the same way as described above, embedded in optical resin and examined under a polarisation microscope.

### *2.4.3. Whole rock chemistry*

Whole rock geochemistry was performed on the same sample set also used for heavy mineral analysis, and was completed with additional coarse-grained sandstone and pelitic samples. About 100 g of rock chips, devoid of cracks and calcite veins, were crushed in polyethylene bags to avoid metal contamination, and powdered in an agate ball mill. Powders were dried at 105 °C, and fused to glass discs using Merck Spectromelt A12 fluxant. Major and trace element concentrations were determined by X-ray fluorescence spectrometry (XRF) using a PANalytical Axios-Advanced instrument at the Geoscience Center Göttingen. Trace element concentrations have 1-2% relative precision. Loss on ignition values (LOI) were determined after overnight heating of two aliquots per sample at 1100 °C. Whole-rock geochemical results are summarized in Appendix 2-4.

### *2.4.4. Clay mineralogy*

The <2 µm and <0.2 µm grain size fractions from gently crushed shale and marl samples were separated by gravity settling using Atterberg cylinder, centrifugation and filtration. X-ray diffraction analyses were performed on oriented and non-oriented samples; each sample was analysed in duplicate. Both glycolated and air-dried samples were scanned from 4° 2θ to 70° 2θ for phase identification using the peak heights as a semi-quantitative estimate of phase abundance, and from 7° 2θ to 10° 2θ for illite crystallinity (=Kübler Index: Kübler 1967; Frey 1987). Appendix 2-1 lists the analysed samples. Refer to Petri (2007) for further details.

### *2.4.5. Mineral chemistry*

Chemical compositions of detrital Cr-spinel, tourmaline, garnet and rutile were determined by a JEOL 8900RL electron microprobe, operated in WDS mode at the Geoscience Center Göttingen. Analytical conditions are given in Appendix 2-3; the results of single-grain analyses are listed in Appendices 2-5 to 2-8.

#### 2.4.6. U/Pb geochronology

U/Pb ages on single zircon grains were obtained by laser ablation ICP-MS from polished mineral mounts, employing a Thermo Element 2 sector-field instrument attached to a Nd:YAG ultraviolet laser system ( $\lambda=213\text{nm}$ ; New Wave Research) at GEUS, Copenhagen (Frei & Gerdes, submitted). 90 to 120 crystals were analysed per sample. Off-line reduction of raw data was performed using PEPITA software (Dunkl *et al.*, 2007). Single-crystal ages were calculated by Isoplot 3.50 (Ludwig 2003) and age population distributions were obtained using AGEDISPLAY (Sircombe 2004) considering analyses with their propagated  $2\sigma$  standard errors only within  $\pm 14\%$  of concordance. For the analytical parameters and the single-crystal U/Pb results, refer to Appendices 2-3 & 2-9, respectively.

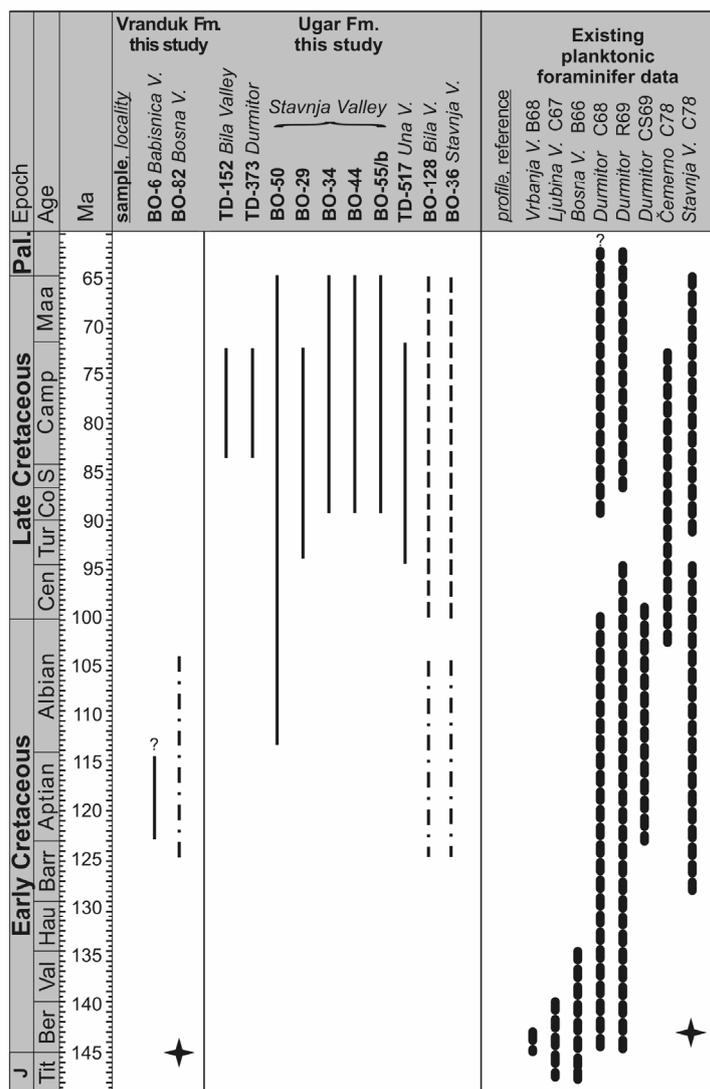

#### 2.4.7. Zircon fission-track analysis

The concentrated zircon crystals were embedded in PFA teflon with two mounts made from each sample. Spontaneous tracks were revealed by etching in NaOH-KOH eutectic melt at  $225^\circ\text{C}$  (Gleadow *et al.*, 1976) for 23 to 74 hours. Neutron irradiations were performed at the research reactor of Oregon State University. The external detector method was used (Gleadow 1981) and, after irradiation, the induced fission tracks in the mica detectors were revealed by etching in 40% HF for 30 min. Track counts were made with a Zeiss Axioskop microscope at  $\times 1000$  magnification combined with a computer-controlled stage system (Dumitru 1993). The FT ages were determined by the zeta method (Hurford & Green 1983) using the age standards listed in Hurford (1998), and visualized using Trackkey (Dunkl 2002). The results will be discussed using Fig. 12, details are given in Appendix 2-10.

## 2.5. Results

### 2.5.1. New constraints on depositional age

Nannofossil assemblages from the Bosnian Flysch, described in this paper for the first time, are scarce; dissolution and over-calcification are rather common. However, their preservation proved sufficient for the age determination. Fig. 3 illustrates the most probable nannofossil ages obtained for each sample, and Appendix 2-2 contains the distribution of the nannofossil species in all Bosnian Flysch samples from this study.

Sample BO-6, taken in the Vranduk Formation, adjacent to the Bosna River profile, contains a diverse Early Cretaceous assemblage with *Braarudosphaera africana* (Aptian to Cenomanian), suggesting that the age of this sample cannot be older than Aptian (Fig. 3; Appendix 2-2). Two more samples from the Vranduk Formation show only unspecific Late Jurassic to Late Cretaceous taxa.

Most samples from the Ugar Formation in the Stavnja River profile and in other localities (Bila Valley, Una Valley and the Durmitor Flysch near Mokro) contain Late Cretaceous nannofossils (Fig. 3). In the Stavnja River

**Fig. 3.** New fossil age data from the Vranduk and Ugar Fm samples (left) and comparison with published biostratigraphic ranges of other profiles (right). Solid black lines: stratigraphic position of zonal marker nannofossil species. Dot-dashed lines: probable age range of derived Urgonian facies fossils and lithoclasts in the sampled sediment. Dashed lines: Stratigraphic range of planktonic foraminifera. Star indicates age of calpionellid-bearing lithoclasts. Individual samples are arranged in columns, and the bars in each column represent the ranges of zonal markers found in that sample. Samples containing exclusively persistent taxa living through several epochs were not plotted. Refer to Table T2 (electronic supplement) for more details. Upper age limit of sample BO-6 is constrained by the mid-Cretaceous thermal overprint affecting the Vranduk Formation (Petri 2007). Thick dotted lines on the right: total, continuous stratigraphic interval in a profile established mostly using planktonic foraminifera by earlier workers. Literature source abbreviations: B68 – Blanchet (1968); C67 – Charvet (1967); B66 – Blanchet (1966); C68 – Cadet (1968); R69 – Rampnoux (1969); CS69 – Cadet and Sigal (1969); C78 – Charvet (1978).

profile, they suggest depositional ages ranging from the Coniacian to the Maastrichtian, which agrees well with the Albian/Cenomanian to Maastrichtian age range established by means of planktonic foraminifera (Charvet 1978). Individual samples collected in the Bila Valley and in the Durmitor Flysch yield Campanian age, and a Turonian to Campanian age was obtained in the Una Valley (N Bosnia). The latter nannofossil ages likewise support results based on planktonic foraminifera in the Durmitor Flysch (e.g. Cadet 1968; Rampnoux 1970) and in N Bosnia (Blanchet 1970). Additional constraints on the maximum depositional age are provided by benthic fossils and datable carbonate clasts. They occur in calcilithites and polymict breccias throughout the Vranduk Formation, and include isolated tests of orbitolinids (*Iraqia simplex*, *Textularia* sp., *Mesorbitolina* sp.) and rudist fragments (hippuritids, requinids, radiolitids). Peloidal biomicrite intraclasts with nebulous texture are also common. These bio- and intraclasts originate from different habitats in a typical Urganian facies carbonate platform, which existed only from the Late Barremian onwards. Figs. 4i-j illustrate the most frequent types of clasts with Urganian facies. Calpionellid-bearing lithoclasts also occur in the Vranduk Formation and are Late Tithonian to Early Berriasian in age based on *Calpionella alpina* (J. Haas, pers. comm.). This may indicate intrabasinal redeposition of latest Jurassic to earliest Cretaceous pelagic sediments. In the Ugar Formation, redeposited Urganian platform members are also common. However, orbitolinids are more abundant and, as a distinctive feature, there is a lack of quartz in their agglutinated tests (Figs. 4b & 4f). Instead, carbonate particles or Rhaxella spicules are incorporated. These contrasting types of orbitolinid tests may indicate that the Urganian facies clasts in the Ugar and Vranduk formations were derived from different carbonate platform habitats; their sea floor sediments being either "clean" lime mud or slightly contaminated by siliciclastics.

In the Ugar Formation, the dark, brown matrix around the Early Cretaceous fragments contains planktonic foraminifera (*Rotalipora appenninica*, Heterohelicidae, Globotruncanidae, Hedbergellidae and Pitonellidae; Fig. 4c shows an example), which collectively indicate that the Cenomanian most probably represents a maximum depositional age for the Ugar Formation in the Stavnja Valley (Fig. 3).

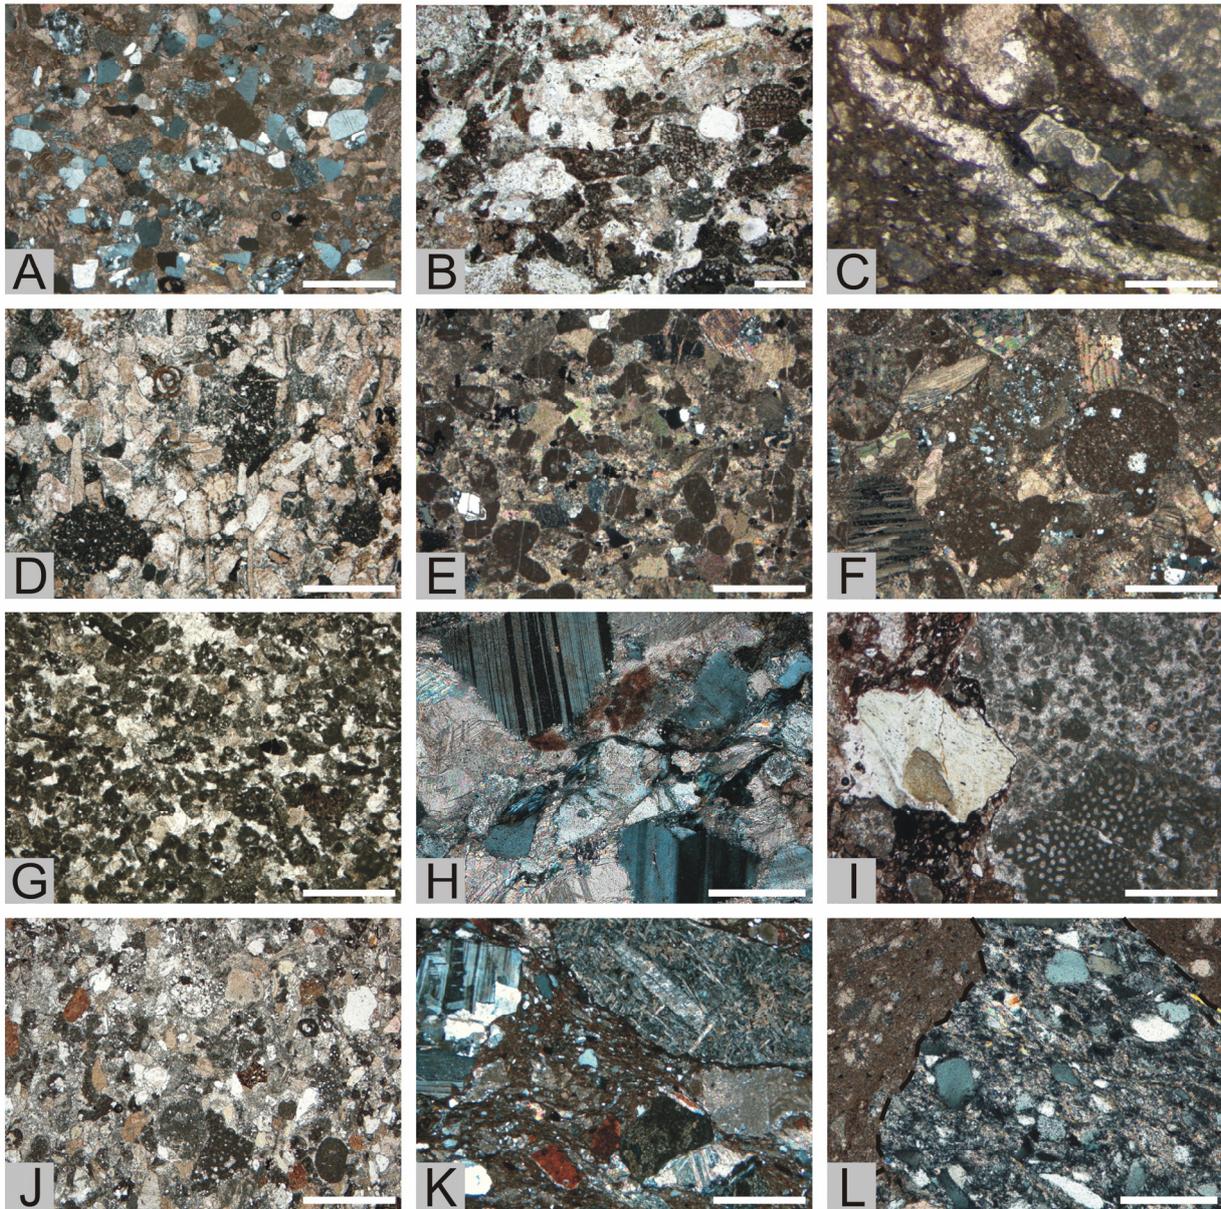

### 2.5.2. Petrography

The most common rock types among the sandstone blocks found in the DOZ mélange are litharenites. In contrast, the Vranduk and Ugar formations are built up of litharenites (including calcilithites), shales and marls. The coarse-grained lithologies greatly differ within the two flysch formations: poorly sorted polymict breccias occur in the Vranduk Formation, whereas in the Ugar Formation breccias are dominated by carbonate clasts. The main petrographic characteristics of sandstones and breccias in the DOZ mélange and the two Bosnian flysch formations are briefly described below.

*DOZ mélange:* The samples comprise poorly sorted litharenites to sublitharenites with angular mono- and polycrystalline quartz grains, plagioclase and K-feldspar, and lithoclasts of mafic volcanic rocks and serpentinite, as well as quartz arenite, quartzose siltstone, shale and phyllite. Carbonate framework grains were not observed.

*Vranduk Formation:* Litharenites to lithic wackes are occasionally composed of up to 40% carbonate grains. Sublitharenites, greywackes, calcarenites and pelagic biomicrites are less frequent. Major framework components include angular monocrystalline quartz, plagioclase (often with dense lamellae of polysynthetic twinning), chert, mafic volcanic lithoclasts (of variolitic to subophitic texture) and serpentinite. In addition, chlorite flakes and Cr-spinel grains often occur. Carbonate grains include litho- or intraclasts (mainly lime mudstones), peloids, rudist fragments and orbitolinids. In the Bosna Valley profile, reddish radiolarite fragments commonly occur, the radiolaria occasionally being calcified. Other framework grains, such as potassium feldspar, polycrystalline quartz, both foliated and non-foliated quartz-mica aggregates, amphibolite, "granitoid" lithoclasts (quartz-feldspar aggregates), quartz arenite, quartzose siltstone and shale, are subordinate.

*Ugar Formation:* Calcarenites and carbonate breccias with variable amounts (0 to 50%) of siliciclastic grains are the typical lithologies; greywackes are rare. Framework components commonly include carbonate clasts (lime mudstone/wackestone litho- or intraclasts, peloids), rudist fragments and orbitolinids as well as angular monocrystalline quartz. Less frequent is polycrystalline quartz, whereas feldspar, quartz-mica aggregates, mafic volcanic lithoclasts and Cr-spinel grains were observed in a few samples in subordinate amounts only.

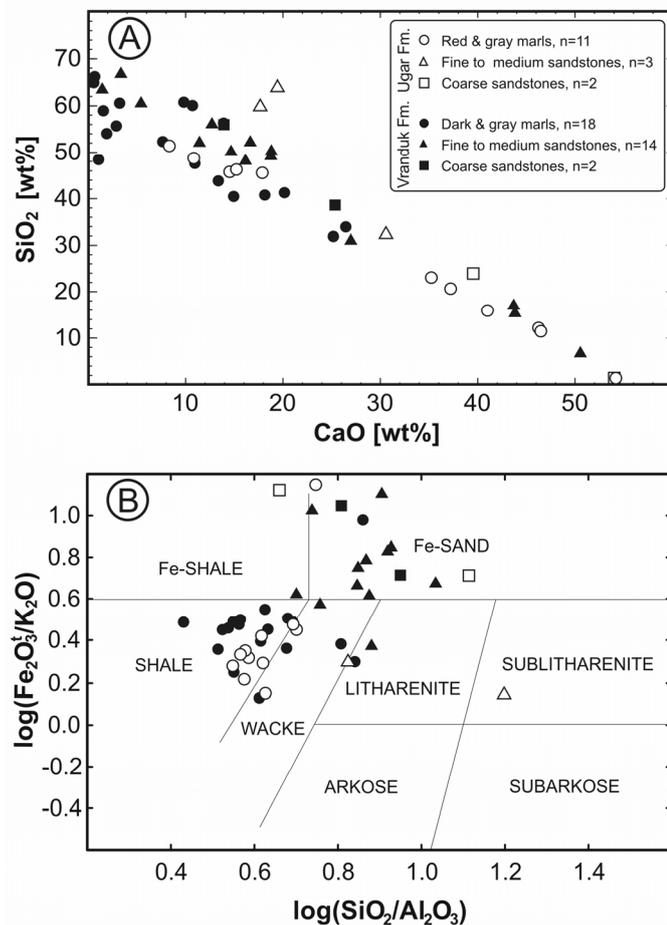

**Fig. 4.** Microphotographs of characteristic sandstone and breccia varieties in the Ugar Formation (a-f) and Vranduk Formation (g-l) of the Bosnian Flysch. +N: crossed polarizers. Scale bar is usually 1 mm; for (c), (h) and (l) it is 250  $\mu\text{m}$ . (a) Calcareous litharenite with mono- and polycrystalline quartz, chert, micritic carbonate rock fragments and bioclasts, +N, sample BO-31, (b) calcarenite with orbitolinids, BO-18, (c) bicarinate *Globotruncana* sp. indicative of a Senonian age, in the red pelitic matrix of a matrix-supported carbonate breccia, BO-36, (d) calcarenite with bioclasts and red biomicrite rock fragments, BO-129, (e) calcarenite with peloids, bioclasts, chert and monocrystalline quartz, +N, BO-5, (f) calcarenite with orbitolinid and rudistid bioclasts, +N, BO-51, (g) calcarenite (pelsparite) with chert and Cr-spinel grains, BO-85/b, (h) grains of plagioclase feldspar and quartz in calcareous litharenite, +N, BO-75, (i) carbonate rock fragment (pelbiosparite) and chlorite flake in polymict breccia, BO-82/2, (j) calcareous litharenite with quartz, chert, radiolarite, carbonate rock fragments, orbitolinid and rudistid bioclasts, TD-153, (k) plagioclase, mafic volcanic lithoclast of intersertal texture, serpentinite and radiolarite in polymict breccia +N, BO-82/6, (l), sublitharenite rock fragment in red finer-grained matrix, +N, TD-145.

Many samples in the Vranduk and Ugar formations show characteristic diagenetic features. Replacement of chert and radiolarite lithoclasts and plagioclase by calcite patches or rhombohedra is common. Calcite often replaces clayey sandstone matrix, in addition to abundant calcite veinlets crosscutting the texture. Small (80-160  $\mu\text{m}$ ), euhedral albite crystals may occur in carbonate-dominated arenites. There, they replace micritic carbonate, especially peloids and ooids.

### 2.5.3. Whole-rock geochemistry

The concentrations of major and several trace elements of pelites and arenites from both flysch formations are summarized in Appendix 2-4. In the sample set a strong negative correlation appears between  $\text{SiO}_2$  and  $\text{CaO}$ , with  $\text{SiO}_2$  concentrations varying between 1.6 and 77.0 wt% and  $\text{CaO}$  ranging from 0.5 to 54.1 wt% (Fig. 5a). This trend is accompanied by a likewise strong positive correlation between  $\text{CaO}$  and LOI, indicating that  $\text{CaO}$  is almost entirely carbonate-bound. Therefore, a continuous mixing trend can be established from the Vranduk to the Ugar formations, where the siliclastic proportions are diluted by additional carbonate to various degrees. A slight deviation from this trend is mostly related to pelitic samples having higher Al-proportions in the silicate fraction.

**Fig. 5.** Major element geochemistry of the Bosnian Flysch sediments. (a)  $\text{CaO}$ – $\text{SiO}_2$  plot showing the generally higher carbonate contents of the Ugar Formation samples in comparison to the Vranduk Formation (b) Classification of the flysch sandstones based on the ratios of  $\text{SiO}_2/\text{Al}_2\text{O}_3$  vs.  $\text{Fe}_2\text{O}_3^t/\text{K}_2\text{O}$  (Herron 1988).

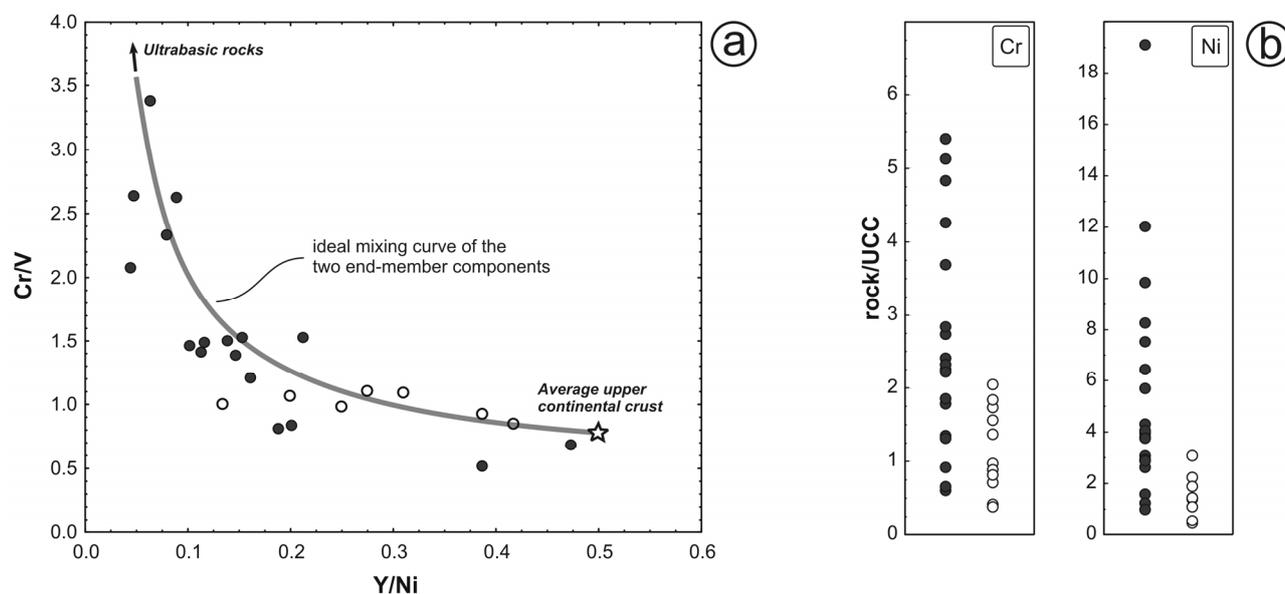

Our data show a conspicuous stratigraphic control on this mixing trend, with the Vranduk Formation being richer in siliciclastic material, whereas in the Ugar Formation the carbonate proportion increases up to almost those of pure calcarenites. However, as is evident from Fig. 5a, the transition is continuous with minor overlap, and shows no abrupt jump in carbonate content between the Vranduk and Ugar formations.

Fig. 5b shows the results of the major element discrimination procedure based on Herron (1988). Most pelites fall into the field of shale, with no pelite sample reaching the Fe-shale field. By contrast, both the coarse and the fine- to medium-grained sandstones have mostly Fe-sand compositions. The reason for this behaviour is probably not only related to Fe, as most variation in analyses of carbonate-corrected  $\text{Fe}_2\text{O}_3$  occurs in a limited range of 4 to 8 wt%; this is only slightly above the normal range for lithic arenites and greywackes from active continental margin settings (Pettijohn *et al.*, 1987) and seems largely unrelated to grain-size. Rather, the tendency of  $\text{K}_2\text{O}$  to be enriched in pelites (2 to 3.5 wt%) relative to the sandstones, which show low concentrations (0.2 to 1.5 wt%) when compared to average lithic arenites and greywackes (Fig. 5b), could account for the high  $\text{Fe}_2\text{O}_3/\text{K}_2\text{O}$  ratios of the sandstones.

Selected provenance-sensitive trace elements of the pelitic samples are displayed in the Cr/V vs. Y/Ni plot (Fig. 6a; McLennan *et al.*, 1993) in order to reveal the nature of the source lithologies. Cr/V ratios range from ~0.5 to 3.4 and thus largely exceed average upper continental crust (UCC; according to McLennan 2001), whereas Y/Ni ratios are lower compared to UCC. For the sake of comparison, a mixing curve was also constructed, using the composition of the UCC and that of ultramafic rocks as end-members (Fig. 6a). The majority of the samples plots close to this mixing curve, which provides evidence for the simultaneous erosion of ultramafic lithologies and felsic rocks. The proportion of mafic and/or ultramafic source rocks in most Vranduk samples is distinctly higher compared to the Ugar Formation. UCC-normalized, carbonate-corrected concentrations of Cr and Ni in shales and marls are in agreement with this observation (Fig. 6b). Ni, for example, is up to 10 times enriched in the Vranduk Formation (two more samples have even higher enrichment factors of 12 and 19). Contrary to this, the Ugar samples scatter around the UCC values, with the enrichment factors of Ni ranging between 0.4 and 3 only.

Cr/Ni ratios of the arenitic samples do not exceed (with one exception in Ugar Formation) the Cr/Ni values for ultramafic (2.0) and mafic rocks (5.2) of the Dinarides (Lugović *et al.*, 1991; Robertson & Karamata 1994; Pamić *et al.*, 2002). This indicates

that sediment recycling and, consequently, Cr-spinel concentration is not a significant process in forming these sandstones (von Eynatten 2003). Similarly, Zr/Sc ratios (McLennan *et al.*, 1993) give no evidence for significant zircon concentration.

**Fig. 6.** Trace element geochemistry of the Vranduk and Ugar formations. Only pelitic samples are plotted. Filled and open circles indicate Vranduk and Ugar samples, respectively. (a) Cr/V vs. Y/Ni ratio-ratio plot (McLennan *et al.*, 1993). Calculated mixing line uses ultrabasic (Cr/V=40; Y/Ni~0.0003 – Turekian and Wedepohl 1961) and average upper continental crust (UCC) compositions (Cr/V=0.775; Y/Ni=0.5 – McLennan 2001) as end-members. Star refers to UCC composition. Four Ugar Formation samples had Y and/or Ni concentrations below instrumental detection limit and are excluded from the plot. (b) Carbonate-corrected, UCC-normalized values of Cr and Ni.

#### 2.5.4. Clay mineralogy

Chlorite and illite are the dominant clay-sized minerals in pelites from all units examined. In addition, kaolinite in the Ugar Formation, and serpentine in the DOZ mélange matrix, amount to *c.* 10% of the entire clay mineral assemblages. Kaolinite and serpentine were not detected in the Vranduk Formation pelites. Smectite was detected in several Vranduk samples (refer to Petri 2007 for details); the proportion of smectite in the illite/smectite mixed layer structures is usually below 10% in both the <2 $\mu$ m and <0.2 $\mu$ m size fractions.

In the Vranduk Formation, the Kübler Index (KI) of the  $<0.2\mu\text{m}$  size fractions ranges between  $0.40 \Delta^{\circ}2\Theta$  and  $0.98 \Delta^{\circ}2\Theta$ . In the  $<2\mu\text{m}$  size fractions of the same samples the KI values are consistently lower, varying between  $0.24 \Delta^{\circ}2\Theta$  and  $0.63 \Delta^{\circ}2\Theta$ . These inconsistencies probably indicate the disturbing effects of detrital micas in the  $<2\mu\text{m}$  fraction. The KI data, along with the presence of kaolinite, suggest that both the Vranduk and the Ugar formations experienced only diagenetic overprint. No obvious trend was revealed by the regional distribution of these data.

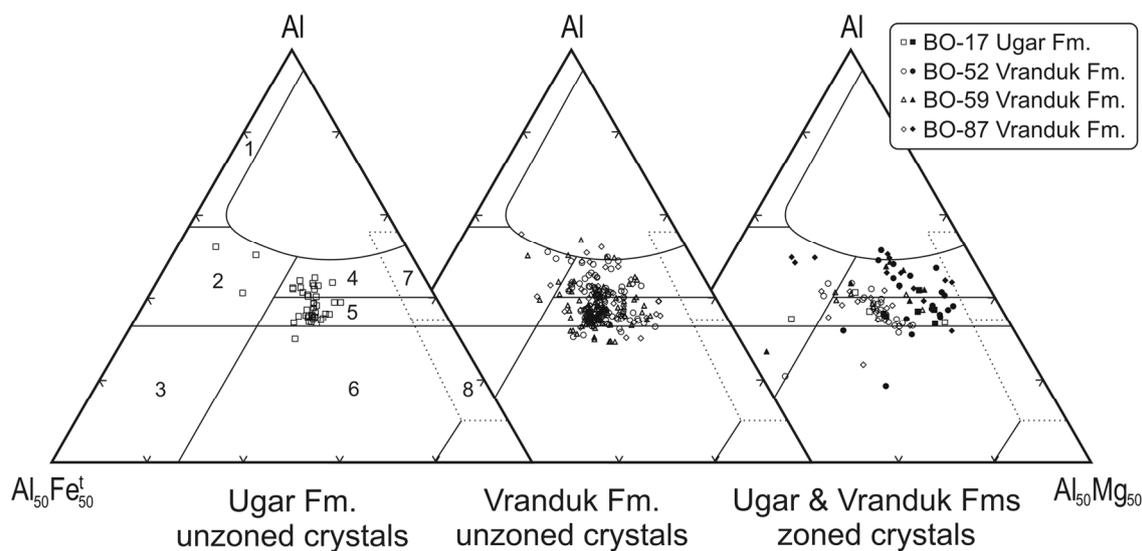

#### 2.5.5. Heavy mineral analysis

The heavy mineral spectra of the Bosnian Flysch are overall dominated by Cr-spinel, especially in the Vranduk Formation. Further species include zircon, rutile, garnet, tourmaline, and lesser amounts of apatite, titanite and monazite (Table 1). In the DOZ mélange, however, Cr-spinel is not predominant, tourmaline and monazite are even absent. The main constituents of the heavy mineral spectra in the DOZ mélange are garnet and zircon, chloritoid, kyanite, clinozoisite, and epidote. Epidote is locally also found in the Vranduk Formation (Table 1). The Ugar Formation differs from the Vranduk Formation by its subordinate garnet content, lower average Cr-spinel concentrations, and the absence of epidote (Table 1). Whereas a significant proportion of zircon in the Vranduk Formation is euhedral with sharp crystal edges, zircons of the Ugar Formation are typically subhedral to rounded, indicating a metapelitic or a mature sedimentary source. Chemical compositions of selected heavy mineral species were determined by electron microprobe to characterize their source in more detail.

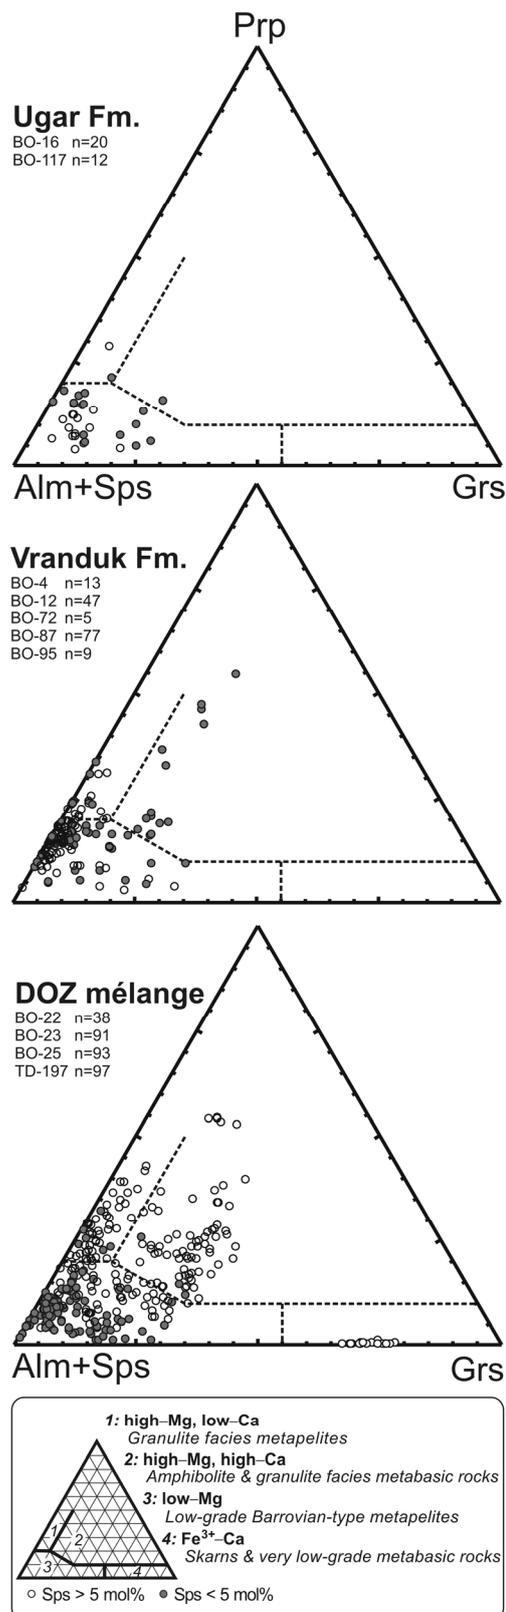

*Tourmaline:* Nearly all crystals are derived from metapelitic sources and have largely similar compositions in the Vranduk and Ugar formations (Fig. 7). The proportion of magmatic-derived tourmaline crystals is rather small. Well-preserved growth zoning and compositional polarity, as revealed by back-scattered electron images, correspond mainly to a Barrovian type, lower-grade metamorphic source (cf. Henry & Dutrow 1996). If outer and inner metamorphic zone compositions are plotted separately (Fig. 7), a general enrichment in Fe is observed towards the rims. The predominance of tourmaline of metamorphic origin is also supported by their high Ti and low Zn contents (up to 0.2 and 0.015 atoms per formula unit, respectively; see Viator 2003).

**Table 1.** Semi-quantitative heavy mineral composition of arenites in the DOZ mélangé, and the Vranduk and Ugar formations. Symbols refer to species abundances: *triangles* predominant, *x*'s common, *circles* subordinate, *dots* very rare.

**Fig. 7.** Ternary plots of tourmaline chemistry in the Fe-Mg-Al system and assignment to probable source lithologies (Henry and Guidotti, 1985). Numbered fields: tourmaline compositions dominantly in (1) Li-rich or (2) Li-poor granitoids, (3) hydrothermally altered granites; (4-5): metapelites (4) coexisting or (5) not coexisting with an Al-saturating phase, (6) skarns, (7) metamorphosed ultramafic rocks, (8) metacarbonates. Filled symbols: cores or inner zones, open symbols: outer zones or unzoned crystals.

**Fig. 8.** Comparison of detrital garnet compositions from the DOZ mélange and the Vranduk and Ugar formations, according to the classification scheme of Morton *et al.*, (2003). Alm: almandine, Sps: spessartite, Prp: pyrope, Grs: grossular.

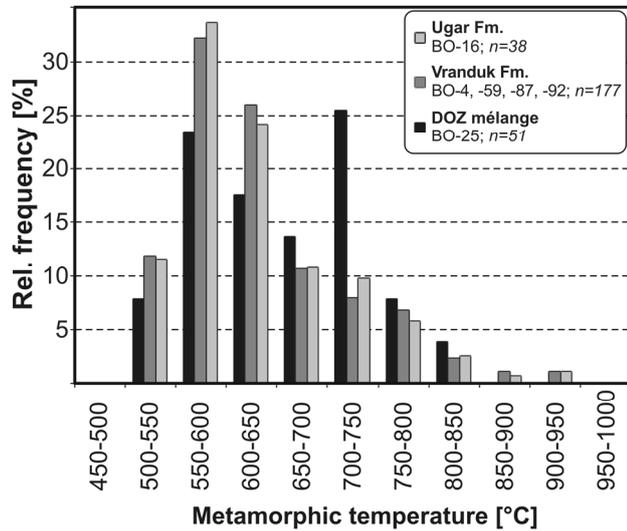

Garnet chemistry indicates a variety of source lithologies, the most dominant being greenschist facies metamorphic rocks. Additional garnet populations are also observed: one is derived, according to the classification scheme of Morton *et al.*, (2003), from amphibolite to granulite facies metapelites (along the almandine-pyrope join) and another one from amphibolite to eclogite facies metabasic rocks (pyrope- and grossular-rich almandines; Fig. 8). The share of the contribution from these high-grade sources is the highest in the DOZ mélange (in total ~45%). It then decreases significantly in the Vranduk Formation (~21%) and probably disappears in the Ugar Fm (only a few grains that plot close to the boundaries; Fig. 8). A small proportion of garnets (c. 4%) derived from skarns or low-grade metabasic rocks also occurs in the DOZ mélange.

Rutile crystals are mostly (60 to 80% throughout the samples) of metapelitic origin, as deduced from their Cr/Nb ratio (Zack *et al.*, 2004a, Triebold *et al.*, 2007), with the remaining portion derived from metamafic lithologies (Appendix 2-6). Zr-in-rutile thermometry was performed on the metapelitic crystals in order to assess source rock metamorphic conditions following Zack *et al.*, (2004b) and Watson *et al.*, (2006). The results yield a broad dis-

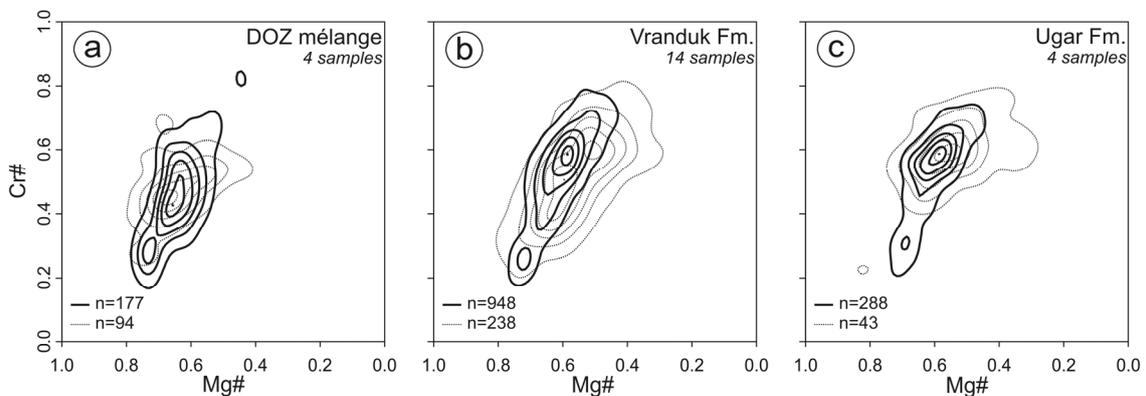

tribution of calculated metamorphic temperatures between c. 500 and 900°C (Fig. 9). The distribution of inferred temperatures in the detritus of the DOZ mélange most likely consists of two components:

one ranging from 650-700 to ~850 °C, and one between 500 and 650-700 °C. This is different from the both flysch formations which appear to be dominated by a single population with a mode between 550 and 700 °C (Fig. 9).

*Cr-spinel* chemical data from the DOZ mélange and from the Vranduk and Ugar formations indicate abundant (65 to 87%) mantle-derived spinels and a subordinate magmatic-derived spinel population, based on the criterion by Lenaz *et al.*, (2000), taking 0.20 wt% TiO<sub>2</sub> as a "threshold" value (Fig. 10). The Cr number [Cr# = Cr/(Cr+Al)] of mantle-derived spinels range from 0.20 to 0.75, with more than 50% of the analyses lying between 0.45 and 0.65. This is explained by the dominance of harzburgitic lithologies in a mixed lherzolitic-harzburgitic ophiolite zone, or simply by abundant mantle rocks of transitional harzburgitic character. Occasional across-sample variations in the range of Cr# in the Vranduk and Ugar formations do not affect the overall picture, but reveal local variations in ophiolite petrology.

**Fig. 9.** Thermometry of detrital rutile from the DOZ mélange and the Vranduk and Ugar formations. Histograms show the distribution of metamorphic temperatures recorded by single rutile crystals of metapelitic origin (Cr<Nb) as calculated from their Zr content according to Watson *et al.*, (2006).

**Fig. 10 (previous page, bottom):** Geochemistry of detrital Cr-spinel from (a) the DOZ mélange and (b) the Vranduk and (c) Ugar formations, presented by data density contouring of all data points. Contours were derived by two-dimensional kernel density estimation using the *kde2d* function of the software package *MASS* in *R* environment. Contouring covers 90, 70, 50, 30 and 10% of the entire dataset. Ellipses in bold lines refer to Cr-spinel crystals with TiO<sub>2</sub> values <0.2 wt% (peridotitic origin), those in dotted lines account for TiO<sub>2</sub> values >0.2 wt% (magmatic origin).

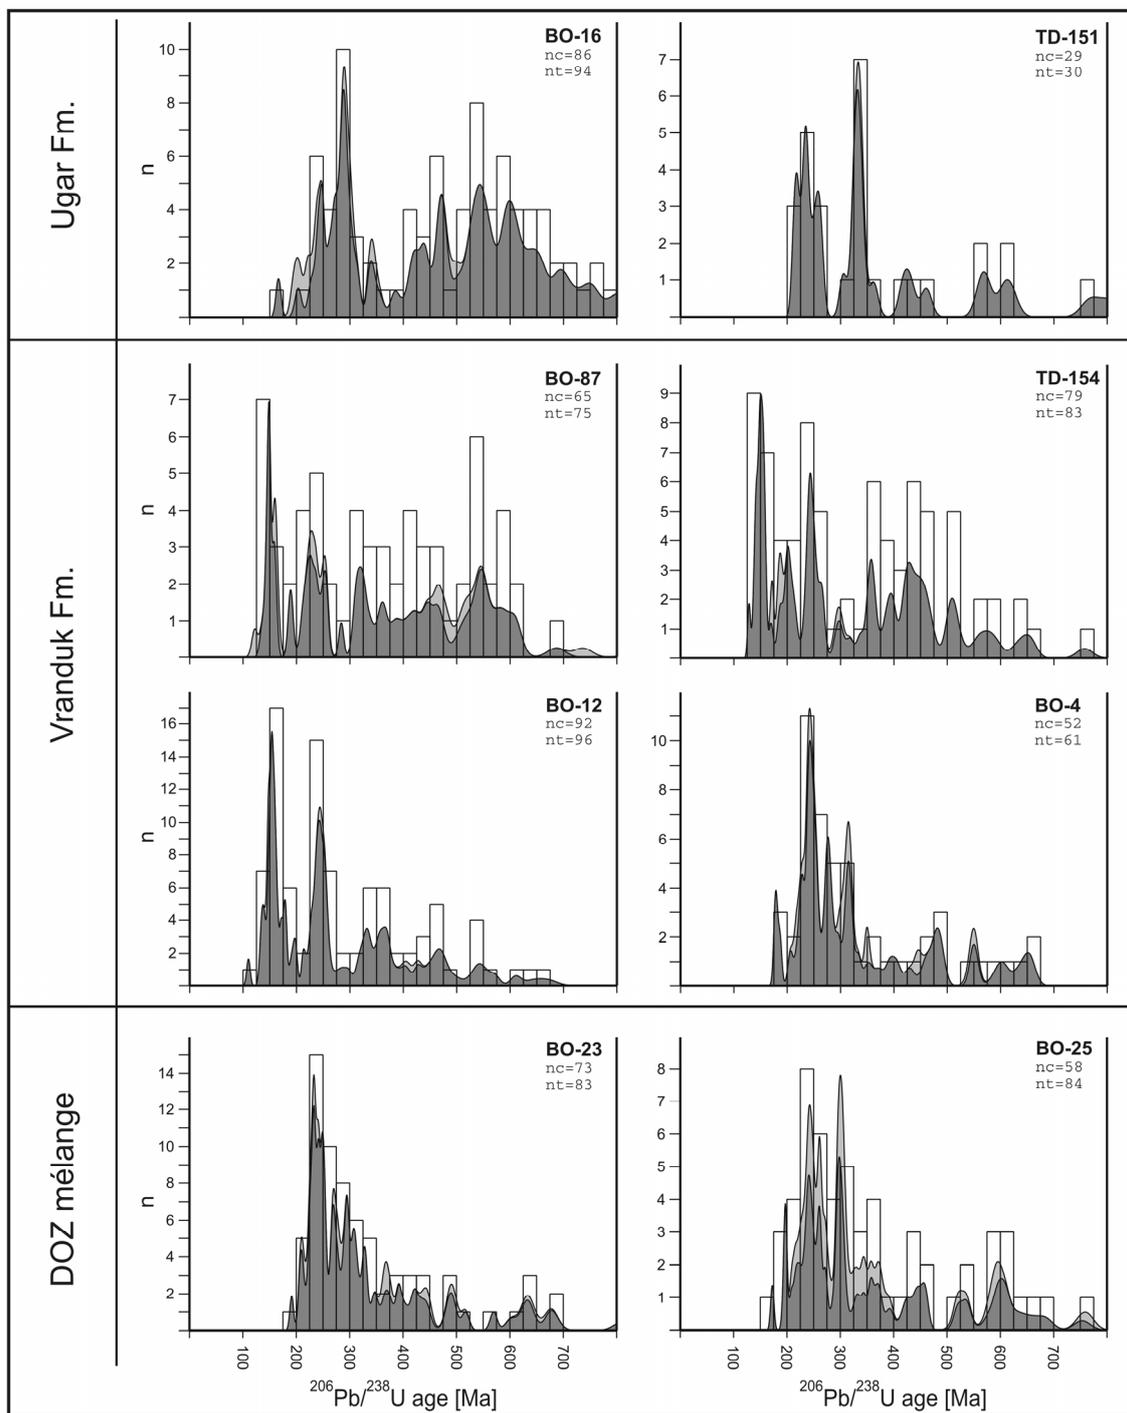

### 2.5.6. Geochronology

#### 2.5.6.1. Zircon U/Pb dating

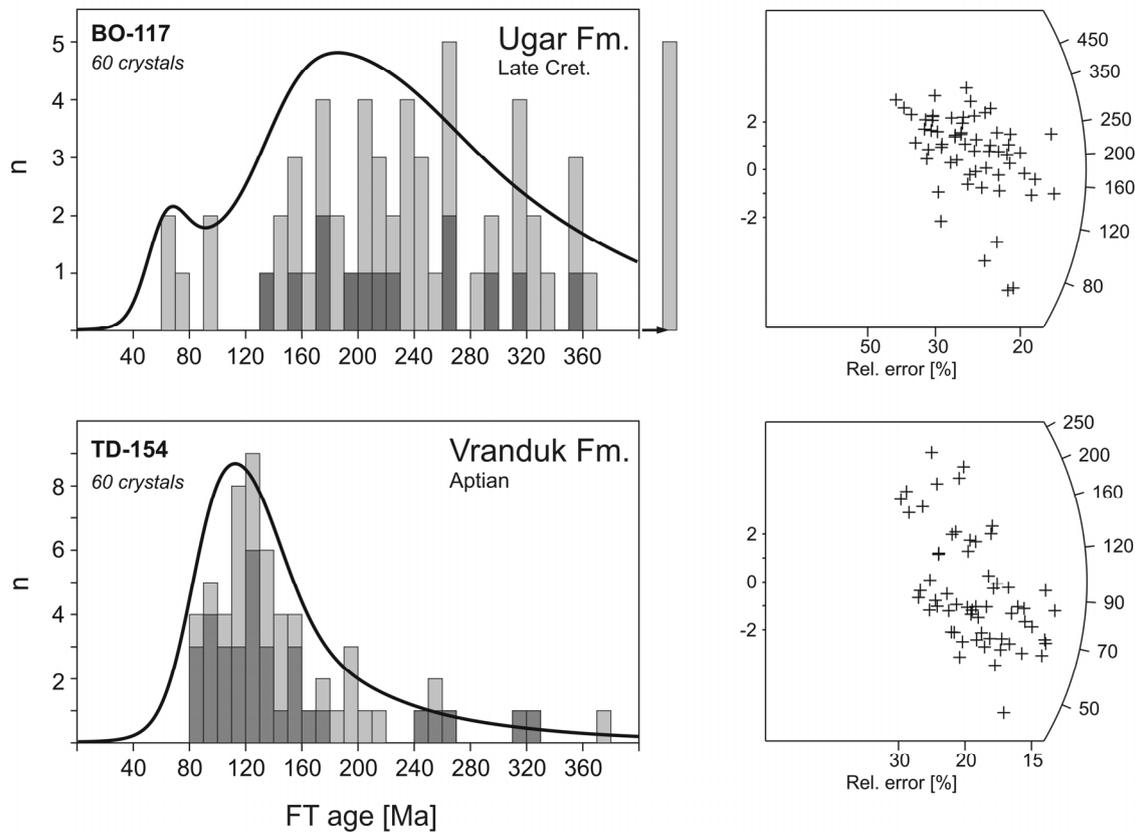

Detrital zircon U/Pb age data show a marked contrast among the three formations studied, apart from the ubiquitous Permo-Triassic ages (Fig. 11). A Permo-Triassic population, with a minor admixture of Variscan, Caledonian and Pan-African ages, dominates zircon age spectra from the ophiolite mélange. Age spectra of Vranduk zircons display Caledonian, Variscan, Permo-Triassic, and in 3 out of 4 samples, a characteristic Middle/Late Jurassic population with a mode at around 150 Ma. In the Ugar Formation, Permo-Triassic, Variscan and several pre-Variscan populations prevail, with no signs of Jurassic or Cretaceous contribution. The U/Pb ages clearly indicate changing source rocks from the Jurassic mélange formation to Late Jurassic and finally Cretaceous flysch sedimentation.

#### 2.5.6.2. Zircon fission track analysis

Single grain zircon fission track geochronology was performed on selected, zircon-rich arenitic samples, one each from the Ugar and the Vranduk formations. The results are given in Fig. 12. In the Vranduk sample around half of the dated crystals are euhedral, whereas euhedral crystals make up only some 20% in the Ugar sandstone. The majority of the single crystal ages range between 80 and 200 Ma in case of the Vranduk sample. The single grain age distributions (Appendix 2-10) were tested by PopShare computer software (Dunkl & Székely 2002) in order to identify the FT age populations. The youngest and dominant FT age population within the Vranduk Formation lies at  $121 \pm 21$  Ma; an older, more diffuse age group is also present.

**Fig. 11.** Zircon U/Pb age distribution in the DOZ mélange, and the Vranduk and Ugar formations. Dark grey area indicates probability density distribution of single-grain age data concordant at the 86-114% level. Histogram also shows the filtered data. Light grey area represents all data. Grains older than 800 Ma are very subordinate and were excluded from the plot. nt: number of all accepted age analyses; nc: number of concordant age data. Calculations according to Sircombe (2004).

**Fig. 12.** Zircon single grain fission track age distributions in the Vranduk and Ugar formations. Dark grey bars express the frequency of euhedral zircons, while light grey bars show all grains. The grey lines represent age spectra (probability density plots) and they were computed for all crystals according to Hurford *et al.*, (1984). Radial plots are according to Galbraith (1990).

The age distribution in the Ugar sample is wider compared to the Vranduk sandstone. Here a small and young age component is present at around 80 Ma, while some 90% of the single grain ages form a very diffuse distribution covering an age range between the Early Palaeozoic and the Jurassic. The frequency maximum in the age distribution of the Vranduk sample coincides with a frequency low in the Ugar sample.

## 2.6. Discussion

A large number of new single-grain mineral chemical data (over 3000 electron microprobe analyses), together with clay mineralogical, whole-rock geochemical and geochronological data gathered in this study, allows for a comprehensive characterization

of the source area of the two Bosnian Flysch units, as well as that of the sandstone blocks in the DOZ mélange. In the following, we evaluate the biostratigraphic and sedimentary provenance data to assess existing views (e.g. Charvet 1980; Pamić *et al.*, 1998) on the Cretaceous erosion history of the Central Dinaride segment of the Alpine orogen.

#### *2.6.1. Provenance of sandstones incorporated in the DOZ mélange*

In addition to low-grade metamorphic (typically Fe- and Mn-rich garnet) and small amounts of ophiolitic (mainly Cr-spinel) detritus, also specific heavy mineral species are identified in the sandstone blocks of the DOZ mélange which proved largely absent in the Vranduk and Ugar formations (Table 1). They include kyanite, two chemical populations of garnet indicating amphibolite facies metabasic and amphibolite to granulite facies metapelitic source lithologies (Fig. 8) and finally, a rutile population revealing higher-temperature (650-700 to 850 °C, i.e. amphibolite to granulite facies) metamorphic conditions of their source rocks (Fig. 9). These mineral signatures can most probably be attributed to the sub-ophiolitic metamorphic soles in the DOZ. On the other hand, zircon U/Pb age spectra (Fig. 11) clearly demonstrate that the detritus was also sourced from the continental margin of Adria exposing Palaeozoic basement rocks and their Permo-Triassic cover. The high proportion of sedimentary lithic fragments among the framework components, and possibly also the presence of "unstable" heavy mineral species (Table 1), hint at relatively short transport distances.

The composition of the sandstone blocks is interpreted in terms of a combined sediment supply into a trench environment both from the basal parts of the overriding ophiolitic slab and from the Adriatic margin, followed by local sediment recycling in the trench.

#### *2.6.2. Provenance of the Vranduk Formation*

Apart from abundant quartz and subordinate feldspar, the framework components of the Vranduk sandstones and breccias indicate derivation from a composite source dominated by ophiolitic lithologies, but also comprising carbonates and metamorphic

rocks. Lithic fragments mainly include serpentinised mafic/ultramafic rocks, altered basalt fragments, chert, red radiolarite, greywacke and shale (Figs. 4g & 4j-l). Limestone fragments are also common and yield, among other components, Urgonian facies benthic fauna of a Late Barremian or younger age. One sample from the hemipelagic strata close to the Bosna Valley section yields calcareous nannofossils indicative of an Aptian maximum age (Fig. 3; Appendix 2-2). As supported by petrographic observations, the relatively low carbonate content (mostly <20 wt% CaO) of the Vranduk Formation is partly related to carbonate lithoclasts, and possibly also to intrabasinal carbonate particles.

Throughout the Vranduk Formation, clay mineral assemblages of the pelitic lithologies are dominated by illite/smectite mixed-layer structures. Kaolinite and serpentine were not detected in these samples. This composition conforms to weathering in a mafic-dominated source area, where smectitic soils tend to develop and where lateritic weathering is absent (Thiry 2000). The source rocks of the detrital component of illite were anchi- to epizonal metapelites (e.g. slates, phyllites), eroded together with the ophiolites. Proximity of the exposed ophiolite slices is also shown by trace element systematics (Fig. 6). Pelite Cr/V ratios and carbonate-corrected Cr and Ni concentrations are elevated with respect to the UCC composition and suggest direct input from ophiolitic sources. The Cr/Ni ratios of arenites are within the range of the Dinaride mafic to ultramafic rocks and, thus, preclude significant mineral concentration due to reworking. Finally, a well-represented population of Middle to Late Jurassic ages appears in the zircon U/Pb spectra (Fig. 11), which can likely also be connected to the exhumed ophiolitic sequence and will be discussed later.

In addition to the ophiolites, subordinate amounts of metamorphic source components were also admixed to the Vranduk Formation detritus. This is indicated by: (1) the detrital component of illite, (2) the presence of quartz framework grains, (3) the intermediate position of most samples on the Cr/V–Y/Ni mixing curve which links ultrabasic and UCC composition (Fig. 6a), and (4) heavy mineral occurrences and chemistry.

Zircon, metamorphic tourmaline, the majority of garnet showing Fe- and Mn-rich compositions and accessory amounts of monazite and titanite document the erosion of a diverse suite of low-grade metamorphic lithologies. Zircon U/Pb geochronology shows a predominance of Permo-Triassic, Variscan and pre-Variscan crystallization ages (Fig. 11). These data indicate that the major source of the continental detritus of

the Vranduk Formation were Palaeozoic to Permo-Triassic low- to very low-grade metapelitic sequences, probably located on the Adriatic plate. A minor garnet population from amphibolite-facies metabasic source rocks (Fig. 8) may indicate continued erosion of the sub-ophiolitic metamorphic soles, but contribution from the rare amphibolite facies basement units of the Adriatic plate (Pamić & Jurković 2002; Pamić *et al.*, 2004) can not be entirely ruled out.

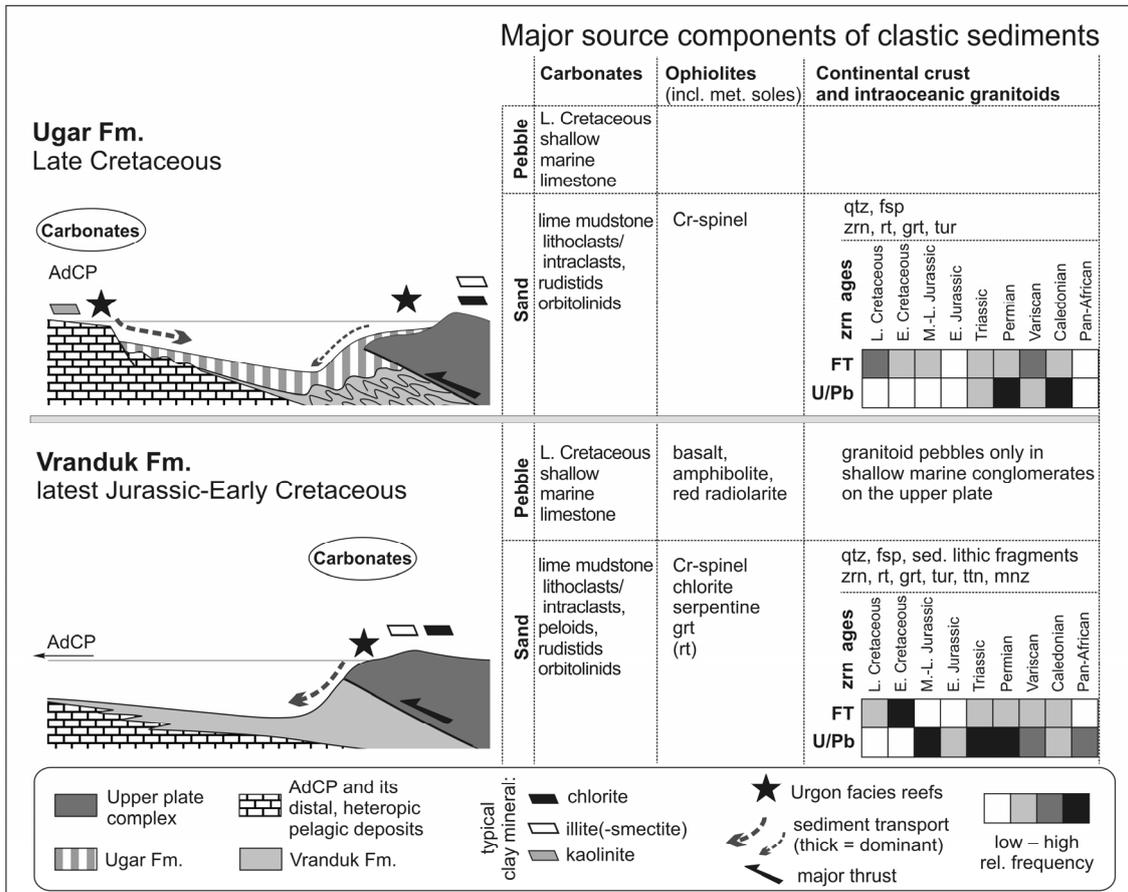

The comparatively uniform population of zircon fission track ages at around 120 Ma indicates Early Cretaceous, nearly synsedimentary cooling of the source area below mid-crustal temperatures (Fig. 12) which agrees well with the major phase of cooling of the Adriatic basement (Milovanović 1984, Árkai *et al.*, 1995; Belak *et al.*, 1995; Judik *et al.*, 2006).

In summary, our results suggest that the Vranduk Formation records Early Cretaceous exhumation of the Adriatic plate occurring relatively shortly (in less than 20 Ma) after ophiolite obduction. The catchment area included both continental basement and ophiolitic units, capped by short-lived Urgon facies reefs that were immediately redeposited onto the clastic fan.

### *2.6.3. Provenance of the Ugar Formation*

The Ugar Formation is distinguished from the Vranduk Formation by its overall dominance of carbonate clasts, inferred to have been largely derived from the Adriatic Carbonate Platform (AdCP) by many previous workers (e.g. Aubouin 1973). With respect to its rather subordinate siliciclastic source components, several lines of evidence point to a sediment source, which neither entirely matches the eroding DOZ (at least with its structure and composition being as it is known today), nor can it be completely credited to the recycling of the Vranduk Formation. These siliciclastic source components thus also require direct erosion of continental basement units. The signatures of carbonate and siliciclastic detritus are further discussed below.

The high carbonate concentration of the Ugar Formation arenites is distinct from most arenites found in the Vranduk Formation (Fig. 5). The pelites also reveal a similar difference, although Ugar Formation pelites may have been influenced by a higher flux of pelagic carbonate sedimentation beyond their detrital carbonate component. Carbonate-corrected, UCC-normalized concentrations of elements typical for ma-

**Fig. 13.** Sketch summarizing the new provenance data for the Vranduk and Ugar formations. The ophiolitic, continental and carbonate detritus of the Vranduk formation was eroded exclusively from the upper plate, while the sediments of Ugar formation were derived from both sides of the basin (the carbonate gravity flows and the lateritic clay from AdCP, the siliciclastic material from the upper plate).

fic/ultramafic lithologies, such as Cr and Ni, show no marked anomaly for the pelites of the Ugar Formation, and scatter around UCC composition (Fig. 6). These values are 2 to 3 times lower than those of the Vranduk Formation. Combined with low Cr/V ratios and elevated Y/Ni ratios in the Ugar Formation, the trace element data suggest that dilution by carbonate alone is not responsible for the relative scarcity of detrital ophiolitic components. In fact, there is a predominance of felsic components in the siliciclastic portion of the Ugar Formation pelites in comparison with the Vranduk Formation.

Although carbonate debris (orbitolinids, rudist fragments, lithoclasts) are similar in both formations, the following observations suggest that the Ugar Formation was sourced from a carbonate platform with a different setting from that previously supplying the Vranduk Formation with Urgonian facies clasts: (1) orbitolinids agglutinate carbonate particles and *Rhaxella* spicules instead of quartz, and (2) there is a salient age

gap of at least 15 Ma between the bioclasts and the Upper Cretaceous pelagic matrix (Fig. 3). These features, along with the predominance of carbonate detritus in the Ugar Formation, suggest the erosion of a relatively thick carbonate succession, previously deposited on a platform where no siliciclastics were shed to. These data confirm that the AdCP, a thick and isolated carbonate platform located to the SW of the flysch basin and comprising a thick Cretaceous carbonate sequence (Vlahović *et al.*, 2005), represents the source area of the carbonate detritus, in line with earlier models (e.g. Aubouin 1973).

The clay minerals of red marl intercalations in the thin-layered carbonate sequences of the Ugar Formation are dominated by illite/smectite and, contrary to the Vranduk Formation, they contain kaolinite as well. In general, kaolinite in fine-grained hemipelagic sediments indicates highly matured, lateritic soils developed in the source area, although lateritic weathering in tectonically active areas characterized by high erosion rates is not typical (Bárdossy & Aleva 1990; Thiry 2000). However, the Mesozoic sequence of the AdCP, located in a more external paleogeographical position with respect to the site of the deposition of the Ugar Formation, is punctuated by several bauxite and palaeosol horizons (Vlahović *et al.*, 2005), the clay mineral fraction of which is dominantly kaolinite (e.g. Šćavničar 1978). It is thus probable that also the kaolinite in the red shale was derived from the AdCP, as a result of the erosion of its weathering products.

A change in the character of the source area in respect of the felsic detritus is well constrained by the chemistry of detrital garnet and by zircon age data. The Ugar Formation is characterized mostly by a single, almandine-rich garnet population, exclusively derived from low-grade metamorphic sources (Fig. 8). Permo-Triassic zircon crystals and variable amounts of Variscan to pre-Variscan grains are the prominent U/Pb age components in the Ugar Formation (Fig. 11). Although the Vranduk Formation also contains a marked Permo-Triassic group and a rather heterogeneous distribution of pre-Permian age components as well, it comprises a significant Middle to Late Jurassic population (Fig. 11) which is absent in the Ugar Formation.

The zircon FT age data (Fig. 12) are well in line with the U/Pb age data: they also call for contrasting source areas for the two formations. Zircon FT age spectrum of the Ugar Formation contains a 80 Ma group (Fig. 12), which could indicate rapid Late Cretaceous exhumation of the Adriatic basement (Fig. 14). This age group could however, from a geochronological point of view, fit well also with other events: (1) the early stage

of the Late Cretaceous to Palaeogene acid to intermediate igneous activity in the Sava Zone (Pamić 1993, 1998; Starijaš *et al.*, 2005), (2) connected with HT/LP metamorphism (Pamić 1993, 1998; Balen *et al.*, 2003; Starijaš *et al.*, 2006; Krenn *et al.*, 2008) and in the (3) 'banatite belt' of the Southern Carpathians and Apuseni Mts. (Kräutner *et al.*, 1984; Wiesinger *et al.*, 2005), as well as (4) with the characteristic Late Cretaceous thermal event recorded in the SE part of the Tisza-Dacia Unit basement rocks (Pamić 1998; Tari *et al.*, 1999; Árkai *et al.*, 2000; Balen *et al.*, 2003; Lelkes-Felvári *et al.*, 2003; Schuller 2004; Starijaš *et al.*, 2005, 2006; Krenn *et al.*, 2008). However, as the detrital zircon U/Pb age spectra record no contribution from Upper Cretaceous igneous rocks, the 80 Ma FT age group of the Ugar Formation more probably reflects a metapelitic rather than magmatic source. Because such a thermal event is not typical for the Adriatic basement, we can not exclude that this minor detrital component is connected to the exhumation of the Sava Zone and/or SE Tisza-Dacia basement units in the Late Cretaceous.

Derivation of the low-grade metamorphic detritus in the Late Cretaceous Ugar Formation from the Bosnian Schist Mountains (BSM) is possible on petrologic grounds, but is contradicted by the structural position of the BSM, which forms the basement of the Pre-Karst (and Bosnian) units (Aubouin *et al.*, 1970; Schmid *et al.*, 2008). Also, the Palaeogene K/Ar and Ar/Ar ages that are frequent in the BSM (Pamić *et al.*, 2004) preclude its erosion in the Late Cretaceous.

In summary, our data suggest that the clastic material of the Ugar Formation was derived from at least three principal sources; (1) dismembered elements of the AdCP, and subordinately (2) ophiolitic units and (3) Variscan low-grade metamorphic basement units (including their Permo-Mesozoic cover), parts of which were affected by a thermal overprint of Late Cretaceous age (Fig. 14). The data also demonstrate that recycled Vranduk Formation sediments did not represent a significant source for the clastic components in the Ugar Formation.

#### *2.6.4. Do the Vranduk and Ugar formations share a common provenance?*

The contrasting palaeocurrent directions and lithofacies, as well as the discrepancies reflected by the heavy mineral and geochronological signatures of the Vranduk and Ugar formations suggest that contrasting source rock associations exerted a strong con-

trol on the composition of the basin fill. Yet, the provenance signatures with respect to the siliciclastic source components share some comparable aspects, and this is briefly discussed below.

The heavy mineral spectra of both formations include Cr-spinel, a mineral that is characteristic for obducted ophiolites (e.g. Zimmerle 1984). The chemical composition of the spinels indicates a mixed source area exposing lherzolite- and harzburgite-dominated ophiolites, although a single source of "transitional harzburgites", or Type-II peridotites (Dick & Bullen 1984), is equally possible. As shown in Fig. 10, a great part of the spinel compositions exhibit Cr# values between 0.40 and 0.65, and their distribution in the field of Cr# and Mg# is comparable. The proportion of spinels of magmatic origin is similarly low in both formations: about 20% in the Vranduk Formation and 13% in the Ugar Formation (Figs. 10b & 10c). Thus, there is little difference in the ophiolitic source lithologies in time, although the ratio of ophiolitic to continental source rock volumes was smaller during the Late Cretaceous on the basis of whole-rock trace element data (Figs. 6a-b).

The petrology of the felsic crystalline source rock assemblages could also have been, in part, comparable, as can be deduced from the chemical compositions of tourmaline. In both formations, chemical composition and internal texture of tourmaline crystals identify low-grade metamorphic source rocks, similar to those constituting the metapelitic basement of the East-Bosnian–Durmitor (e.g. Rampnoux 1970) and Drina-Ivanjica (e.g. Podubsky 1970; Djoković 1985) units. In addition, the occurrence of a prominent rimward zoning with increasing Fe and decreasing Mg is also a common feature in tourmaline from both formations.

Distribution of calculated metamorphic temperatures using detrital rutile covers a broad range with most data ranging between 500 and 850 °C. This large range of high temperatures may correspond to a uniform contribution from the sub-ophiolitic metamorphic soles, but garnet from such rocks is not detected in the Ugar Formation and is rather subordinate in the Vranduk Formation. Alternatively, and more probably, in both formations most of these rutile crystals were derived from older sediments and low-grade metapelites of the Adriatic plate, which did not experience the temperature conditions necessary for Zr re-equilibration in the rutile lattice, resulting in "inherited" temperatures (Zack *et al.*, 2004a; Triebold *et al.*, 2007).

The above data indicate that the major source of the sand-sized siliciclastic components in both the Vranduk and the carbonate-dominated Ugar formations included

comparable rock associations with ophiolites and low- to very low-grade metamorphic continental basement units. The heterogeneity, and contrasting thermal histories of these lithological units on the upper plate, possibly combined with drainage evolution (e.g. the NE-ward shift of the coastline upon the DOZ; Charvet 1980), are reflected by changes in the chemistry of detrital garnet and spinel, and in zircon chronology.

#### 2.6.5. Acid intraoceanic magmatism in the Jurassic

Zircon U/Pb age spectra of the Vranduk Formation (Fig. 11) suggest a pulse of acid to intermediate magmatism in the Middle-Late Jurassic in the Neotethys Ocean. Melt generation was largely contemporaneous with, or closely followed intraoceanic subduction, as reflected by the ages of metamorphic sole formation (about 180 to 160 Ma – Okrusch *et al.* 1978; Parlak & Delaloye 1999; Dimo-Lahitte *et al.*, 2001; Olker *et al.*, 2001; Smith 2006 and references therein) and the age ranges of zircon crystallization (about 165 to 140 Ma). Obvious mechanisms for generation of acid to intermediate magmatic rocks in an intra-oceanic setting can be explained by (1) plagiogranite formation at the spreading ridge; (2) island-arc magmatism; and (3) anatexis of metasediments below the ophiolite thrust sheet.

Hitherto there has been no evidence for any voluminous, acid to intermediate Jurassic magmatism that is related to island-arc development in the Dinaride segment of the Neotethys (e.g. Pamić *et al.*, 2002, Dimitrijević *et al.*, 2003) in spite of ample evidence for the existence of intra-oceanic subduction in the Neotethys (see Smith 2006, for a review). Recently however, mafic dykes were reported which intersect the DOZ ophiolites and display island arc geochemical signatures (Lugović *et al.*, 2006).

Plagiogranitic differentiates may be voluminous (e.g. Pamić & Tojerkauf 1970, Bébien *et al.*, 1997) and thus, in principle, capable of producing detritus in such amount that would be sufficiently represented in the turbiditic Vranduk Formation. In this case, an active oceanic ridge would be required at the time of subduction, as melt generation appears to slightly post-date intra-oceanic subduction. Such a scenario has recently been documented in the Vourinos ophiolite (Hellenides) by precise zircon U/Pb geochronology (Liati *et al.*, 2004).

An alternative explanation for the observed age patterns is offered by the anatexis of HT metamorphic rocks at the base of the overriding ophiolite sheets. Jurassic S-type

granites are known to have intruded many ophiolitic units and their metamorphic soles in the Dinarides–Hellenides (e.g. Borsi *et al.*, 1966, Anders *et al.*, 2005, Resimić-Šarić *et al.*, 2005), that will be discussed elsewhere (Mikes *et al.*, submitted).

## **2.7. Summary: source area evolution of the Bosnian Flysch**

In this chapter we outline several steps that played a major role in the evolution of the Bosnian Flysch basin and its surrounding source areas. Fig. 13 summarizes the most important provenance data for the situation in Early Cretaceous (Vranduk Formation) and Late Cretaceous (Ugar Formation) times. Fig. 14. provides a tentative tectono-thermal synthesis of the zircon-supplying source areas based on thermochronological data published previously and obtained in this study.

### *2.7.1. Middle to Late Jurassic: intraoceanic subduction*

Intraoceanic subduction within the Neotethys resulted in vast amounts of ophiolite bodies exposed at the overriding oceanic plate. Sandstone blocks within the Jurassic DOZ mélange record erosional events linked to the plate convergence. Sandstone composition indicates a dual source with ophiolites and their high-grade metamorphic soles at the upper plate and with detritus derived from the more distally-located continental margin of Adria. The sediments underwent local reworking, consistent with an erosional-depositional scenario in a highly active trench setting. If the oceanic ridge was located continentward of the subduction zone as depicted in Fig 14, then the trench sedimentation could be controlled by detritus from the Adriatic basement only after the oceanic ridge was subducted, that had previously posed a barrier for trenchward sediment transport.

### *2.7.2. Jurassic–Cretaceous transition: obduction and metamorphism at the continental margin of Adria*

Inverse heat transfer from the obducted hot ophiolites caused a regionally widespread, epizonal thermal overprint in the upper part of the Adriatic plate (Fig. 14). Deep crustal levels of both the oceanic plate and the continental margin suffered largely coeval HP/LT metamorphic overprint (Okrusch *et al.*, 1978; Milovanović *et al.*, 1995; Most 2003) related to both intraoceanic subduction and the subsequent obduction onto Adria. The main phase of cooling took place already in the Early Cretaceous (Milovanović 1984, Árkai *et al.*, 1995; Belak *et al.*, 1995; Judik *et al.*, 2006). However, basal detachments related to the ophiolite emplacement and nappe advancement possibly gave rise to exhumation of small continental crustal slices and to their incorporation into the thrust wedge already from the latest Jurassic onwards as shown by earliest Cretaceous coarse-grained continental crustal detritus in sediments sealing the DOZ mélange (Charvet 1978; Neubauer *et al.*, 2003).

### 2.7.3. Early Cretaceous sedimentation: Vranduk Formation

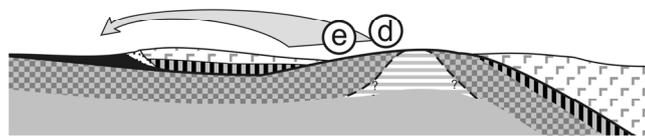

Sediments formed in front of the leading edge of the ophiolite–continental basement thrust wedge complex were subsequently accreted to the base of the thrust wedge, parts of which were exposed to erosion again. Clastic wedge development commenced already at the Jurassic–Cretaceous transition, with the submarine fan deposits prograding SW-ward onto the pelagic sequence of the 'Zone Bosniaque'. Tips of the growing imbricate slices that achieved shallow bathymetry were rapidly colonised by Urgonian facies reefs. These build-ups and their ophiolitic substrate were immediately redeposited onto the clastic fan (Fig. 13).

Erosion, drainage evolution and nappe emplacement could all result in slight changes in source rock composition between incipient obduction and Early Cretaceous flysch deposition. The ophiolitic detritus records an increasing volume of harzburgites exposed to erosion. The obducted oceanic thrust pile contained Jurassic acid to intermediate magmatic bodies as well, interpreted as plagiogranites formed at the ridge, or as S-type granitoids produced by anatexis of subducted oceanic sediment (Fig. 14). Granulite facies metapelitic rocks of the sub-ophiolitic metamorphic soles were no longer eroded, likely due to their extremely small volume relative to the ophiolitic sheet (cf. Karamata *et al.*, 1970, their Fig. 1).

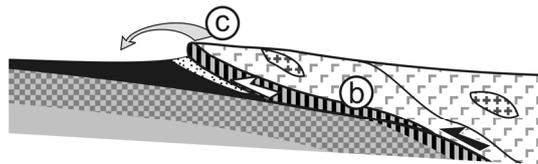

The relatively rapid exhumation and erosion of Adria-derived continental crustal units in the late Early Cretaceous is indicated by a largely synsedimentary age component around 120 Ma in the detrital zircon FT age spectrum of the Vranduk strata (Fig. 14). Parts of the clastic wedge underwent burial and folding in the mid-Cretaceous as suggested by a locally developed erosional unconformity on top of the Vranduk Formation (Figs. 3 & 13; Dimitrijević 1982 p.14; Csontos *et al.*, 2003; Schmid *et al.*, 2008 p.25), and by K/Ar age dating of illite from Vranduk Formation shales (Petri 2007).

**Fig. 14.** Cartoon summarizing the development of the zircon FT ages in tectonic units providing *siliciclastic* detritus to the Vranduk and Ugar formations. (a) Zone of zircon FT reset in the Adriatic basement due to the inverse heat transfer from the overriding hot ophiolites and tectonic load. (b) Obduction is followed by thrusting of the overprinted continental slices that were detached from the topmost level of the lower plate. (c) Early Cretaceous erosion of Adria-derived basement slices is documented by synsedimentary zircon FT ages in the Vranduk Formation. (d) In the Late Cretaceous, the lower plate experienced fast exhumation: the thin upper layer of the Adriatic margin with completely reset zircon FT ages was removed, and a wide range of Jurassic and pre-Jurassic zircon FT ages were supplied. Although these ages are predominant in the Ugar formation, (e) a minor age component with Late Cretaceous zircon FT ages is also present. This can be interpreted by exhumation of deeper-seated, hitherto undated crustal levels of the Adriatic plate, whereas temporally it also agrees with the early stages of collision of Adria with Tisza-Dacia (not shown) implying that the Late Cretaceous catchment already included the docking upper plate. See text for discussion.

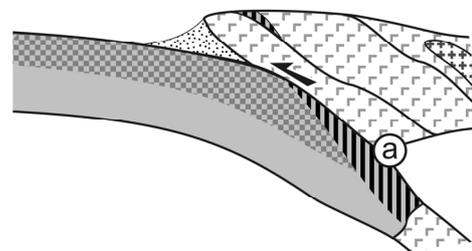

Sedimentation of Ugar Fm. (from ca. 100 Ma)

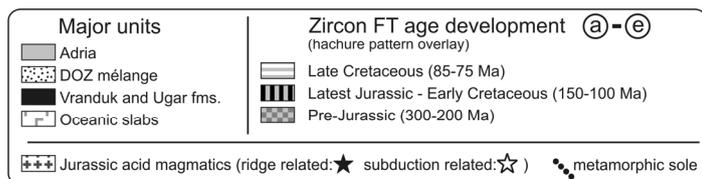

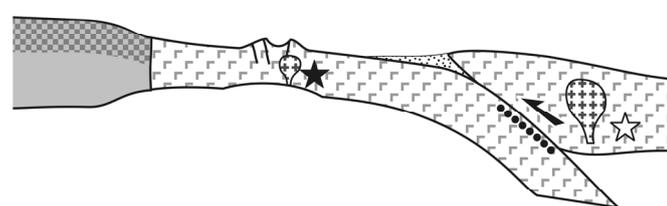

Sedimentation of Vranduk Fm. (from ca. 145 Ma)

Onset of obduction onto Adria (ca. 150 Ma)

Intra-oceanic subduction (ca. 180-160 Ma)

*2.7.4. Late Cretaceous Ugar sedimentation: increasing carbonate contribution and changes in the hinterland*

Propagation of the folded imbricate wedge towards the SW led to a platformward migration of the actual depozone. Vast carbonate mass flows released from the AdCP margin were intercalated with Scaglia Rossa-type Upper Cretaceous basin sediments. The origin of the suspended matter can be located on both basin margins, most likely representing a mixture from both areas. Sand-sized siliciclastic components were derived from the DOZ and the underlying, continental crustal thrust sheets of Adria, parts of which experienced fast exhumation. Notably, this c. 80 Ma cooling event has been largely unknown in the Adriatic basement so far.

In the light of the largely E-directed palaeocurrent indicators the site and mechanism of intermingling of the carbonate and sand-sized siliciclastic components prior to the final deposition of the Ugar Formation remains ambiguous. Signs of continued convergence during the Cenozoic, such as fault propagation, basin migration and cannibalistic sediment reworking further toward SW, are seen in the imbricate wedges of Cenozoic flysch of the AdCP (Chorowicz 1977; Mikes *et al.*, 2008a and references therein).

\* \* \*

The data presented in this paper reinforce previously published tectonic models inasmuch as they relate the deposition of the Vranduk Formation to the adjacent and exhumed ophiolite units (e.g. Aubouin 1973; Charvet 1980; Tari 2002; Schmid *et al.*, 2008). However, although the Vranduk Formation is underlain by pelagic Jurassic strata of the distal Adriatic plate, it represents a SW-ward propagating clastic wedge at the front of the leading edge of the DOZ and a continental thrust sheet complex. Our results thus do not support the model put forward by Pamić (1993) and Pamić *et al.*, (1998) describing the entire Bosnian Flysch in terms of a passive margin sequence of the distal Adriatic plate.

## *Chapter 3*

# Insights into Neotethyan ophiolite petrology at the Dinaride–Alpine– Pannonian triple junction: geochemistry of detrital Cr-spinel from Cretaceous synorogenic sediments

---

This chapter is largely identical to the manuscript entitled:  
"Ophiolitic detritus in Cretaceous clastic formations of the Dinarides (NW Croatia): evidence from Cr-spinel  
chemistry" that is currently in press with the *International Journal of Earth Sciences*  
published OnlineFirst in March 2008, doi:10.1007/s00531-008-0306-3  
authored by:  
Borna Lužar-Oberiter, Tamás Mikes, Hilmar von Eynatten and Ljubomir Babić

# **Insights into Neotethyan ophiolite petrology at the Dinaride–Alpine–Pannonian triple junction: geochemistry of detrital Cr-spinel from Cretaceous synorogenic sediments**

*Borna Lužar-Oberiter, Tamás Mikes, Hilmar von Eynatten and Ljubomir Babić*

## **Abstract**

Cr-spinel is a common heavy mineral in the sandstones of Cretaceous synorogenic sedimentary formations of the NW Dinarides. The rocks occur in isolated exposures in the uplifted basement units of Medvednica, Ivanščica, Žumberak and Samobor Mountains near Zagreb. In this area evidence of the early Alpine evolution of the Dinarides is obscured due to strong dismemberment of pre-Tertiary tectonostratigraphic units resulting from an intense tectonic history, as well as due to the widespread sedimentary cover of the Pannonian Basin. Electron microprobe analyses of detrital Cr-spinels from the Oštrc Formation reveal that in the Early Cretaceous the ophiolitic source area was predominantly composed of harzburgite peridotites and associated cumulate rocks which developed in a supra-subduction zone setting. The supply of Cr-spinels with the same chemical signature remained dominant until the end of the Cretaceous, suggesting that exposed remnants of the same ophiolite belt persisted through the Cretaceous and/or that recycling was significant. Similarities with data reported from the Northern Calcareous Alps and the Transdanubian Central Range imply that a rather extensive harzburgitic ophiolite belt probably extended along the Adriatic margin during the Early Cretaceous. A slight trend of increasing variation in the Cr# is observed from the Early to the latest Cretaceous, suggesting that the source areas became more heterogeneous with the ongoing Cretaceous tectonic evolution. Differences in Cr-spinel compositions in two contemporaneous latest Cretaceous formations are well in line with existing data on heavy mineral proportions, which together identify contrasting hinterland geology for these formations and strongly suggest the coeval existence of two separate basins.

### 3.1. Introduction

Cr-spinel is an important accessory mineral in mafic and ultramafic rocks, though its considerable chemical and mechanical stability make it a common accessory constituent of sedimentary rocks as well (Zimmerle 1984; Morton and Hallsworth 1999). Its potential to survive the sedimentary cycle, unlike other mafic and ultramafic rock components, often leaves Cr-spinel as the only remaining evidence of a once existing source of detritus, making it a promising target of investigation for provenance studies (Morton 1991). Detrital Cr-spinel chemistry has received considerable attention in studies of clastic sediments, particularly those associated with orogenic suture zones where large masses of mafic and ultramafic rocks tend to be obducted onto the upper plate to form extensive ophiolite sequences (Pober and Faupl 1988; Árgyelán 1996; Cookenboo *et al.*, 1997; Arai and Okada 1991; Hisada and Arai 1993; Lenaz *et al.*, 2000, 2003; von Eynatten 2003; Zhu *et al.*, 2004; Faupl *et al.*, 2006).

During processes of partial melting of mantle rocks and fractional crystallization of magmas the partitioning of elements between solid and melt has a profound effect on the composition of Cr-spinel (Irvine 1965, 1967; Kamenetsky *et al.*, 2001). Studies of mafic and ultramafic rocks have identified the degree of partial melting of mantle peridotites, magma chemistry, temperature of crystallization, cooling rate, pressure and oxygen fugacity as influential factors (Dick and Bullen 1984; Sack and Ghiorso 1991; Arai 1992; Kamenetsky *et al.*, 2001). The variable chemistry of Cr-spinel can provide useful information on the petrogenesis of ophiolite members exposed and eroded during the evolution of an orogen, allowing a better understanding of the tectonic history and nature of sediment dispersal.

This study presents single grain chemical data of detrital Cr-spinels from the sandstones of five Cretaceous clastic formations in the NW Dinarides, Croatia (Fig. 1 and 2). The studied formations range in age from Early to latest Cretaceous, and consist of synorogenic deep-marine and shallow-marine sediments. They record important events in the early evolution of the northern Dinarides, including the Dinaride-Alpine transitional area. To date, a considerable amount of single grain Cr-spinel chemical data has been published from sedimentary formations of the Alpine-Carpathian region (e.g. Pober and Faupl 1988; Árgyelán 1996; Lenaz *et al.*, 2000, 2003; Jablonský *et al.*, 2001;

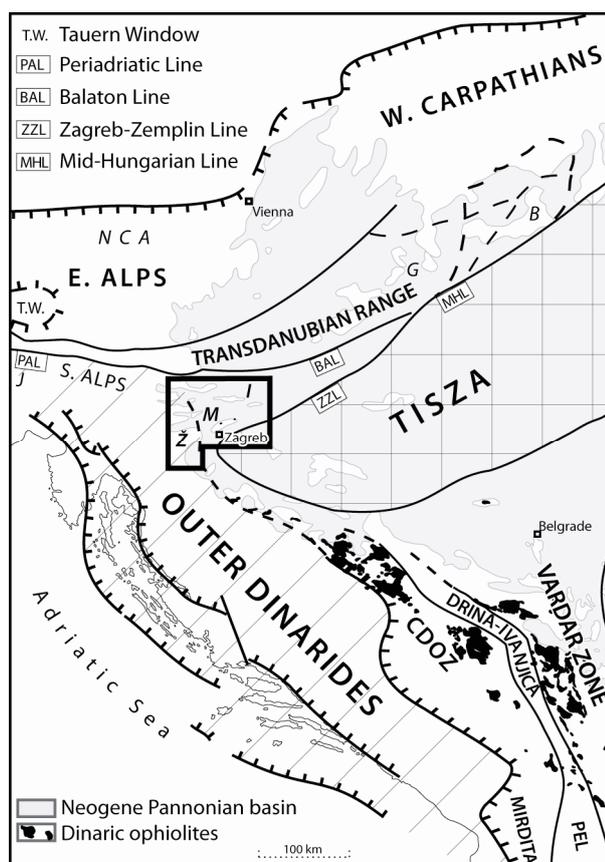

von Eynatten 2003; Sciunnach and Tremolada 2004; Oszczytko and Salata 2005). However, hitherto no data have been available from Cretaceous sediments of the NW Dinarides. Our new data allow comparison to be made with sedimentary formations and potential source ophiolites exposed today in neighboring areas. By means of Cr-spinel chemistry our aim is to better constrain the composition and tectonic history of the obducted ophiolites supplying detritus into sedimentary basins of the NW Dinarides during the Cretaceous.

### 3.2. Geological setting

The Dinarides represent a major segment of the Alpine orogenic belt in SE Europe (Fig. 1). The Outer Dinarides are dominated by thick Mesozoic platform carbonates forming part of the Adriatic plate, while the Inner Dinarides are on the other hand represented by various lithologies, which occur in NW-SE trending tectonic zones (Aubouin *et al.*, 1970; Pamić *et al.*, 1998; Dimitrijević 1982, 2001; Tomljenović *et al.*, in press). Prominent features of the Dinaride nappe stack are extensive ophiolite units. These represent the remnants of the Neotethys Ocean which existed between Eurasian and African continental elements during the Mesozoic, and may have consisted of several ocean branches or marginal basins (e.g. Dimitrijević and Dimitrijević 1973; Robertson and Karamata 1994; Channell and Kozur 1997, Schmid *et al.*, 2008). In the central and SE Dinarides ophiolites occur in two zones: the Central Dinaride Ophiolite Zone (CDOZ) in the SW and the Vardar Zone to the NE. Separating them is the Drina-Ivanjica intermediate unit which has been interpreted as a continental fragment (Aubouin *et al.*, 1970; Dimitrijević and Dimitrijević 1973; Robertson and Karamata 1994), as an out-of-sequence nappe derived from the northern Tethyan margin (Pamić *et al.*, 1998) or as a basement nappe derived from the Adriatic plate (Schmid *et al.*, 2008). These major Dinaride tectonostratigraphic units extend southwards into the Hellenides. Towards the NW, at the Dinaride-Alpine junction in which the study area is located, the Dinaride structural pattern is obscured by Tertiary lateral displacements and considerable clockwise rotation (Haas *et al.*, 2000; Tomljenović *et al.*, 2008), as well as by the Neogene sedimentary cover. The evolution of the Inner Dinaride zones, as well as their northerly continuation is still a matter of debate. In the Alpine-Carpathian region ophiolite occurrences of the western Tethys have been ascribed to

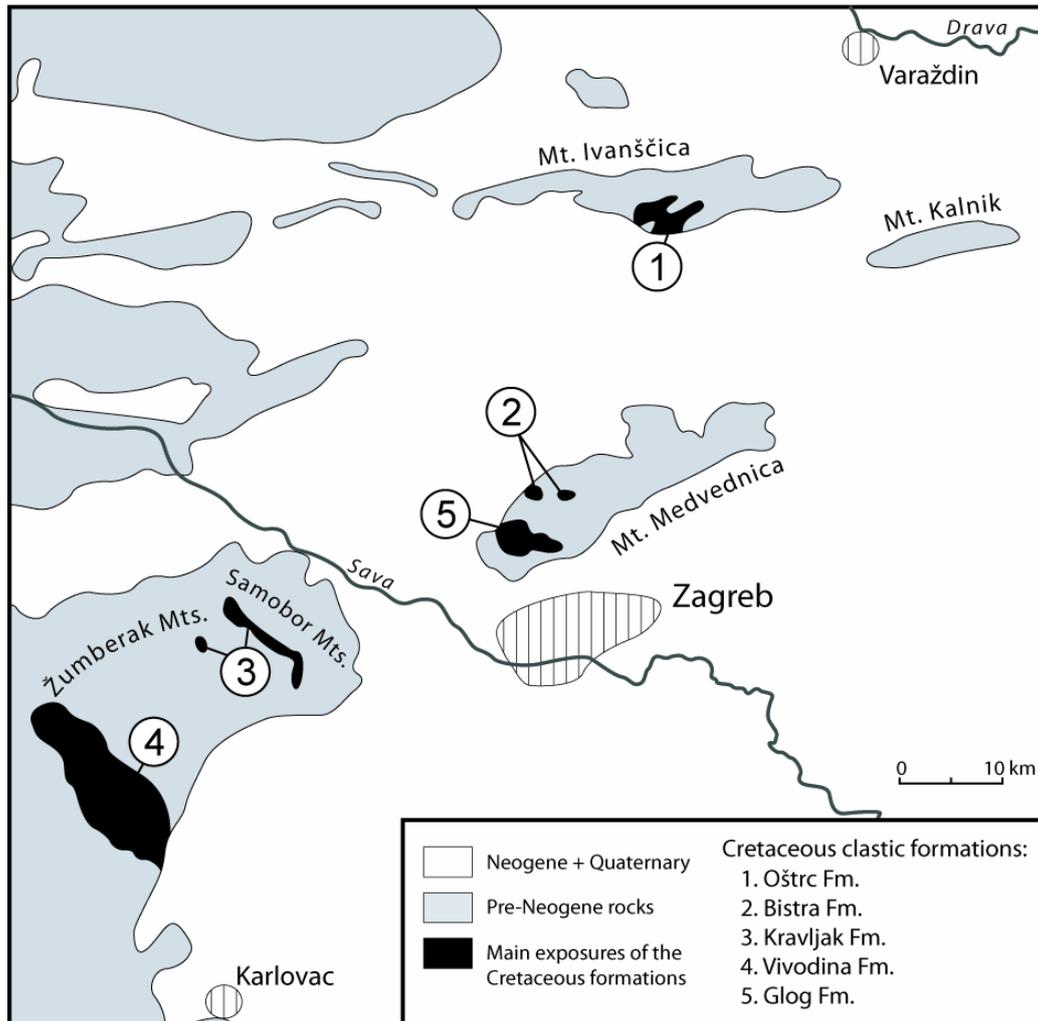

the Meliata domain, while for others, such as those included in the Bükk Mts., a Dinaride affinity has long been recognized (Haas and Kovács 2001, and references therein). The connection of the Meliata domain itself with the southerly Dinaride ophiolite zones has been both advocated (e.g. Kovács 1982; Dal Piaz *et al.*, 1995; Halamić and Goričan 1995; Gawlick *et al.*, 1999) and contradicted (e.g. Kozur 1991; Channell and Kozur 1997). In the NW Dinarides, ophiolite fragments occur within a mélangé complex collectively termed as Repno Complex (Babić and Zupanić 1978). Results obtained from dating both the matrix and the tectonized blocks of the mélangé suggest a Triassic onset of ocean spreading, subduction beginning in the Middle Jurassic, and a Late Jurassic to Early Cretaceous closure of the oceanic basin (Halamić and Goričan 1995; Halamić *et al.*, 1999; Babić *et al.*, 2002).

The Cretaceous clastic formations considered in this Chapter are situated in a tectonically complex region between the Alps, Dinarides and Tisza (Fig. 1). The area bound by the Periadriatic-Balaton and Zagreb-Zemplén Lineaments, the Sava Composite Unit, comprises several juxtaposed structural units of different affinity. The intense dismemberment of this pre-Tertiary unit results from a severe and long-lasting Mesozoic to Cenozoic deformational history (Vörös 1993; Pamić *et al.*, 1998, 2002; Haas *et al.*, 2000; Tomljenović and Csontos 2001; Haas and Péro 2002; Babić *et al.*, 2002; Csontos and Vörös 2004). The studied strata, together with other pre-Tertiary units are exposed only in uplifted basement

**Fig. 1.** Tectonic situation of the Alpine-Dinaric-Pannonian region with the main structural units outlined. Map compiled from different sources, mainly Haas *et al.*, (2000), Haas and Kovács (2001), Aubouin *et al.*, (1970) and Geological Map of Yugoslavia, 1:500000 (F.Y.I., 1970). B = Bükk Mts., G = Gerecse Mts., I = Ivanščica Mt., J = Julian Basin, M = Medvednica Mt., Ž = Žumberak Mts., CDOZ = Central Dinaride Ophiolite Zone, NCA = Northern Calcareous Alps, PEL = Pelagonian unit. Framed area is shown in Fig. 2

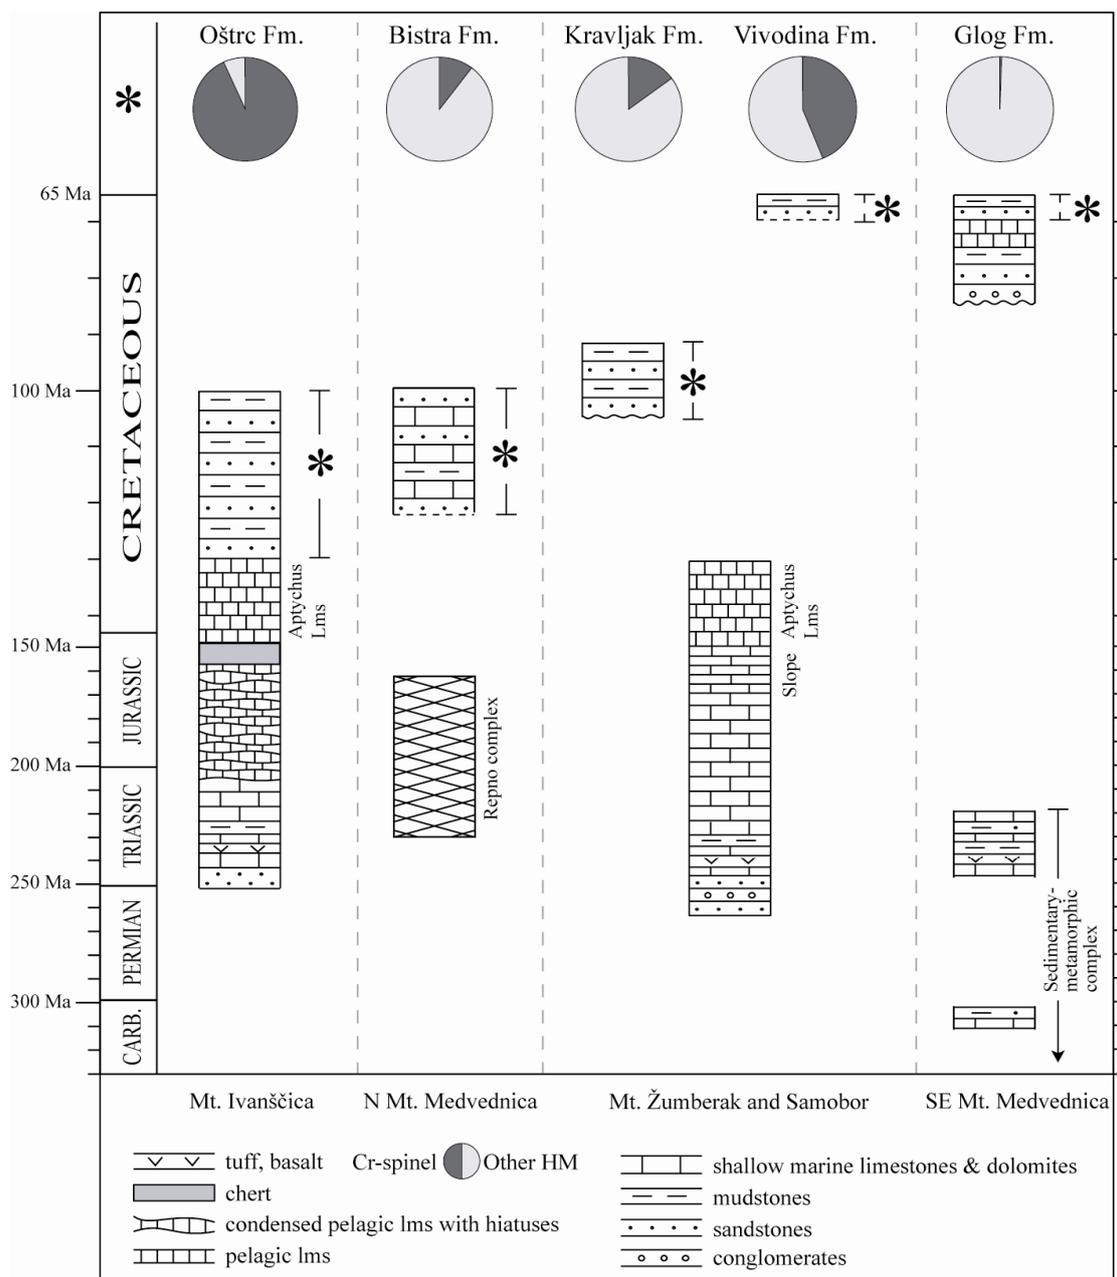

units, or "inselbergs", on the Ivanščica, Medvednica, Žumberak and Samobor Mountains (Fig. 2).

**Fig. 2.** Simplified geological map showing the distribution of the studied formations

The Mesozoic sediments of Mt. Ivanščica consist of deposits of the Adriatic platform and its NE margin which occur in tectonic contact with a Jurassic ophiolitic mélangé (Repno Complex, Babić *et al.*, 2002). These are Late Triassic shallow marine carbonates, Jurassic pelagic limestones and cherts, and Tithonian-Valanginian “Aptychus Limestones” which are overlain by the *Oštrc Formation* (Fig 2.). The Oštrc Fm. is Barremian to Albian in age and dominated by siliciclastic turbidites (Fig. 3; Babić and Zupanić 1973; Babić 1975; Babić and Gušić 1978). Babić *et al.*, (2002) suggested that these sediments were deposited on the subsided carbonate platform margin of the Adriatic plate. Facies and composition records a dramatic change in sedimentation due to the

influx of high amounts of siliciclastic material. Heavy mineral spectra from sandstones of the Oštrc Fm. show a very high proportion of chrome spinel (>90%), indicating, together with abundant mafic and ultramafic lithic fragments, a dominantly ophiolitic provenance with minor continental contribution (Zupanič *et al.*, 1981).

**Fig. 3.** Simplified chronostratigraphic logs of the studied formations and their basement. Average Cr-spinel abundances are presented at the top with pie diagrams (Crnjaković 1981; 1989; Crnjaković *et al.*, 2000; Zupanič *et al.*, 1981; Zupanič 1981). Note that the vertical time scale is not linear.

Two Cretaceous clastic formations were investigated on Mt. Medvednica (Fig. 2). The Aptian-Albian *Bistra Formation* consists of shallow-marine to coastal carbonates and clastic sediments (Gušić 1975; Crnjaković 1989). The shallow-marine environment probably developed on top of the exhumed Jurassic ophiolitic mélangé complex, which also occurs in Mt. Medvednica (Babić *et al.*, 2002). The heavy mineral associations of the sandstones contain ultrastable minerals (zircon, tourmaline and rutile = ZTR), Cr-spinel, and only minor proportions of other minerals (e.g. apatite, garnet, amphibole and epidote). The heavy minerals and framework composition reflect a mixed continental-ophiolitic provenance (Crnjaković 1989). The Maastrichtian *Glog Formation* consists of deep-water sandstone and marl deposits which represent the youngest part of a Senonian alluvial to deep-water succession overlying low-grade metamorphic rocks, as well as the ophiolitic mélangé (Babić *et al.*, 1973; Crnjaković 1981, 1987). This sedimentary-metamorphic complex builds up the “core” of Mt. Medvednica and underwent Early Cretaceous low-grade metamorphism (Belak *et al.*, 1995; Belak 2005). Opinion is divided as to whether it is of Dinaride affinity (Haas *et al.*, 2000), or does it rather derive from an easterly continental block (Tisza or Drina-Ivanjica Unit – Babić *et al.*, 2002). The heavy mineral associations in the sandstones of the Glog Fm. are heavily dominated by ZTR, with only minor proportion of other heavy minerals (Crnjaković 1981). It is important to note that in the studied Glog samples, Cr-spinel occurs only in trace amounts, which is considerably less than in any of the other formations.

The Albian-Cenomanian *Kravljak Formation* and the Maastrichtian *Vivodina Formation* are both deep-water turbiditic deposits and occur in the Žumberak and Samobor Mts. (Fig.2), located in the SW edge of the Sava Composite Unit (Babić 1974; Zupanič 1981; Devidé-Nedéla *et al.*, 1982). Probably, these formations record deposition on the distal Adriatic margin in the Late Cretaceous, and are laterally equivalent to the “Zone Prekarstique” (Babić 1974) described further to the SE in Bosnia-Herzegovina by Blanchet *et al.*, (1970). The onset of clastic deposition in this area thus occurred earlier than elsewhere on the carbonate platform (Babić 1974; Čosović *et al.*, 2008; Mikes *et al.*, 2008a). Heavy mineral associations from the sandstones of these formations contain ZTR, Cr-spinel, and garnet as well as a minor proportion of other mineral species (e. g. epidote, amphibole, chloritoid), indicating derivation from both ophiolitic and continental sources (Zupanič 1981; Crnjaković *et al.*, 2000).

### 3.3. Sampling and analytical procedures

Samples were taken from fine to medium grained sandstone beds, taking care to avoid sampling of weathered rock. Cr-spinel grains were obtained using standard heavy mineral separation procedures. Sandstone samples were crushed, dry sieved down to <0.250 mm, and the heavy fraction pre-concentrated using a Wilfley-table. Carbonate was removed by 5% cold acetic acid treatment. Heavy minerals were separated by hot LST Fastfloat ( $\rho=2.85 \text{ gcm}^{-3}$ ), embedded in epoxy and polished for microprobe analysis. Most sprinkled mounts contained sufficient amount of Cr-spinel grains, whereas Glog Formation spinels were separated by hand-picking due to their low abundance in the samples. Measured grains range in size from coarse silt to very fine sand.

In total we have analyzed Cr-spinels from 17 sandstone samples taken from 5 different formations (Oštrc=7, Bistra=3, Kravljak=2, Vivodina=3, Glog=2). Chemical data of 773 detrital Cr-spinel grains were obtained using a JEOL electron microprobe (JXA-8900RL) equipped with five wavelength dispersive spectrometers at the Geoscience Center Göttingen. Analyses were performed using an accelerating voltage of 20 kV, a beam current of 20 nA and a 3  $\mu\text{m}$  beam diameter. Mg, Al, Cr, Fe, V, Si, Ti, Mn, Ni and Zn were analyzed. One spot analysis was performed in the center of each grain. Measured grains range in size from coarse silt to very fine sand. No zoning was evident based on back-scattered electron images, neither were ferrian chromite rims encountered. Ferric iron content was calculated based on charge balance assuming stoichiometry, following the procedure of Barnes and Roeder (2001). All data are listed in Appendix 3-1.

### 3.4. Chemical characteristics of Cr-spinels in the studied Cretaceous formations

The chemical composition of Cr-spinel is commonly presented by values which display considerable variation, such as Cr# ( $\text{Cr}/(\text{Cr}+\text{Al})$ ), Mg# ( $\text{Mg}/(\text{Mg}+\text{Fe}^{2+})$ ),  $\text{TiO}_2$  and  $\text{Fe}^{3+\#}$  ( $\text{Fe}^{3+}/(\text{Cr}+\text{Al}+\text{Fe}^{3+})$ ). During processes of partial melting in the mantle Cr is strongly partitioned into the solid as compared to Al which preferentially partitions into the melt. This makes the Cr# of Cr-spinel an excellent indicator of the degree of partial melting which its host peridotite underwent, since the degree of depletion is often sug-

gestive of the tectonic setting (e.g. mid-oceanic ridge or supra-subduction zone). The causes for the variation of Mg# are more complex. The partitioning of Mg and Fe<sup>2+</sup> is affected by the relative activities of Cr and Al in spinel, causing a shift towards lower Mg# with increasing Cr# (Dick and Bullen 1984). Furthermore, Mg# is dependent on temperature and cooling rate, as well as magma chemistry during crystallization and re-equilibration processes. The TiO<sub>2</sub> content and Fe<sup>3+</sup># differ between Cr-spinels from residual mantle peridotites ('residual' or 'mantle' spinels) and those formed by crystallization of the extracted melt ('magmatic' spinels). Residual spinels have low TiO<sub>2</sub> (<0.2%), while those originating from cumulate and extrusive volcanic rocks tend to have higher TiO<sub>2</sub> (>0.2%) (e.g. Kamenetsky *et al.*, 2001).

#### 3.4.1. Oštrc Formation

In the Cr-spinels from the sandstones of the Oštrc Formation Cr# values range from 0.39 up to 0.81, mostly (88%) between 0.50 and 0.70. Only 2% of the analysis fall below 0.45 (all of these coming from only one of the seven Oštrc samples). The Mg# displays a relatively wide range, from 0.37 to 0.76. Of the analyzed grains, 28% display TiO<sub>2</sub> concentrations above 0.2%. It is interesting to note that a few of the grains display high TiO<sub>2</sub> concentrations, up to 2.17%. When the residual spinels alone (<0.2 % TiO<sub>2</sub>) are plotted on the Cr# vs. Mg# diagram (Fig. 4), most of the data fall within the harzburgite field defined by Pober and Faupl (1988). Following the classification of Dick and Bullen (1984), they resemble Type II alpine-type peridotites which are thought to evolve through a complex multistage melting history as may be encountered in a subduction zone. The high Ti magmatic spinels (>0.2 % TiO<sub>2</sub>) display a shift towards lower Mg#, as in the Fe-Ti trend of Barnes and Roeder (2001). Their similar range of Cr# values to the residual spinels (with a tendency towards higher Cr#), high Fe<sup>3+</sup> and TiO<sub>2</sub>, along with lower Mg# suggests that these spinels could be the products of fractional crystallization and re-equilibration at lower temperatures due to slow cooling (Arai 1992; Kamenetsky *et al.*, 2001), and thus probably derived from cumulate members containing disseminated Cr-spinel of the same ophiolite source (Dick and Bullen 1984; Pober and Faupl 1988; Barnes and Roeder 2001). On the Al<sub>2</sub>O<sub>3</sub> vs. TiO<sub>2</sub> discrimination diagram (Fig. 5) proposed by Kamenetsky *et al.*, (2001), the residual spinels concentrate in the middle of the field of suprasubduction zone peridotites. Meanwhile, the

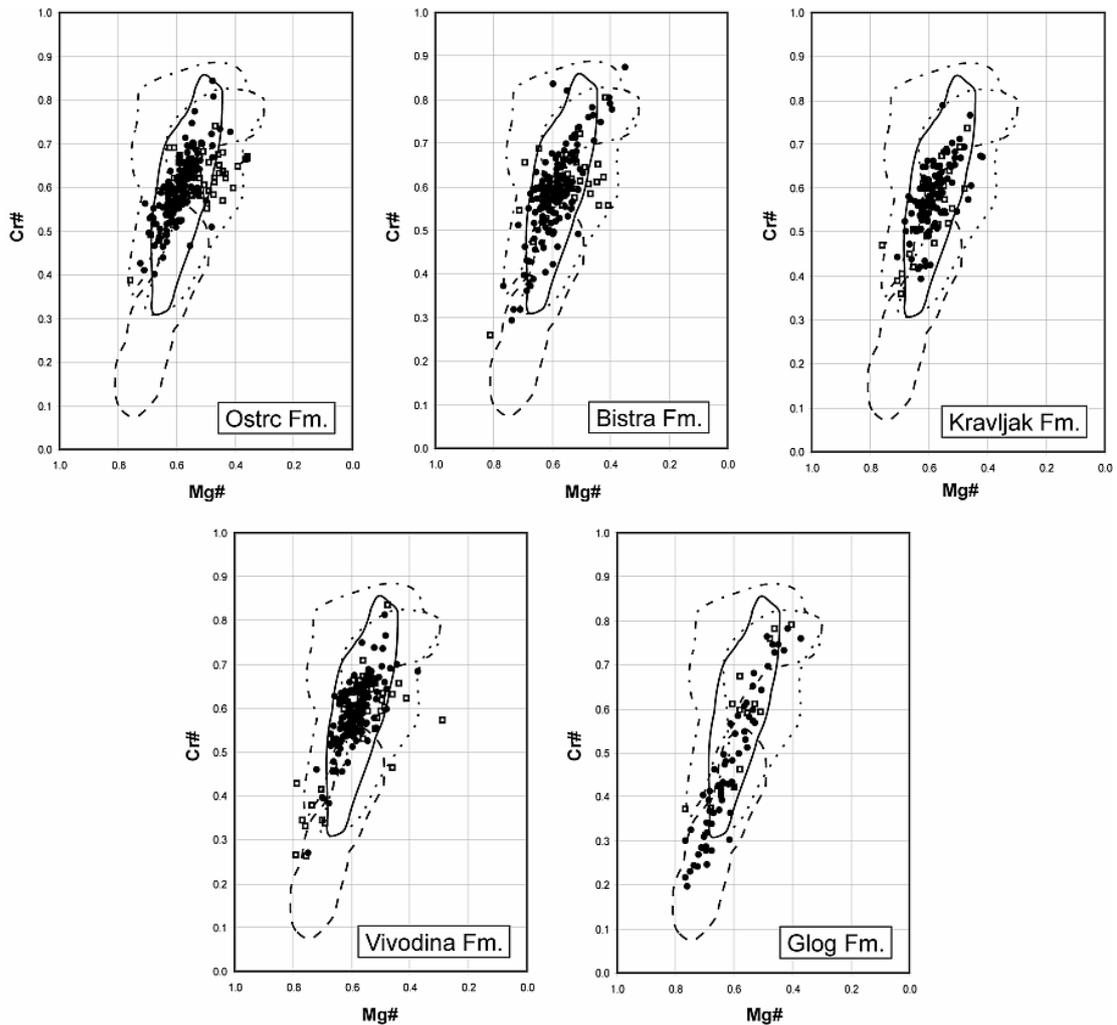

magmatic spinels fall within fields defining volcanic rocks from different settings, but mostly group in the border region between MORB and arc basalts. The same can be observed on the  $\text{TiO}_2$  vs.  $\text{Fe}^{3+\#}$  diagram when comparing the data with compositional fields proposed by Arai (1992). Several grains display compositions such as those found in ocean island basalts (i.e. intra-plate basalts).

### *3.4.2. Bistra Formation*

Generally, high-Cr harzburgitic spinels predominate in the Early Cretaceous Bistra Fm. (Fig. 4), although the Cr# ranges differ noticeably between the three studied samples. Sample 05-H/B-201 contains spinels with Cr# above 0.50. A single outlier is a relatively high-Al spinel with a Cr# as low as 0.30. Similar to the spinels of the Oštrc Fm., the residual spinels of sample 05-H/B-201 fall predominantly within the harzburgite field, while the magmatic spinels display higher Cr# and shift towards lower Mg# values. Spinel from sample 05-H/B-216 have Cr# values above 0.40. Unlike in the two previous samples, in sample 05-H/B-207 Cr# values spread in a wider range, from 0.26 to 0.87. The proportion of magmatic spinels is also variable among the three studied samples (24%, 13% and 19%). Overall, the variability between the samples suggests that the source area was rather heterogeneous and included small exposures of less depleted residual peridotites and magmatic rocks.

### *3.4.3. Kravljak Formation*

The Cr-spinels from sandstones of the Albian-Cenomanian Kravljak formation display a range of Cr# values from 0.36 to 0.79, with only 2% of the data falling below 0.40. Most of the grains (83%) cluster within the 0.50-0.70 Cr# range, falling predominantly within the harzburgite field (Fig. 4). 24% of the spinels can be classified as magmatic, the maximum recorded  $\text{TiO}_2$  being 1%. On the  $\text{Al}_2\text{O}_3$  vs.  $\text{TiO}_2$  diagram most of the spinels fall within the field of suprasubduction peridotites, while the magmatic grains fall predominantly in the MORB field (Fig. 5).

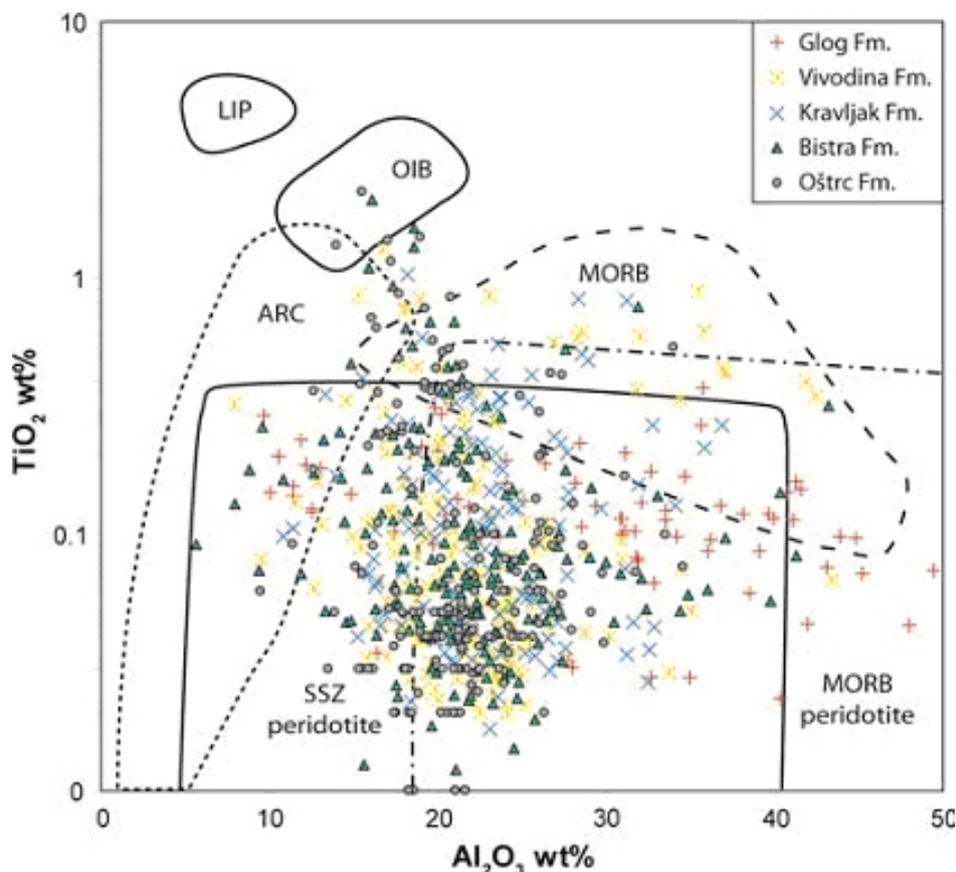

**Fig. 4.** Cr# vs. Mg# diagrams of Cr-spinels from each formation. Fields after Pober and Faupl (1988). *full line* harzburgites, *dashed line* lherzolites, *dotted line* cumulates, *dash-dot* podiform chromites, *full circles* spinels with  $<0.2\%$   $\text{TiO}_2$ , *open squares* spinels with  $>0.2\%$   $\text{TiO}_2$ .

#### 3.4.4. Vivodina Formation

In the Maastrichtian Vivodina Formation Cr-spinels display a wide range of Cr# and Mg# values (0.26-0.84 and 0.29-0.79, respectively), but concentrate (85%) within the 0.5-0.7 Cr# range like in the other formations. 20% of the spinels classify as magmatic. These high  $\text{TiO}_2$  spinels concentrate in two groups on the Cr#-Mg# diagram (Fig. 4). The first group is characterized by high Cr# and low Mg#, very similar to those identified as cumulate spinels in the older formations (Ostrc, Bistra and Kravljak Fms.). The second group, however, displays low Cr# and higher Mg#, which is a characteristic

of Cr-spinels identified in abyssal basalts (Dick and Bullen 1984). On the  $\text{Al}_2\text{O}_3$  vs.  $\text{TiO}_2$  diagram, these tend to fall within the MORB field (Fig. 5). The residual spinels group in the middle of the suprasubduction zone field of the same diagram, as in the samples from the older three studied formations.

**Fig. 5.**  $\text{TiO}_2$  vs.  $\text{Al}_2\text{O}_3$  diagram with Cr-spinel data from all five formations. Fields after Kamenetsky *et al.*, (2001). MORB mid-ocean ridge basalt, OIB ocean-island basalt, LIP large igneous province, ARC island-arc magmas, SSZ supra-subduction zone.

### 3.4.5. Glog Formation

Of all the studied samples, the Cr-spinels from the Glog Fm. display the greatest range of Cr# values (0.2-0.79). The Cr# values spread continuously across the entire range (Fig. 4), lacking the predominance of high-Cr spinels identified in the other formations. The proportion of grains with  $\text{TiO}_2$  content above 0.2% is 16%. The highest recorded  $\text{TiO}_2$  content is 0.36%, much lower than in the other formations.

### 3.5. Provenance and paleogeographic relations

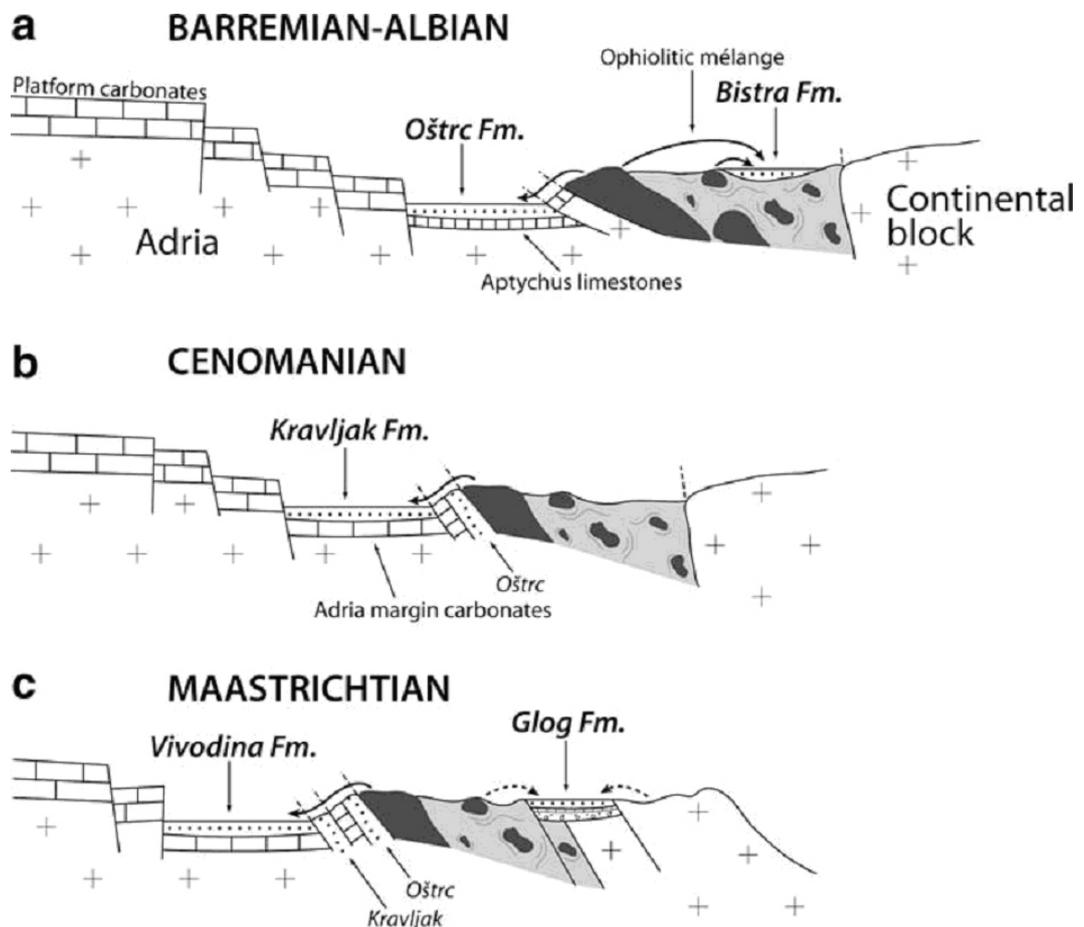

Following the Tithonian-Hauterivian period, which was marked by widespread deposition of deep marine *Aptychus* limestones and marls, the closure of the western Tethys Ocean triggered a strong influx of siliciclastic material onto the passive margin of the Adriatic plate. This change in sedimentary regime is evident on Mt. Ivanščica, where from the Barremian up to the Albian deep marine clastic sediments rich in ophiolitic detritus (Oštrc Fm.) were deposited on top of pelagic limestones (Fig. 6a). Considering the ubiquity of ophiolitic lithoclasts and Cr-spinel, a source area consisting primarily of obducted ophiolites must have come into close proximity of the Oštrc Basin (Zupanič *et al.*, 1981; Babić *et al.*, 2002). The chemical compositions of the Cr-spinels (Fig. 4) indicate that these exposed ophiolites consisted mostly of harzburgitic peridotites and associated cumulate rocks, i.e. oceanic mantle and lower crustal rocks. The eroded mantle peridotites underwent a considerable degree of partial melting prior to their obduction, above the limit normally achieved at mid-oceanic ridges (Dick and Bullen 1984), and instead likely evolved in a supra-subduction zone setting. These characteristics of the source area apparently did not change significantly during continuous erosion and deposition of the Oštrc Fm., as no systematic change in Cr-spinel composition is detected among the seven studied samples.

In addition to Mt. Ivanščica, Early Cretaceous formations containing abundant ophiolitic detritus are well known in the Northern Calcareous Alps (NCA; Rossfeld Fm.) and the Transdanubian Central Range (Gerecse Mts.). Facies and petrologic similarities among these sedimentary successions have been recognized by previous authors (e.g. Decker *et al.*, 1987; Faupl and Wagreich 1992; Császár and Árgyelán 1994), and a common provenance, the suture zone of the Tethys Ocean has been suggested (Poher and Faupl 1988; Árgyelán 1996; Babić *et al.*, 2002). A comparison of Cr-spinel data from all three areas (Fig. 7) lends support for a common provenance of the ophiolitic material. Although they are today separated by hundreds of kilometers due to Tertiary tectonic displacement, during the Mesozoic the NCA and the Transdanubian Central Range sat adjacent to one another along the Tethyan passive margin (Kázmér and Kovács 1985; Schmidt *et al.*, 1991; Vörös and Galács 1998). During this time Mt. Ivanščica probably held a more southerly position and may represent an important link to the Inner Dinaride realms. A rather extensive ophiolite belt containing large harzburgite bodies, capable of providing large quantities of detritus over a regional scale, may have ex-

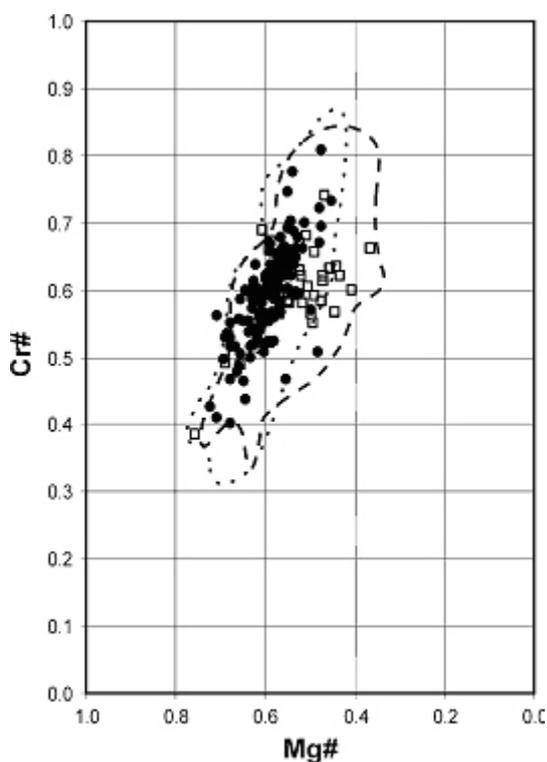

tended during the Early Cretaceous along the Adriatic margin, from the area of the NCA in the north to the Dinarides (Fig. 8). Today, in the surroundings of the northernmost Dinarides and in the East Alpine-Carpathian region there are no major exposures of mantle rocks. They are restricted to smaller dismembered occurrences mostly within mélangé complexes of the Sava Zone (Pamić 1997; Slovenec and Pamić 2002), the Alps and the Western Carpatians (Kozur 1991). Large ultramafic bodies are exposed in the CDOZ, in places occurring as several kilometers thick slices of oceanic lithosphere (e.g. Pamić *et al.*, 2002). From the peridotites of the two major zones in the Inner Dinarides, Maksimović and Majer (1981) reported both high-Cr (common to the Vardar Zone) and low-Cr spinels (common to the CDOZ), but in fact there is likely to be a gradual transition in the degree of depletion of the mantle rocks within these zones (Pamić 1983). The northwesternmost peridotites of the CDOZ, such as those occurring in the Banija region, south of the study area, are lherzolitic with low-Cr spinels (Maksimović and Majer 1981), ruling them out as potential remnants of the obducted ophiolites which supplied the Oštrc Fm. Although the ophiolites of the CDOZ were already obducted in the Early Cretaceous (Pamić *et al.*, 2002; Robertson and Karamata 1994), detritus produced by their erosion was not transported into the Oštrc Basin. Rather, a connection to the Vardar Zone, where harzburgites predominate, is more conceivable (Fig. 8). The unusual spread in the Al content of the high-Ti spinels in some of the studied formations (Fig. 5) may be suggestive of a back-arc basin origin of the magmatic rocks from which some of these grains are derived from (Arai 1992; Kamenetsky *et al.*, 2001).

The ophiolite source supplying most of the detritus of the Early Cretaceous Bistra Fm., exposed on Mt. Medvednica, was mostly similar in composition to that supplying the Oštrc Fm. in that high-Cr spinels dominate. Babić *et al.*, (2002) suggested that the Bistra Fm. developed as a shallow basin on top of the ophiolitic mélangé (Repno complex) whose remnants occur in the N part of Mt. Medvednica. Serpentinized harzburgites as well as cumulate ultramafics with relatively high-Cr spinels are present as smaller tectonized blocks within this mélangé (Šimunić and Pamić 1989; Slovenec and Lugović 2000) and may have presented a potential source (Fig. 6a). The variability encountered among the individual samples of the Bistra Fm. may reflect the smaller catchment area of the shallow marine environment and the heterogeneous nature of the mélangé, which incorporated ophiolite fragments of slightly varying composition.

The supply of Cr-spinels from ophiolites with the same chemical signature as those supplying the Oštrc Fm. continued at least until the latest Cretaceous along the NE margin of the Outer Dinarides, as evident from the data obtained from the Kravljak and Vivodina Fms. Recycled Cr-spinels from older sedimentary formations being incorporated into propagating nappes (e.g. the Oštrc) may have represented an important source (Fig. 6b and 6c). However, the presence of ophiolite-derived lithoclasts and a relatively high proportion of Cr-spinels in the heavy mineral fraction of the Vivodina sandstones (up to 70%; Zupanič *et al.*, 1981) suggest that exposed remnants of the above mentioned ophiolite belt persisted along the margin of the Adriatic plate at least until the end of the Cretaceous (Fig. 6b and 6c).

**Fig. 6.** Schematic cross-sections portraying the Cretaceous tectonic evolution of the study area and the major sources of Cr-spinels (thick black arrows) for the five studied formations. See text for details.

**Fig. 7.** A comparison of the data from the Oštrc Fm. with those published for the Rossfeld Fm., Northern Calcareous Alps (dashed line) and Gerecse Mts., Transdanubian Central Range (dotted line). Full circles = spinels with  $<0.2\%$   $\text{TiO}_2$ ; open squares = spinels with  $>0.2\%$   $\text{TiO}_2$ .

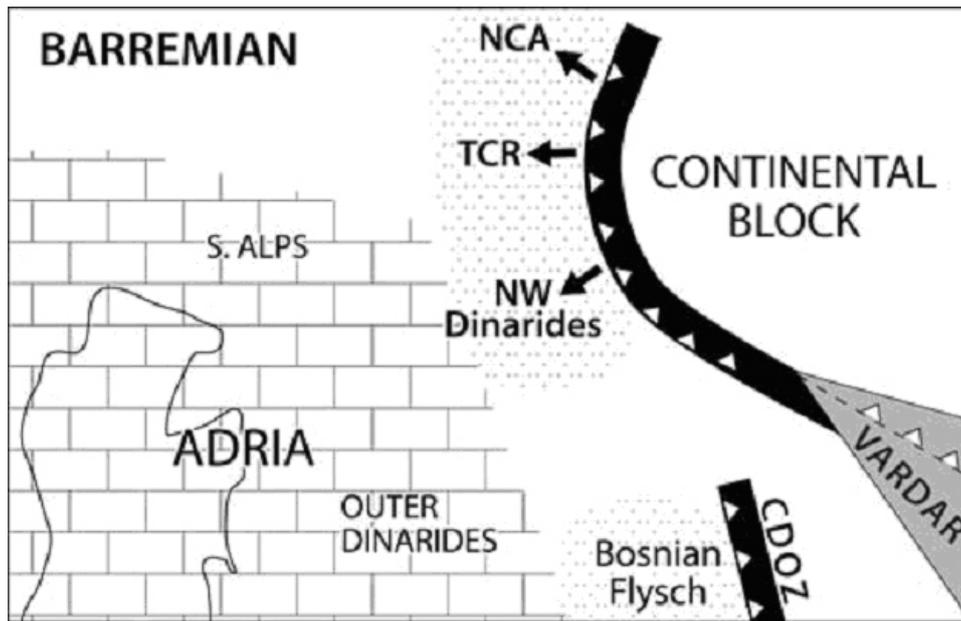

detritus in the Glog sandstones originated from an entirely continental hinterland probably composed of the sedimentary-metamorphic complex of Mt. Medvednica (Crnjaković 1979). The dominant availability of felsic continental lithologies for erosion in the source area likely accounts for the small proportion of Cr-spinel in the HM spectra of Glog sandstones. The differences in Cr-spinel chemistry of the coeval Vivodina and Glog formations can be reconciled by the erosion of a heterogeneous ophiolite mélange source containing peridotite blocks of different degrees of depletion (Fig. 6c). Together with contrasting heavy mineral data and differences in the underlying lithology, these results suggest the coeval existence of two separate basins.

Although the supply of high-Cr spinels prevailed in general, a slight trend of increasing variation in the Cr# (among both residual and magmatic spinels) is noticeable from the Early to the latest Cretaceous, suggesting that the source areas became more heterogeneous with the ongoing Cretaceous tectonic evolution of the Dinaride-Alpine

An additional source of Cr-spinels is recorded in the Maastrichtian. A number of grains in the Maastrichtian Vivodina sandstones (Fig. 4 and 5) have compositions similar to those reported for abyssal/MORB basalts (Dick and Bullen 1984; Kamenetsky *et al.*, 2001). Lenaz *et al.*, (2000) obtained very similar results from Cr-spinels in the Maastrichtian to Middle Eocene sediments of the Julian Basin in the Southern Alps (Fig. 1), which imply a possible common provenance and a paleogeographic connection between the Julian and Vivodina basins.

The presence of many low-Cr# spinels in the Glog Fm. requires a separate source from that which supplied the other formations examined. The Glog Fm. belongs to a Senonian succession lying on a tectonized basement (Fig. 6c), presumably deposited in a piggy-back basin (Babić *et al.*, 2002). The

region. Pober and Faupl (1988) and von Eynatten (1996) identified a trend of increasing lherzolitic component from Early to Late Cretaceous among sedimentary formations of the NCA and the Drauzug which had a “southern provenance”, i.e. sourced by the Tethys suture (Rossfeld Fm., Lavant Fm. and parts of the Gosau-type sediments).

**Fig. 8.** Paleogeographic sketch map of the Dinaride-Alpine region during the Barremian. NCA = Northern Calcareous Alps; TCR = Transdanubian Central Range; CDOZ = Central Dinaride Ophiolite Zone.

### 3.6. Conclusions

1. Detrital Cr-spinel grains in the Early Cretaceous Oštrc Formation on Mt. Ivanščica display relatively high Cr#. The ophiolite source consisted of harzburgitic mantle peridotites and associated cumulate rocks which developed in a supra-subduction zone setting.

2. There is a similarity in detrital Cr-spinel compositions between the Oštrc Fm. and those reported from contemporaneous formation in the NCA and the Transdanubian Central Range. A rather extensive harzburgitic ophiolite belt, capable of providing large quantities of detritus over a regional scale, probably extended along the Adriatic margin during the Early Cretaceous, from the area of the NCA in the north to the northernmost Dinarides.

3. The supply of Cr-spinels high in Cr# remained dominant throughout the Cretaceous. A likely source were exposed remnants of the W Tethyan ophiolite belt, while recycling from Early Cretaceous sediments also played an important role.

4. The Cr-spinels from the Maastrichtian Glog Fm. on Mt. Medvednica were derived from a source of different composition as compared to the contemporaneous Vivodina Fm. in the Žumberak Mts. Together with contrasting heavy mineral data and differences in the underlying lithologies, these results imply the coeval existence of two separate basins.

5. The source areas became more heterogeneous with the ongoing Cretaceous tectonic evolution, which is suggested by the increasing variation in the Cr# of Cr-spinels from the Early to the latest Cretaceous.

## **Abstract**

Three independent single-grain geochronometers applied to detrital minerals from Central Dinaride sediments constrain the timing of felsic magmatism that associated the Jurassic evolution of the Neotethys. The Lower Cretaceous clastic wedge of the Bosnian Flysch, sourced from the Dinaride ophiolitic thrust complex, yields magmatic monazite and zircon grains with dominant age components of  $164 \pm 3$  Ma and  $152 \pm 10$  Ma, respectively. A unique tephra horizon within the Mesozoic Adriatic Carbonate Platform was dated at  $148 \pm 11$  Ma by apatite fission track analysis. These consistent results suggest that leucocratic melt generation in the Central Dinaride segment of the Neotethys culminated in Middle to Late Jurassic times, coeval with and slightly post-dating sub-ophiolitic sole metamorphism. Monazite growth and explosive volcanism call for supra-subduction zone processes at the convergent Neotethyan plate margin. New compilation of geochronological data demonstrates that such Jurassic felsic rocks are widespread in the entire Dinaride-Hellenide orogen.

#### 4.1. Introduction

A characteristic element of the Dinaride-Hellenide orogen of SE Europe is an extensive, complex belt of Jurassic ophiolites, representing the obducted remnants of the Neotethys ocean (Fig. 1). The parallel map appearance of two belts of ophiolitic units (Dimitrijević and Dimitrijević, 1973) gave rise to a vigorous debate on their relation. Models include the existence of two oceanic basins, either separated by an intraoceanic "microcontinent" (Robertson and Karamata, 1994; Karamata *et al.*, 2006), or opened consecutively in an arc/back-arc system (Pamić *et al.*, 2002). Alternatively, a single oceanic basin is proposed, the fragments of which were emplaced as ophiolite thrust sheets to different distances onto the overridden continental plate (Kober, 1912; Bernoulli and Laubscher, 1972; Schmid *et al.*, 2008). Although now there is consensus that oceanic convergence was not associated with significant island arc igneous activity (Ivanov *et al.*, 1987; Pamić *et al.*, 2002; Dimitrijević *et al.*, 2003), an increasing number of petrological and geochemical data point to island arc affinity in the Dinaride ophiolites, and also in other equivalent ophiolite sequences in Albania, in the Hellenides and in the Bükk and Apuseni Mts. The island arc signatures are explained by the development of an intra-oceanic supra-subduction-zone (SSZ), the remains of which now preferentially occur as the "eastern" ophiolites (e.g. Aigner-Torres and Koller 1999; Robertson, 2004; Beccaluva *et al.*, 2005; Bortolotti and Principi 2005; Bazylev *et al.*, 2006; Lugović *et al.*, 2006; Rassios and Moores 2006; Smith 2006; Dilek *et al.*, 2008).

Felsic magmatic rocks invariably associate the ophiolite sequences. Although small in volume, they are widespread in the Dinarides-Hellenides and their tectonically displaced units, such as the Apuseni Mts. and the Gemer-Bükk Unit (Fig. 1). They can be subdivided into three major genetic groups; (1) oceanic plagiogranites, generated at the region of mid-ocean spreading and at the SSZ (Majer and Garašić, 2001; Beccaluva *et al.*, 2005; Dilek *et al.*, 2008); (2) calc-alkaline magmatic suites at an immature island arc (Máthé and Szakmány, 1990; Bortolotti *et al.*, 2004; Dilek *et al.*, 2008); and (3) anatexis of gabbro, amphibolite and sediments of the subducted slab beneath the overriding hot oceanic plate (Pearce, 1989; Koepke *et al.*, 2007). K/Ar, Ar/Ar and Sm/Nd geochronological data of sub-ophiolitic metamorphic soles range between 178 and 161 Ma, marking the Middle Jurassic onset of intra-oceanic subduction (e.g. Okrusch *et al.*,

**Fig. 1.** Tectonic framework of the the Carpatho-Pannonian-Dinaride-Hellenide area showing the distribution of Jurassic Neotethyan ophiolites and other major tectonic units. Position of felsic magmatic bodies associating the ophiolites is indicated by numbers, as referred to in Table 1 and Fig. 8. Only dated occurrences were included. Map compiled after Jacobshagen, 1986; Papanikolaou, 1997; Csontos and Vörös, 2004; and Schmid *et al.*, 2008.

**Table 1.** Published radiometric age data from felsic magmatic rocks associating Neotethyan ophiolites of the Carpatho-Pannonian-Dinaride-Hellenide orogen. Early Cretaceous apparent ages are also included whenever local geologic context suggests a slightly older crystallization age. Refer to Fig. 8 for a graphical overview of the these data. n.s.: not specified in the cited work; wr: whole-rock; plag: plagioclase, cel: celadonite, CL: cathodoluminescence-controlled in-situ dating; ŽOC: Ždraljica Ophiolite Complex; DGC: Demir Kapija–Gevelija Ophiolite Complex. Numbered comments: (1) 11.4 ± 4.5 Ma whole-rock K/Ar age (Arva-Sós *et al.*, 1987); (2) 92.9 ± 3.7 < 2 μm sericite K/Ar age (*ibid*); (3) single-grain, step heating experiment; (4) single-grain, multiple spot fusion experiment; (5) multigrain, step heating experiment; (6)–(9) corrected from 156 ± 3 Ma, 168 ± 7 Ma, 150 ± 2 Ma and 150 Ma respectively, by Spray *et al.*, (1984), using the decay constant by Steiger and Jäger (1977).

1978; Spray *et al.*, 1984; Dimo-Lahitte *et al.*, 2001; Olker *et al.*, 2001; Chiari *et al.*, 2003; Smith 2006).

Here we present the results of detrital monazite and zircon geochronology and apatite fission track (FT) thermochronology from Central Dinaride Mesozoic sediments genetically linked to Neotethyan evolution, and use these data to further constrain the existence and timing of Jurassic subduction. We also review complementary geochronological data from other segments of the Neotethyan ophiolites.

#### **4.2. Geological setting of the sampled units**

Intensely folded, the Mesozoic '*Zone Bosniaque*' sediments (Aubouin *et al.*, 1970) are tectonically sandwiched into the SW-vergent Dinaride thrust system (Fig. 1). They are overlain by Neotethyan ophiolite thrust sheets floored by continental basement nappes of the Adriatic plate (Aubouin, 1973; Schmid *et al.*, 2008), and overlie the large Adriatic Carbonate Platform (AdCP – Vlahović *et al.*, 2005). The '*Zone Bosniaque*' includes a thick Late Jurassic to Cretaceous flysch sequence sourced from the upper plate complex (Aubouin 1973; Mikes *et al.*, 2008b). Recently, its Early Cretaceous part (Vranduk Formation) revealed heavy mineral associations including zircon and minor monazite. The zircon U/Pb age spectra comprise a Late Jurassic age population (Mikes *et al.*, 2008b).

The AdCP is a Late Palaeozoic to Paleogene carbonate-dominated platform attaining 8-10 km in thickness (Vlahović *et al.*, 2005). It formed the SW basin margin during the Mesozoic evolution of the '*Zone Bosniaque*', and was converted into the tectonic footwall of the Outer Dinaride thrust pile during Tertiary compression (Fig. 1; Aubouin *et al.*, 1970; Chorowicz, 1977; Charvet, 1980; Tari, 2002; Mikes *et al.*, 2008a; Schmid *et al.*, 2008). Late Jurassic sequence of the AdCP is distinguished by its felsic tephra intercalations ('*Lemeš-Schichten*', Furlani, 1910; Šćavničar and Nikler, 1976). Pelagic fossils indicate a Kimmeridgian to Lower Tithonian age for this horizon (Ziegler, 1963; Chorowicz and Geysant, 1972; Vlahović *et al.*, 2005).

### 4.3. Analytical methods

Accessory minerals were separated from three medium-grained sandstone samples in the Vranduk Fm. and from a fresh, friable felsic tephra sample of Lemeš. Sampling localities are shown in Fig. 1 and listed in Appendix 4-4. Methods of preparation, analysis and data processing for in-situ zircon U/Pb geochronology were outlined in detail by Frei and Gerdes (2008) and Mikes *et al.* (2008b). Procedures of apatite FT analysis followed Dunkl *et al.* (2001). Total (Th-U)/Pb geochronology of monazite was carried out in-situ by electron microprobe analysis (Montel *et al.* 1996; Jercinovic *et al.*, 2008). Five to ten spots were placed on homogeneous internal domains in each monazite grain, to reduce age uncertainty (Williams *et al.*, 2006). In the absence of age mapping (Williams *et al.*, 1999; Goncalves *et al.*, 2005), this approach helped reducing the risk of analyzing volumes that consist of different age domains. Details of the analytical procedure, age calculation, error treatment and age deconvolution are provided in Appendix 4-5. Elemental detection limits (d.l.) are quoted at the 3 $\sigma$  level throughout.

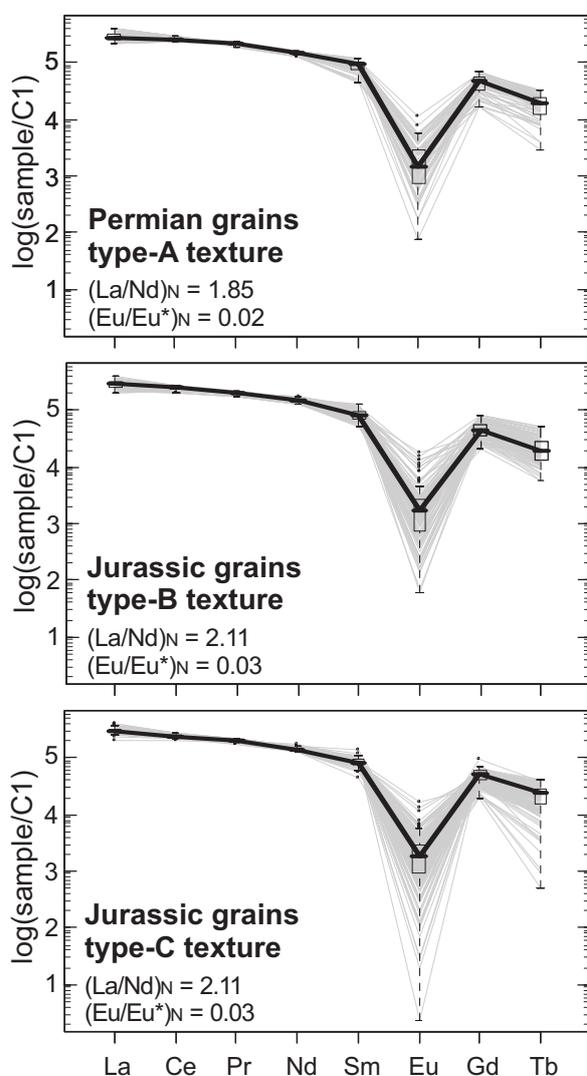

### 4.4. Results

#### 4.4.1. Monazite dating

A total of 496 single-spot total (Th-U)/Pb age datum was acquired on 79 grains from three samples. Analytical results are listed in Appendix 4-2. Only little inter-sample difference was noticed in chemistry and texture, thus the results are discussed together.

ThO<sub>2</sub> concentrations are typically in the range between 3 and 7 wt%, with UO<sub>2</sub> generally not exceeding 0.8 wt%. About 95% of the measured Pb contents range from 186 to 835 ppm, significantly above the d.l. of ca. 90 ppm. Most Eu concentrations do not exceed 800 ppm (d.l.: 270 ppm), Sr was below d.l. (120 ppm). Chondrite-normalized rare earth element (REE) concentrations show a slight decrease from light REE to middle REE. All grains with Eu above d.l. display a strong negative Eu-anomaly with Eu/Eu\* mostly around 0.02 and invariably <0.3 (Fig. 2). Y<sub>2</sub>O<sub>3</sub> concentrations vary in a wide range from 0.14 to 5.3 wt%, although they are more restricted in the Permian grains (Fig. 3).

The analyses define two well-separated age populations (Fig. 4, Table 2): a predominant Middle/Late Jurassic group with a total (Th-U)/Pb age of  $164 \pm 3$  Ma; and a minor Early/Middle Permian group with a total (Th-U)/Pb age of  $274 \pm 13$  Ma.

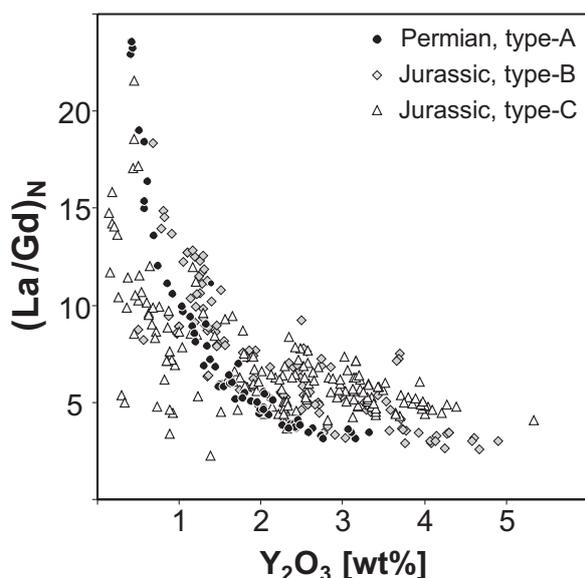

**Fig. 2.** Chondrite-normalized REE patterns of the detrital monazite grains. Plots subdivided on the basis of grain age and textural assignment (see Fig. 5). Grey lines connect all single spots, black line represents their median. Boxes and whiskers comprise the central 50% and 95% of the data, respectively. Note that in ca. two-thirds of the analyses, Eu was below the d.l. (ca. 270 ppm). This implies that the actual overall range of the Eu anomaly in these detrital grains can be a few orders of magnitude larger than displayed. La/Nd and Eu/Eu\* are median values. Chondrite composition taken from Taylor and McLennan, 1985.

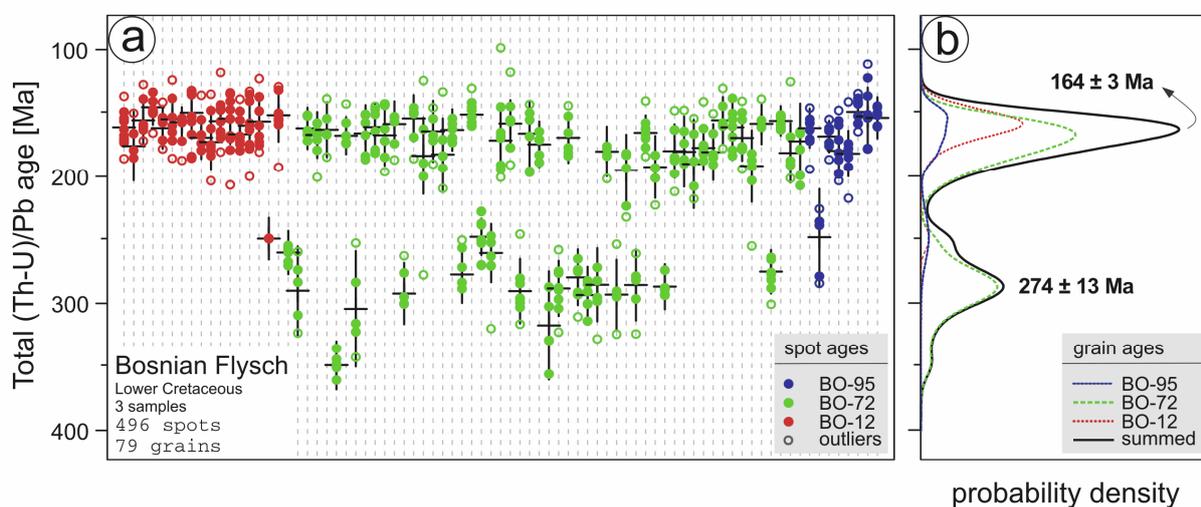

The BSE images reveal several distinct texture types, mainly controlled by Th and Y distribution (Fig. 5). Type A is distinguished by slightly rounded crystals, with very fine oscillatory zoning combined with sector growth, the sector boundaries often being slightly diffuse. Type B grains are euhedral and exhibiting a composite zoning of large internal domains with homogeneous intensity distribution and sharp boundaries, surrounded by simple, oscillatory zoned rims. Type C also comprises euhedral grains but with a complex patchwork of irregular, curvilinear to flame-like domains in grain interiors. This latter texture is suggestive of fluid-controlled dissolution-precipitation processes following monazite growth (Putnis, 2002; Harlov *et al.*, 2007). BSE images allow to examine a possible relationship between age data and textural patterns.

Type A grains typically yielded Permian dates, whereas most Type B and C grains gave Jurassic dates. The ages neither show an obvious interrelation with the degree of textural disturbance, nor with spot position in the grain. This suggests either the interaction of monazite with fluids of low (epidote-amphibolite facies) maximum tempera-

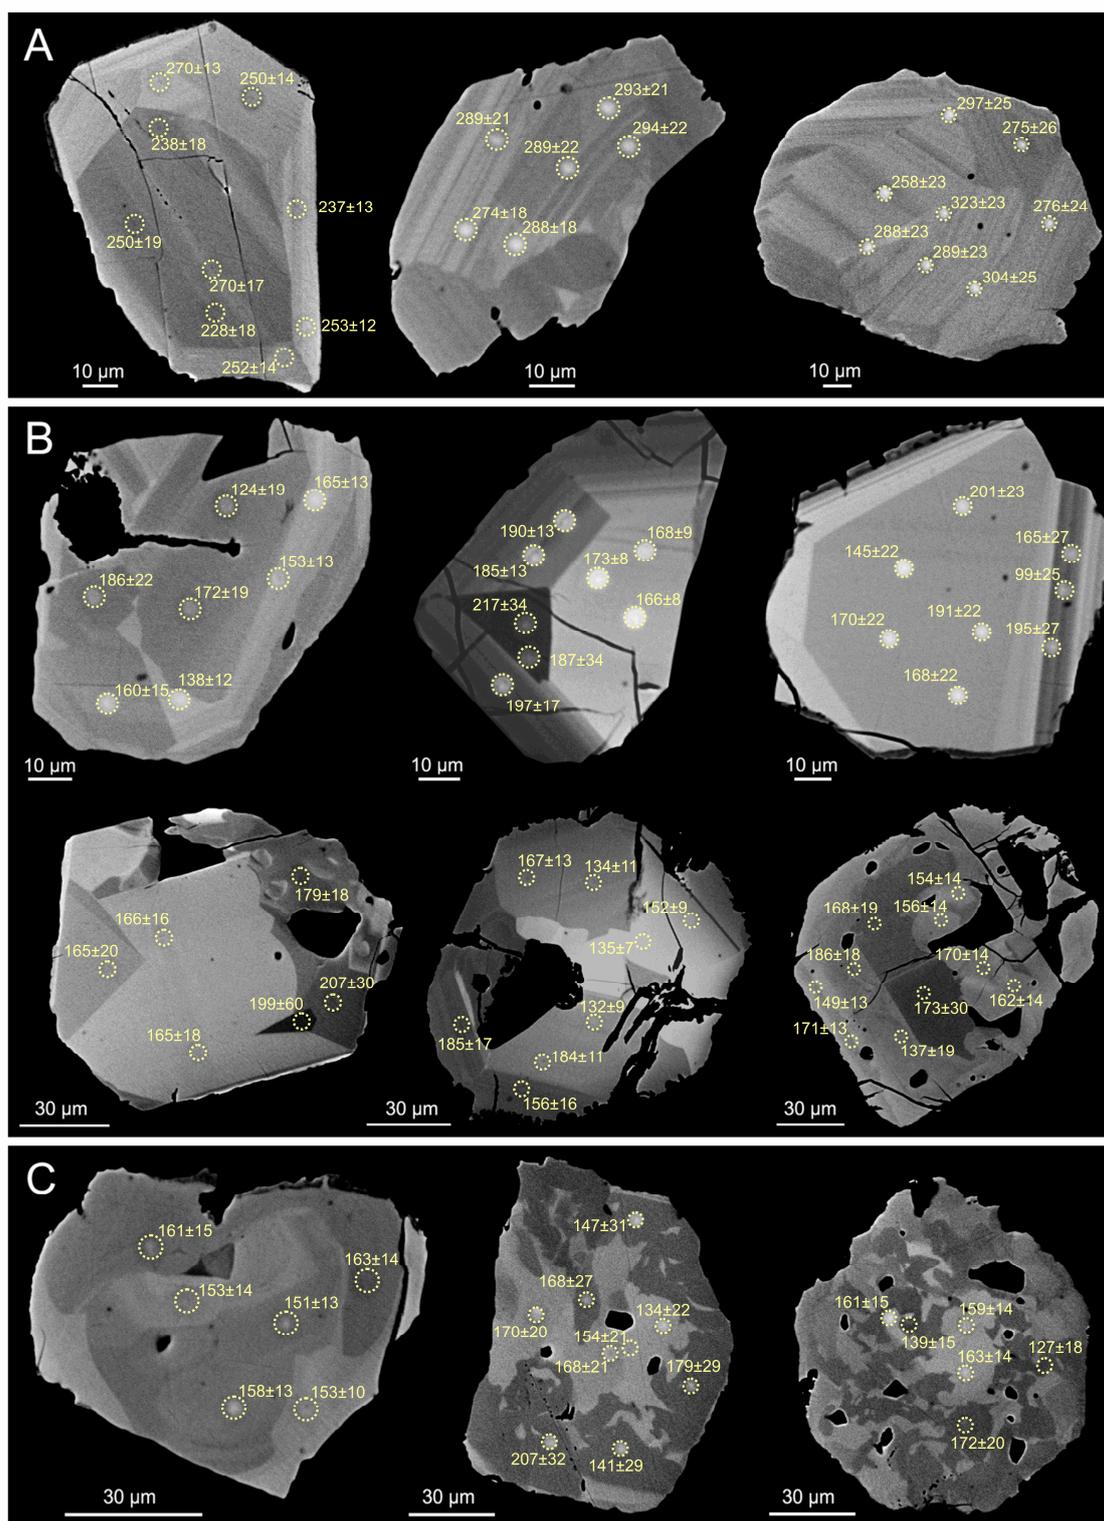

tures, leaving its Th-U-Pb element systematics largely undisturbed after crystallization (Teufel and Heinrich, 1997; Seydoux-Guillaume *et al.*, 2002, 2004), or points to a higher-temperature, high-pH autometasomatic overprint that resulted in (Th-U)/Pb ages indistinguishable from those of the undisturbed crystals (Harlov *et al.*, 2007; Koepke *et al.*, 2007).

**Fig. 3.** Chondrite-normalized La/Gd ratios as a measure of light REE fractionation, plotted against  $Y_2O_3$  concentrations. Symbols subdivided on the basis of grain age and textural assignment (see Fig. 5). Note the difference in REE behaviour between the age populations. Chondrite composition taken from Taylor and McLennan, 1985.

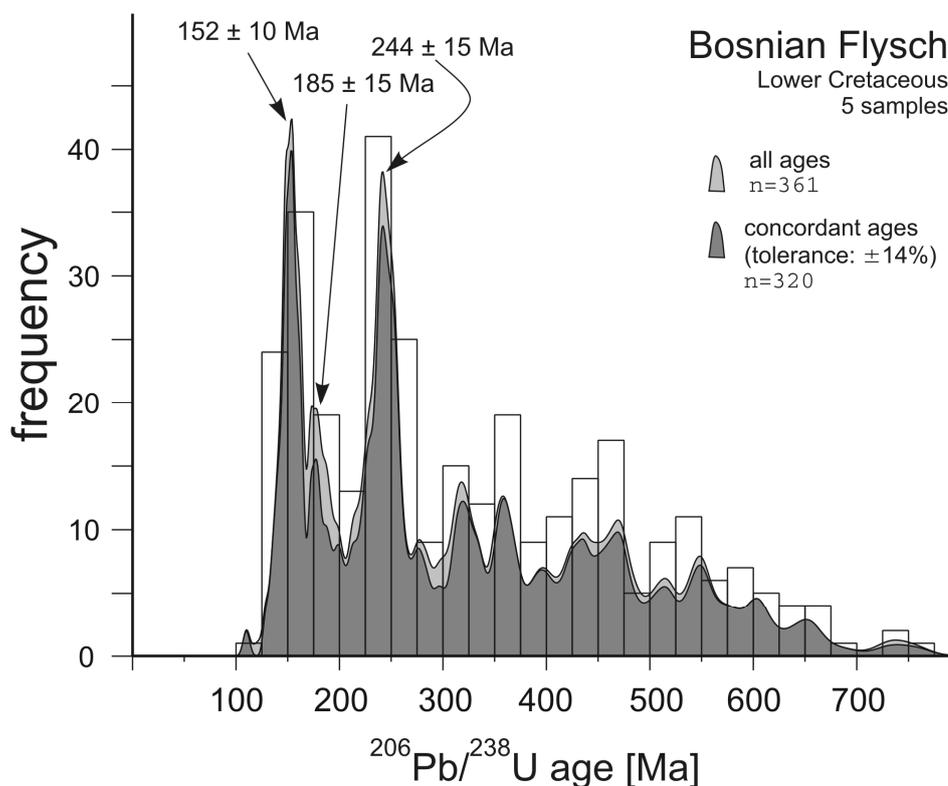

**Fig. 4.** EPMA (Th-U)/Pb chemical age distribution of detrital monazite grains from the Lower Cretaceous Vranduk Formation of the Bosnian Flysch. **(a)** Dot-chart showing individual spot ages, arranged vertically for each grain. Single grain ages were calculated by the weighted average of all spot ages passing the Grubbs-test (see electronic supplement for details). Thin vertical bars:  $2\sigma$  confidence interval around the mean grain ages (horizontal marks). **(b)** Single-grain age distribution and the most probable ages ( $\pm 2\sigma$  s.e.) for both the Jurassic and Permian populations. Refer to Table 2 and Appendix 4-6 for details of age deconvolution.

**Fig. 5.** Characteristic textural patterns of the detrital monazite grains as revealed by back-scattered electron imaging. Spot ages (in Ma,  $\pm 2\sigma$  s.e.) are also shown. **Type A:** subangular grains with fine oscillatory zoning locally combined with sector growth. Sector boundaries are usually slightly diffuse. This texture type is typical for most grains dated as Permian. **Type B:** mostly euhedral grains exhibiting a composite zoning of large internal domains with homogeneous intensity distribution and mostly sharp boundaries, surrounded by simple, oscillatory zoned rims. **Type C:** mostly euhedral grains with complex patchwork of irregular, rounded to flame-like domains, suggestive of fluid-controlled dissolution-precipitation processes after monazite growth. Grains of texture types (B) and (C) typically yielded Jurassic ages. No correlation was found between the intensity of textural disturbance and the variance of spot ages.

#### 4.4.2. Zircon U/Pb geochronology

Oscillatory zoning and euhedral crystal shape was indicated by a BSE survey prior to the dating procedure. Age results from the Vranduk Fm. sample are listed in Appendix 4-3. In the following, we evaluate these data together with another detrital zircon U/Pb dataset from the same stratigraphic unit (Mikes *et al.*, 2008b). 89% of the single-grain ages are within  $\pm 14\%$  of concordance with their propagated  $2\sigma$  standard errors, with the summed  $^{206}\text{Pb}/^{238}\text{U}$  age spectrum of 361 grains from five samples revealing a broad scatter in zircon age distribution (Fig. 6). At least two age clusters characterize the dataset; a Late Jurassic and a Permo-Triassic group with their modi around 152 and 245 Ma, respectively. Each of them accounts for about 20% of all dated crystals. A minor but probably distinct Early/Middle Jurassic population around 185 Ma partly overlaps the Late Jurassic population (Fig. 6, Table 2). Age distributions of individual samples are comparable, although one out of five samples does not contain a significant Jurassic population (Mikes *et al.*, 2008b).

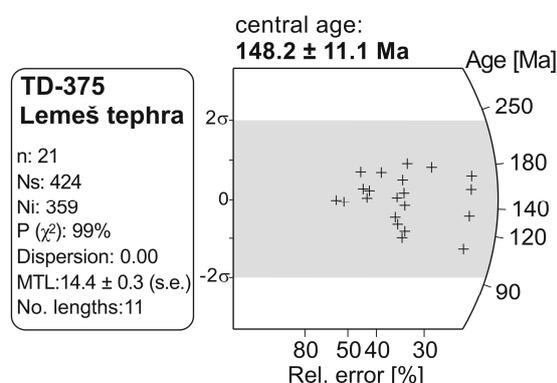

**Fig. 6.** Summed distribution of detrital zircon single-grain U/Pb ages from five sandstone samples of the Lower Cretaceous Vranduk Formation of the Bosnian Flysch. Data partly taken from Mikes *et al.*, (2008). Subordinate grains older than 800 Ma (14% of the dataset) are not shown. Age distribution calculation according to Sircombe (2004). Arrows indicate the most probable population ages in the <290 Ma portion (see also Table 2).

## 4.4.3. Apatite fission track dating

Analytical results of the Lemeš tephra sample are shown in Fig. 7. The age distribution is unimodal, with a central age of  $148 \pm 11$  Ma, consistent with the Kimmeridgian–Lower Tithonian biostratigraphic age assignment of the host strata (see above). Track-length distribution ( $14.4 \pm 0.3$   $\mu\text{m}$ ;  $n=11$ ) gives no evidence for track annealing and significant post-depositional heating. The obtained low FT age dispersion suggests a single-component population with no detrital admixture. The apatite FT age is interpreted as indicating Late Jurassic volcanic activity.

**Fig. 7.** Results of apatite FT dating of the Lemeš tephra sample. Radial plot according to Galbraith (1990). The largely unannealed tracks (mean track length:  $14.4 \pm 0.3$   $\mu\text{m}$ ) suggest that Late Jurassic and younger horizons of the AdCP did not experience significant post-depositional heating. Low age dispersion points to a single age component in the Lemeš tephra, i.e. no contribution from detrital grains. Central age calculated according to Galbraith and Laslett (1993).

s.d. (1 $\sigma$ , Ma)	-	-	-	70.8	72.0
fraction (%)	-	-	-	46.6 (24.7)	47.0 (24.9)

**Table 2.** Summary of the geochronological results, showing the major age populations. Deconvolution of composite age spectra of monazite and zircon was performed independently by Popshare (Dunkl and Székely, 2002) and Isoplot (Ludwig, 2003) softwares, which yielded consistent results. A most probable age along with its 2 $\sigma$ ( $\pm$ ) standard error is assigned for each separated age component. The 1 $\sigma$ ( $\pm$ ) standard deviations indicate the age range produced by ca. 68% of all grain ages within that component. The zircon dataset was truncated at 290 Ma to facilitate a meaningful deconvolution in the discussed age range. Values in parantheses express the fractions as related to the whole (not truncated) zircon dataset ( $n=361$ ). See Appendix 4-6 for statistical details.

## 4.5. Discussion

### 4.5.1. Magmatic origin of the Jurassic apatite, monazite and zircon crystals

The significance of the Late Jurassic tephra layer preserved in the AdCP sequence is that it records explosive volcanism coeval to Neotethyan convergence, an event for which no geochronological record has been previously available in the Dinarides.

Monazite growth from melt is evidenced by the sharp oscillatory zoning of the grains. This is corroborated by the marked negative Eu anomaly (e.g. Nagy *et al.*, 2002; Buick *et al.*, 2006), and by the elevated  $Y_2O_3$  concentrations (up to 5.3 wt%), as Y would preferentially be fractionated into garnet during metamorphism (Gibson *et al.*, 2004). The texturally disturbed grains are likely of the same generation as those exhibiting a normal oscillatory growth: the two texture types yield comparable ages, and intact textural domains are occasionally preserved in some grains. Magmatic monazite is common to felsic, Ca-poor peraluminous melts but is rare in peralkaline environment where light REE are fractionated into apatite and allanite (Watt and Harley 1993). The textural and REE variations (Figs. 3 & 5) can be explained in terms of coeval growth from separate melts each with slightly distinct element budget and degree of differentiation.

As for zircon, 96-98% of the Jurassic age population exhibits a Th/U ratio  $>0.1$  (typically 0.05-1.1; Appendix 4-3), characteristic of magmatic growth (Rubatto, 2002), although the validity of this approach was questioned (Harley *et al.*, 2007). A metamorphic origin however, is unlikely also for zircon because the evolution of the Dinaride passive margin during Late Jurassic obduction did not involve any high-temperature metamorphic event (Schmid *et al.*, 2008; Mikes *et al.*, 2008b).

### 4.5.2. Regional comparisons

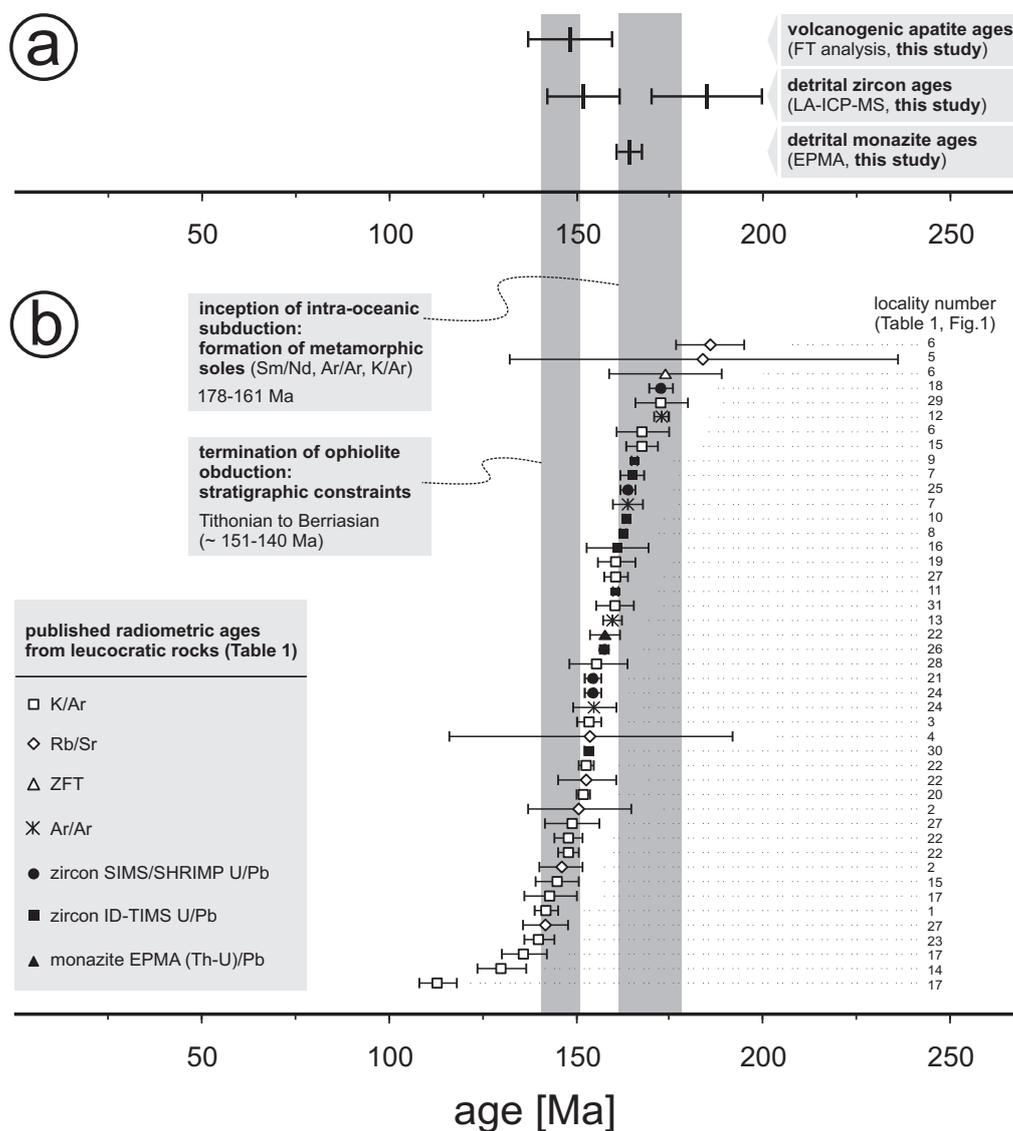

Felsic igneous rocks associate Jurassic Neotethyan ophiolites in the Carpathian-Pannonian-Dinaride-Hellenide region at several locations, either intruding mafic/ultramafic lithologies or interfingering with *mélange* deposits. Several radiometric age determinations are published for these rocks and are compiled in Table 1 and Fig. 8. Combining these geochronological results with the geochemical

characteristics of the ophiolites (Pamić *et al.*, 2002; Bortolotti *et al.*, 2004; Dilek *et al.*, 2008), source assignment of the dated zircon and monazite crystals becomes ambiguous. From the Middle Jurassic on, oceanic felsic magmatism likely occurred coevally at several settings: at the site of late-stage mid-oceanic spreading, at the SSZ and/or island arc, and via sub-ophiolitic anatexis of underplated oceanic sediments. Analytical uncertainty renders the separation of the various magmatic events and the sole metamorphism difficult (Dimo-Lahitte *et al.*, 2001; Liati *et al.*, 2004).

Our results show that felsic magmatism in the Dinarides was coeval to and also shortly followed the sole metamorphism of the intraoceanic subduction zone (Fig. 8). The geochemical diversity of the plagiogranite bodies investigated so far suggests the addition of crustal components (especially Th, LREE, Zr, Hf) to their source magmas (e.g. Bébien *et al.*, 1997; Aigner-Torres and Koller, 1999), which is a viable scenario above SSZ's (Flagler and Spray, 1991; Pearce, 2003; Metcalf and Shervais, 2008). Explosive volcanism, generation of peraluminous to metaluminous melts from which monazite was crystallized, and previous data showing significant crustal component in the Jurassic plagiogranites and granitoid complexes (Pearce 1989; Aigner-Torres and Koller, 1999; Resimić-Šarić *et al.*, 2005; Anders *et al.*, 2005) all suggest that Dinaride SSZ magmatism played a more important role than considered in previous tectonic reconstructions (Pamić *et al.*, 2002; Dimitrijević *et al.*, 2003). Duration of these processes was constrained to a <30 Ma period by the early Mid-Jurassic onset of subduction and the latest Jurassic completion of ophiolite obduction (Fig. 8).

#### 4.6. Conclusions

Three independent geochronometers applied to detrital minerals from Central Dinaride sediments constrain the timing of Jurassic felsic magmatism in the Neotethys Ocean. Magmatic monazite from synorogenic Vranduk Formation sandstones reveals a dominant  $164 \pm 3$  Ma age component. Zircon U/Pb age spectra contain an age population at  $152 \pm 10$  Ma. Additionally, a tephra horizon in the Adriatic Carbonate Platform bordering the clastic basin is dated at  $148 \pm 11$  Ma, yielding the first Dinaride geochronological datum for explosive volcanism related to Neotethyan convergence. The major period of leucocratic melt generation was restricted to Middle to Late Jurassic times, coeval to and slightly post-dating sub-ophiolitic sole metamorphism. Crystallization of

**Fig. 8.** Comparison of the new geochronological data to published radiometric ages from felsic magmatic rocks associating Neotethyan ophiolites of the Carpatho-Pannonian-Dinaride-Hellenide orogen, as compiled in Table 1. (a) Apatite FT (central age  $\pm 2\sigma$  s.e. – Fig. 7), and detrital monazite and zircon geochronological results (population ages  $\pm 2\sigma$  s.e. – see full age spectra in Figs. 4 and 6, resp.). (b) Distribution of the published ages. Legend symbols are arranged in an upward increasing approximate order of thermal sensitivity of the geochronometer used. An estimated error of 5% is assigned to age data for which no error range was specified in the cited work. Note that higher-temperature chronometers (filled symbols) yield older dates than lower-temperature chronometers (empty symbols), and plot closer to the well-constrained age range of the sub-ophiolitic metamorphic soles (right vertical grey bar, 178-161 Ma, see text for references). Within the limit of analytical uncertainties and regional age scatter, felsic magmatism appears to have started coeval with intraoceanic subduction in the early Middle Jurassic (reflected by the sole Ar/Ar ages, that remained largely unaffected by Eoalpine overprint reaching subgreenschist facies) and continued until the at least the Kimmeridgian (reflected by the youngest "high-temperature" geochronologic datum at c. 153 Ma). Note that only lower-temperature chronometers yield post-obduction dates. Biostratigraphic age of the oldest unconformable deposits overlying the obducted Dinaride ophiolites is Tithonian to Berriasian (Mercier, 1966; Bortolotti *et al.*, 1971; Charvet and Termier, 1971; Charvet, 1973).

zircon and especially monazite is consistent with crustal geochemical signatures (elevated Th, LREE, Zr, Hf) reported from both SSZ plagiogranites and calc-alkaline, felsic metaluminous to peraluminous granitoid rocks over the entire Dinaride-Hellenide orogen. Introduction of crustal components into the magmatic source region of these felsic suites was likely controlled by intraoceanic subduction commencing in early Middle Jurassic times.

## *Chapter 5*

# Calcareous nannofossil age constraints on Miocene flysch sedimentation in the Outer Dinarides

---

This chapter is largely identical to the manuscript entitled:  
"Calcareous nannofossil age constraints on Miocene flysch sedimentation in the Outer Dinarides (Slovenia, Croatia, Bosnia-Herzegovina and Montenegro)"  
that has been published in July 2008 in:  
Tectonic Aspects of the Alpine-Dinaride-Carpathian System (Siegesmund, S., Fügenschuh, B. & Froitzheim, N., eds). *Geological Society of London, Special Publications* 298: 335-363, doi:10.1144/SP298.16

# **Calcareous nannofossil age constraints on Miocene flysch sedimentation in the Outer Dinarides**

*Tamás Mikes, Mária Báldi-Beke, Miklós Kázmér, István Dunkl and Hilmar von Eynatten*

## **Abstract**

Flysch deposits are associated with the Outer Dinaride nappe front. They overlie Eocene platform carbonate to bathyal marl successions that subsequently cover Cretaceous platform carbonates of Apulia and the Dinaride nappes. Planktonic foraminifer biostratigraphy indicates Eocene age of flysch sedimentation. New calcareous nannofossil data reveal that several assemblages are present; besides the dominant Mid-Eocene species, Cretaceous, Palaeocene, Oligocene and Miocene taxa were also identified throughout the entire flysch belt. Widespread occurrence of nannofossil species of zone NN4-6 indicate that flysch deposition lasted up to at least Mid-Miocene. Ubiquitous occurrence of various pre-Miocene taxa demonstrate that extensive, possibly submarine sediment recycling has occurred in the Cenozoic.

As flysch remnants are typically sandwiched between thrust sheets, these new stratigraphic ages give a lower bracket on deformation age of the coastal range. The data provide a link between Cretaceous compression in the Bosnian Flysch and recent deformation in the Adriatic offshore area.

## **5.1. Introduction**

Cenozoic synorogenic clastic rocks overlie an upward-deepening Eocene carbonate platform to bathyal marl succession of the Apulian foreland and of the outermost parts of the SW-vergent Outer Dinaride thrust belt (Fig. 1). Established mostly on the basis of planktonic foraminifera, and locally by calcareous nannofossils, the stratigraphic age of the deposits has been traditionally placed into the Mid- or Late Eocene (Table 1). A SE-directed orogen-parallel younging of Palaeogene sedimentation has been inferred by Piccoli and Proto Decima (1969).

Recent calcareous nannofossil studies indicate, however, that at several locations in the central and SE part of the basin system clastic deposition lasted up to the Middle Miocene (review in de Capoa and Radoičić 2002). In addition, tectonic slices of older flysch series dated or inferred to be of Late Cretaceous and Palaeogene age are found in the inner part of the Dinaride imbricate thrust belt occupying structurally higher positions.

These contradictory data pose a series of important questions that need to be addressed in detail:

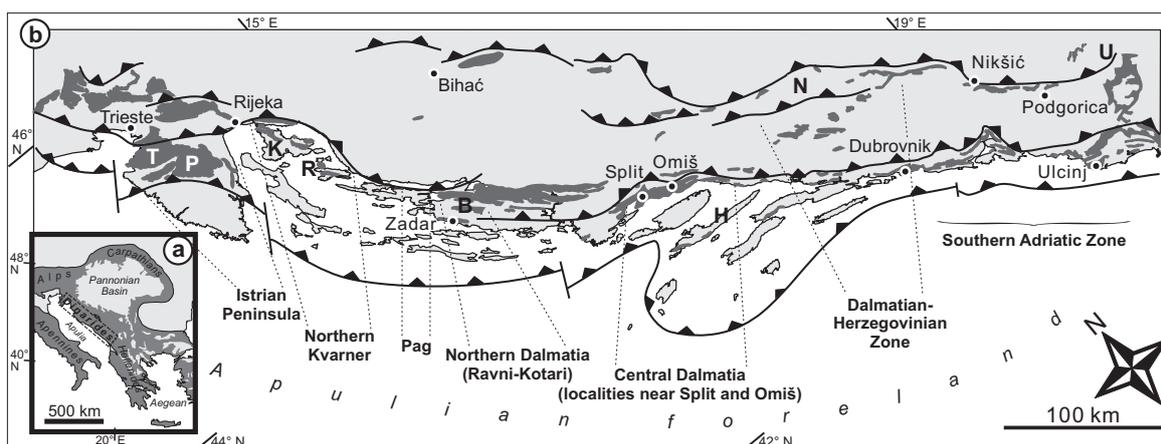

- (1) Can ages younger than Eocene be demonstrated in the NW parts of the coastal flysch zone, too?
- (2) Why do the age data from planktonic foraminifera and calcareous nannofossil studies seem to mismatch?
- (3) Where and when did flysch deposition start? Are the deposits in the main belt and those preserved in narrow thrust slices related?
- (4) Does revised biostratigraphy support the idea of diachronic onset of deposition along the orogenic front?
- (5) What is the bearing of such young stratigraphic ages on the understanding of the Outer Dinaride geodynamic evolution?

In the present paper, new results of a calcareous nannofossil study are reported, obtained from several flysch localities throughout the Outer Dinaride region. Areas of large-scale regional sampling included the Trieste-Koper and Pazin Basins at Istrian Peninsula, the Northern Kvarner Islands (Krk and Rab), Pag Island, Šopot section near Benkovac in Northern Dalmatia, Central Dalmatia, Southern Dalmatia, Montenegro

coast as well as the “Dalmatian-Herzegovinian Zone” of Southern Bosnia-Herzegovina and Montenegro inland (Fig. 1, Appendix 5-2).

## 5.2. Geological setting and sedimentology

The Outer Dinarides and their foreland are dominated by the thick deposits of the Adriatic Carbonate Platform (AdCP – Vlahović *et al.*, 2005) that existed throughout the entire Mesozoic until its final drowning in the Mid-Eocene. Structurally, it consists of two parts: the lower plate corresponds to autochthonous Apulia, while the upper plate forms a broad, ca. 100 km wide zone made up of the Dinaride nappes and imbricate thrust sheets. These units are built up mainly of Cretaceous rudistid limestones and Eocene foraminiferal limestones and marls and are covered by Tertiary flysch that inter-fingers with and underlies shallow marine to continental clastic sediments. For extensive reviews of the Cenozoic stratigraphy the reader is referred to Drobne (1977); Marjanac and Čosović (2000) and Čosović *et al.*, (2008). The carbonate nappes are thrust by the folded, Mesozoic units of the Bosnian Flysch and its low-grade metamorphic, Palaeozoic basement, the Bosnian Schist Mountains (BSM). They underwent Early Cretaceous metamorphism and the BSM was exhumed during the Eocene-Oligocene (Pamić *et al.*, 2004; Petri, 2007).

(b) Schematic geological setting of the Outer Dinarides with locations of the major sampling areas. Light grey: substrate of the flysch – mainly Palaeozoic to Mesozoic formations, dominantly platform carbonates. Dark grey: Cenozoic flysch and associated shallow marine sediments in the Outer Dinaride foreland basin system. T, Trieste-Koper Basin; P, Pazin Basin; K, Krk Island; R, Rab Island; B, Benkovac town; H, Hvar Island; U, Kuči Thrust; N, Nevesinjsko Polje. Position of thrusts after the Geological Map of Yugoslavia (F.G.I. 1970), Tari (2002) and Schmid *et al.* (2006).

The Outer Dinaride flysch is part of the fill of a large foreland basin system at the front of the thrust wedges (Fig. 1). Sub-basins stretch from the Southern Alps along the Adriatic Sea coastline as far to the SE as the Hellenides. Stratigraphic position of the flysch is described in terms of a Palaeogene marine sequence overstepping the Cretaceous platform. The underlying foraminiferal ramp covers a regionally widespread unconformity and started to develop in the Palaeocene with paralic deposits. Facies development indicates transgression throughout the Early to Middle Eocene but the sequence is punctuated with a number of short-lived subaerial exposure events probably due to the interplay of eustatic oscillations in a shallow marine environment and the effects of ongoing compressional tectonics affecting the Adriatic area already since the Cretaceous (Channell *et al.*, 1979; Mindszenty *et al.*, 1995; Pamić *et al.*, 1998). The Eocene carbonate unit is rarely thicker than 200 m and is overlain by the "Transitional Beds" – a deepening-upward shelf to shallow bathyal sequence several tens of metres thick, characterized by increasing amount of pelagic biota, glauconite and silt upsection. Its thin lower part is referred to as "Marl with crabs", passing upwards into the thick "*Globigerina* Marl" (e.g. Juračić 1979; Čosović *et al.*, 2004).

The flysch rests upon the "*Globigerina* Marl". Their contact is conformable at places but angular or erosional unconformities have been often reported (e.g. Marinčić 1981; Marjanac *et al.*, 1998; Marjanac 2000). Due to repetitive thrusting, flysch profiles are usually truncated and less than 100-400 m thick. The offshore succession resting on the Apulian plate is gently folded, reaches up to the Neogene, and may exceed 1000 m in thickness (e.g. Tari-Kovačić 1998).

Turbidite beds are dominantly composed of siliciclastics with variable (0-50%) amounts of carbonate admixture. In the N part of the basin, palaeocurrent data were interpreted as resulting from largely SW-directed primary, and SE-directed deflected (longitudinal) flows (e.g. Magdalenić 1972; Babić and Zupanić 1983; Orehek 1991). Radial current directions are commonly found in Central Dalmatia, resulting from complex basin floor topography and multiple flow reflection (Marjanac 1990).

A clear NE-directed flow direction can be observed in the N part of the basin on carbonate debrites and calciturbidites that intercalate into the siliciclastic succession (Engel 1974; Babić and Zupanić 1996). The coarser-grained debrites range in composition from breccia consisting exclusively of well-cemented Eocene foraminiferal limestone lithoclasts, through mixed ones having much isolated larger foraminifer tests and rhodoliths beside the lithoclasts, to pure grain- or matrix-supported debrites made

up of *Nummulites* tests. Marl and Upper Cretaceous limestone clasts are subordinate (Skaberne 1987; Magdalenić 1972; Hagn *et al.*, 1979; Marjanac and Marjanac 1991; Radoičić *et al.*, 1991; Tunis and Venturini 1992; Babić *et al.*, 1995; Marjanac 1996; Tomljenović 2000; Bergant *et al.*, 2003; Pavlovec 2003).

Based on its narrow appearance in map view and the – largely scattered – uniform, longitudinal, SE-directed palaeoflow indicators, the flysch basin has been interpreted as a single major elongated trough (e.g. Marinčić 1981). However, flysch deposits at places rapidly grade upsection into thick sandstone beds deposited in shallow shelf environments, pointing to a complex, dissected basin floor topography with different subsidence histories in the individual domains (Zupanič and Babić 1991; Babić *et al.*, 1993; Babić and Zupanič 1998). Rapid upward decrease of water-depth in the upper part of the thin flysch sequences have also been observed in other localities at the Island of Pag and in Northern Dalmatia (Lj. Babić, pers. comm. 2005).

### 5.3. Present status of flysch biostratigraphy

Traditionally, Cenozoic clastic strata stretching along the Adriatic coast have been regarded as Middle to Late Eocene in age. Ages based on planktonic foraminifera and partly on nannofossil range from Early Eocene to Early Oligocene, mostly Bartonian to Priabonian, as summarized in Table 1. Piccoli and Proto Decima (1969) recognized that the ages become progressively younger towards the SE. Since then, deposition of the flysch in the coastal zone has been commonly explained in terms of a SE-directed diachroneity (Marjanac and Čosović 2000; Čosović *et al.*, 2008, and references therein).

Upper Eocene to Lower Oligocene planktonic foraminifera described from Pazin and Motovun localities in Istria and from Hvar Island by Marinčić (1981), and from sites near Split by Grubić and Komatina (1963) received little attention in subsequent works. Recently, Šparica *et al.* (2005) reported Upper Oligocene larger foraminiferal, calcareous nannofossil and pollen assemblages from the Pićan profile in Istria.

The first notion of onshore Neogene is from Puškarić (1987) who proved distinct biozones in two nearby profiles on Hvar Island by means of calcareous nannofossils: NP17 (Bartonian) and NN1 (Uppermost Chattian to Lower Aquitanian). Nannofossil studies of de Capoa revealed Early to Middle Miocene ages up to Serravallian from a considerable number of localities in the central and SE part of the flysch basin (Radoičić *et al.*, 1989, 1991; de Capoa and Radoičić 1994a, b; de Capoa *et al.*, 1995; de Ca-

**Table 1.** Overview of published age data from the Outer Dinaride flysch. Offshore and sporadic mainland data are not included. Whenever available, standard planktonic foraminifer or calcareous nannoplankton biozones are also indicated. Results yielding Neogene age are marked bold for clarity. Abbreviations: np - nannofossils, pf - planktonic foraminifera, lf - larger foraminifera, po - palynomorphs, mo - mollusc macrofauna

## Notes:

- (1) Drobne *et al.* (1979) report Lower, Middle and Upper Lutetian as well as Upper Eocene planktonic foraminifera and Middle Lutetian nannoplankton from the Pićan flysch. They conclude that age of the strata is Middle Lutetian.
- (2) Age younger than the LO of *Discosaster lodoensis* and *D. kuepperi*, but older than the FO of *Isthmolithus recurvus* and may correspond to the zones NP12-15 as re-interpreted by Jerković & Martini (1976).
- (3) Pelagic foraminifera with different biozonal ranges within Middle Lutetian.
- (4) Flysch contains arenaceous species of Foraminifera, which markedly contrast the *Globigerina* in the "Transitional Beds". The change appears just above the "Nummulite breccia" and was observed at several localities in Istria (Buzet, Kotle, Draguč).
- (5) Summarizing description of 20 samples. Reworked Palaeocene and Lower Eocene forms are also reported.
- (6) reworked Middle Eocene forms are also reported.
- (7) "similarly as in Split region" (Marjanac *et al.* 1998).

poa and Radoičić 2002). Their results are summarized in Table 1. Quantitative test data from nanofossil counting by Radoičić *et al.* (1989) suggest that Miocene forms constitute only a few percent of the dominantly reworked nanofossil assemblage at any locality.

#### 5.4. Methods

Pelitic rocks were collected for nanofossil analysis throughout the flysch belt (Appendix 5-2). This study does not replace detailed sectionwise biostratigraphic work, yet it represents an exemplary sampling of the most suitable outcrops in the entire basin, as such performed for the first time. Rocks were sampled in five various facies: (1) laminated hemipelagic pelite, (2) pelite rip-up clasts found within sandstone turbidite beds, as well as (3) plastically deformed pelite fragments included in clast-supported carbonate breccia or in (4) *Nummulites* debrite, finally, (5) the pelite matrix of matrix-supported debrites made up of limestone clasts and *Nummulites* tests. The small sampled volume of the clasts (few mm<sup>3</sup>) required extreme clean conditions during preparation to avoid contamination.

Standard smear slides were prepared from a total of 69 crushed samples using no chemical treatment or centrifugation. Slides were examined under the microscope in normal and cross-polarized lights at 1250× magnification.

Stratigraphic evaluation was performed for each sample individually, since correlated or thick continuous profiles were not sampled. Evaluation was based on stratigraphic ranges of the taxa alone [from the first (FO) to the last (LO) occurrences, see Appendix 5-1], without using any additional geological information. Species older than the youngest assemblage were also determined and registered, so as to gain information on recycling. In flysch deposits where recycled forms are typically the most abundant, species LO-s are only relevant to the age of the „original” assemblage in the sediment they were eroded from. Sedimentation ages were always established by forms having the youngest FO. In cases where a narrow biozone was proven (e.g. the most frequent NP16), it does not necessarily follow that a „peak sedimentation event” occurred within that zone.

As many long-lived Cenozoic taxa reach into the Neogene, the identified specimens could be either autochthonous or allochthonous, but both types may also occur together in

the sample and cannot be distinguished from each other. This is crucial insofar as abundance of the youngest zonal markers was often found to be extremely low.

Calcareous nannofossil classification in this paper follows Bown and Young (1997) for the Mesozoic and Young and Bown (1997) for the Cenozoic. Ranges of Cretaceous species are from Burnett (1998) and Perch-Nielsen (1985a), while Palaeogene species ranges are from Perch-Nielsen (1985b) and Báldi-Beke (1977; 1984). With respect to Neogene, the latest summary of Young (1998) was used, a work taking also results from the Mediterranean into consideration (Fornaciari *et al.*, 1996; Fornaciari and Rio 1996). The applied nannoplankton zonation is from Martini (1971).

The nannofossil assemblages examined are mostly of poor preservation and allowed the estimation of abundances only, without exact counting. Our experience has shown that this procedure is good enough for stratigraphic evaluation if flysch samples are dealt with (e.g. Nagymarosy and Báldi-Beke 1993). Species abundances were variable but generally low, which may depend on their preservation upon long-lasting depositional, diagenetic and weathering processes. Special care was taken to search and identify forms smaller than 10  $\mu\text{m}$ , too, as most Neogene taxa occur in this size range.

### **5.5. Results of nannofossil analyses**

A total of 69 samples were analyzed along the Outer Dinaride coastal range from various tectonostratigraphic units. Four of them were barren of calcareous nannofossils. Estimated taxon abundances are summarized in Table 2. Established stratigraphic ranges for each sample are shown in Fig. 2.

The youngest nannofossil assemblages correspond to the zones NN4-6, placing most of the flysch into the Lower to Middle Miocene, most probably the upper part of this interval, i.e. Langhian to Early Serravallian. In addition, there are many reworked specimens from the Upper Cretaceous, and from the Middle and Upper Eocene – many of them having non-overlapping stratigraphic ranges. The obtained Miocene ages of deposition are rather uniform throughout the flysch zone.

### 5.5.1. Istrian Peninsula: Trieste-Koper and Pazin Basins

Fourteen samples were analyzed from the Istrian Peninsula; seven each from the Trieste-Koper Basin (localities Izola, Dekani, Babiči and two nearby sites each at Korte and Momjan) and from the Pazin Basin (Baredine, Kaščerga, Žlepčari, Pićan and Lukačići). Most of them are dominated by Bartonian nannoflora.

At Dekani village (sample TD11) *Pemma* sp. ind., *Chiasmolithus* cf. *modestus* and *Sphenolithus spiniger* indicate Middle Eocene, whereas at the coastal cliffs of Izola (TD13) the co-occurrence of *Chiasmolithus grandis* and *Reticulofenestra placomorpha* correspond to zones NP16-17, Uppermost Lutetian to Bartonian. The same age was proven at Lukačići (TD171), together with a variable Middle Eocene assemblage. At Pićan (PIC-2) a Bartonian to Priabonian age can be established. Few older Eocene species also occur whose ranges do not reach into zone NP16 (*Tribrachiatus orthostylus*: NP11-12, middle part of the Ypresian; *Discoaster septemradiatus*: NP12-14, Upper Ypresian to Lowermost Lutetian).

Scarce but ubiquitous reworked Cretaceous forms include Lower and Upper Cretaceous markers as well.

In subordinate quantity, Miocene forms were also discovered throughout Istria, in all but one sample. The assemblage *Calcidiscus leptoporus*, *C. premacintyreii*, *Coccolithus miopelagicus*, *Reticulofenestra pseudoumbilicus* (partly >7 µm) and, possibly also six-rayed *Discoaster* spp., hint a Miocene age. In the Pićan (PIC-2), Korte (TD15), Babiči (TD16) and Baštini (TD178) localities, specimens of *Helicosphaera carteri* were also identified. *Helicosphaera carteri* has its FO at the base of Miocene worldwide and is a very characteristic form (Photos 13-14 in Fig. 4). Overall, the identified Neogene species define the zones NN4-6 which correspond to Late Burdigalian to Serravallian age. However, at Izola (TD13), Korte (TD15, TD18), Momjan (TD22) and Babiči (TD16) *Reticulofenestra pseudoumbilicus* is dominated by specimens larger than 7 µm, such occur first in the Langhian, close to base NN5. Neogene nannofossils found near Dekani (TD11) is somewhat poorer than at Pićan, indicating either similar or slightly older, Early Miocene age. At Lukačići (TD171), the Neogene is only represented by few and small specimens of *Reticulofenestra pseudoumbilicus*. Of all, the most diverse Miocene assemblage is identified in the Pićan sample (PIC-2), within a rather fresh pelite rip-up clast from the base of a sandstone turbidite bed. *Sphenolithus conicus*, identified in Istria only in sample MOM-3, ranges

from NP25 to NN3 (Upper Chattian to Middle Burdigalian) and is probably reworked due to the presence of *Coccolithus miopelagicus*, *Reticulofenestra haqii* and *R. pseudoumbilicus* in MOM-3.

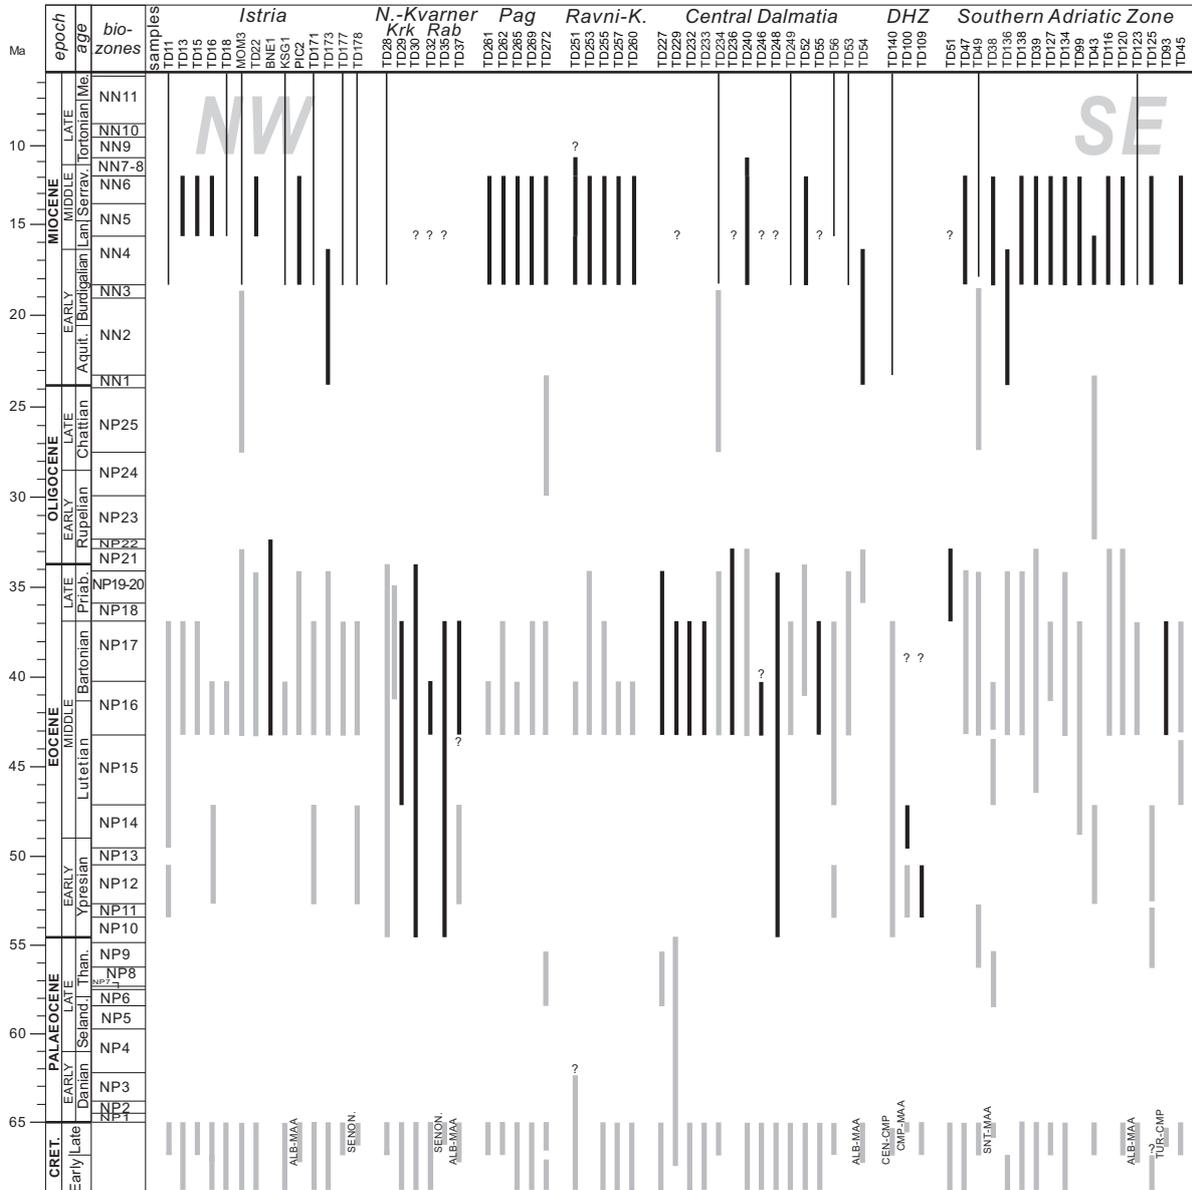

#### 5.5.2. Northern Kvarner

Sampling sites are located on Krk and Rab Islands and on the mainland near Crikvenica. Three out of nine samples are barren of nannofossils, the rest being rather poor. They always contain reworked Cretaceous nannofloral elements.

On Krk, near Draga Bašćanska (TD28) only a poor assemblage was found with *Arkhangelskiella* sp. and abundant *Watznaueria barnesae* suggesting a Late Cretaceous age, together with rare Eocene forms. In the slide only two specimens of *Reticulofenestra pseudoumbilicus* >7 µm were found, pointing to zone NN4 or younger, i.e. not older than Burdigalian. A poorly preserved but rather rich Middle Eocene assemblage is found near Bribir (TD29). Although in this sample most species range from Early to Middle Eocene and *Sphenolithus radians* is rather rare from the NP17 upwards, the FO of the larger forms of *Reticulofenestra placomorpha* is in NP16. The nannoflora of Bribir likely indicates the zones NP15-17 of Mid-Lutetian to Bartonian age. Another sample from Štale near Bribir (TD30) also contains a very poor assemblage, with the identified Upper Cretaceous, Eocene and Miocene taxa being represented with only one specimen each.

Three samples are from the clastic sediments of Rab Island. Near the town of Rab (TD32) a scarce but diverse Palaeogene nannoflora was established. The characteristic forms of *Reticulofenestra placomorpha* (FO in NP16), together with *Sphenolithus furcatolithoides* (LO in NP16) indicate the zone NP16, Uppermost Lutetian to Bartonian. A single specimen of Miocene *Reticulofenestra pseudoumbilicus* was also found here. Similarly, in a poor nannoflora at the port of Lopar (TD35) which contains mostly Senonian and Lower to Middle Eocene nannofloral elements, only one specimen is encountered which resembles *Reticulofenestra pseudoumbilicus*. A likewise poor assemblage was obtained from sample TD37 from Dumići, 1 km NW of Supetarska Draga. Among its Eocene species, *Discoaster lodoensis* has the shortest range, and indicates Late Ypresian to Early Lutetian age (NP12-14). Alternatively, based on

*Reticulofenestra cf. placomorpha*, the Dumići (TD37) assemblage can be evaluated as a younger one (Bartonian), with *Discoaster lodoensis* then being in reworked position.

**Fig. 2.** Stratigraphic position of zonal marker nannoplankton species in the Outer Dinarides. Samples are arranged in columns, bars in each column represent the ranges of zonal markers found in that single sample. N.B.: only species with short zonal ranges are displayed, persistent species living through several epochs are omitted. Black bars mark the youngest assemblages indicating the most probable age of sedimentation. Narrow black lines: Neogene assemblages only comprising species that range beyond the Miocene. Grey bars represent reworked nannoflora. Abbreviations: Ravni-K.: Northern Dalmatia (Ravni-Kotari area), DHZ: Dalmatian-Herzegovinian Zone.

### 5.5.3. Pag Island

Two profiles of the undisturbed, SW-dipping subvertical flysch succession were sampled on Pag Island. At Stara Vas, 10 km SE of Pag town, three samples were taken 9, 45 and 92 m above the foraminiferal limestone (TD261, TD262 and TD265, respectively). Two samples stem from the coastal profile at Vlašići, collected 17 and 34 m above the limestone top (TD269 and TD272, respectively).

In all samples the nannoflora is very diverse, and a particular abundance was observed in the middle portion of the Stara Vas profile (TD262). Overall, the observed Cretaceous elements are rare, but indicate reworking of Upper Cretaceous assemblages (*Arkhangelskiella* sp., *Microrhabdulus* sp.). Majority of the nannofossils are Middle Eocene and most probably belong to zones NP16-17, i.e. Uppermost Lutetian to Bartonian. In the upper sample from Vlašići (TD272), the dominant Middle Eocene assemblage and the isolated Lower and Upper Cretaceous forms are accompanied by single specimens of *Heliolithus kleinPELLI* from the Late Palaeocene (NP6-9) and *Cyclicargolithus abisectus* most probably from the Chattian (NP24-NN1).

The Neogene part of the assemblages consists of three to five species which are identical in all samples throughout. Of these, *Calcidiscus premacintyreii* is characterized by the shortest range, i.e. Late Burdigalian and Early Serravallian (zones NN4-6). The remaining Neogene species have their FO mainly in the Early Miocene but FO of *Reticulofenestra pseudoumbilicus* >7 µm is close to the base of zone NN5, in the Langhian. Although Neogene taxa make up only a very small part of the whole of the assemblages, in sample TD262 they appear to be more abundant than elsewhere in Pag together with a similarly higher abundance of Palaeogene forms.

### 5.5.4. Northern Dalmatia (Ravni-Kotari)

The nearly complete profile exposed by the Šopot railway cut was sampled at four sites (28, 116, 130 and 383 m above the foraminiferal limestone) and an additional sample is from a road cut of the recently constructed Zagreb-Split motorway near Islam Latinski, beneath the Suhovare bridge. Except the section top, all Šopot samples were extracted from fresh rip-up pelite clasts at the base of graded turbidite beds.

The observed nannofossil assemblages bear close resemblance to each other. Reworked Cretaceous coccoliths are rare compared to other parts of the basin system, being represented by *Watznaueria barnesae*. The Palaeogene nannoflora is rather diverse, yet uniform between samples. It is not older than latest Lutetian (zone NP16), as proven by samples bracketing the Šopot section at its base and top (TD251, TD257) and by the Suhovare outcrop (TD260). Although in none of the two intermediate samples in the Šopot section can the Eocene nannoflora be narrowed to NP16, a younger Palaeogene age for these assemblages is unlikely.

Neogene species identified in this unit are similar to those appearing in the Istrian Peninsula and Pag Island. *Calcidiscus premacintyreii*, *Coccolithus miopelagicus* and *Reticulofenestra pseudoumbilicus* occur in each sample in low yet meaningful amounts. Six-rayed *Discoaster* spp. occur in both profiles, while *Calcidiscus leptoporus* and *Helicosphaera carteri* were identified in the Šopot section only. The Neogene assemblage is assigned to the NN4-6 zones, indicating Late Burdigalian to Early Serravallian age.

#### 5.5.5. Central Dalmatia

In Central Dalmatia, near the cities of Split and Omiš, fifteen samples were analyzed. The very scarce reworked Cretaceous nannofossils are represented mostly by *Watznaueria barnesae*, and Eocene nannofossils constitute the vast majority of the diverse and mostly rich assemblages.

Four sites near Mravince (TD227, TD232, TD233 and TD234) reveal a rather similar Palaeogene nannoflora, composed of very abundant but poorly preserved Uppermost Lutetian to Priabonian forms. In addition, older index species also appear in Mravince: *Heliolithus kleinPELLI* (NP6-9, Upper Palaeocene) and *Cyclagelosphaera reinhardtii*, Albian to Palaeocene. In the marl quarry at Mravince (TD229) recrystallized coccoliths dominate the sample and indicate Middle to Late Eocene age (NP16-21). The three most frequent species (*Reticulofenestra bisecta*, *Coccolithus pelagicus* and *Cyclococcolithus formosus*) share a common size and shape, strongly suggesting hydrodynamic control on species composition. Only a few specimens of *Calcidiscus premacintyreii* were found in the sample from the Mravince quarry (TD229) which may place the marl to the zones NN4-6.

We established Miocene ages with more confidence only in a part of the localities. In Jadro Valley, at Vrilo Jadro (TD240), besides Eocene species which define only a broad range of zones NP16-21 (Bartonian to Priabonian) also five Neogene taxa occur. Of these, *Calcidiscus premacintyreii* and *Reticulofenestra pseudoumbilicus* define the zones NN4-6, placing the age of these beds between Late Burdigalian and Early Serravallian.

Of the samples taken at Mravince, a pelite lithoclast extracted from a grain-supported *Nummulites* debrite (TD234) yielded comparatively abundant Neogene nannoflora: *Sphenolithus conicus* (Upper Chattian to Middle Burdigalian; probably reworked), as well as *Coccolithus miopelagicus*, *Reticulofenestra haqii* and *R. pseudoumbilicus*, corresponding to an age not older than Late Burdigalian.

Another pelite lithoclast (TD56) from a limestone breccia exposed by the large abandoned quarry of Omiš also yielded rather diverse Neogene nannofossils; *Helicosphaera carteri*, *Coccolithus miopelagicus*, *Reticulofenestra haqii*, *R. pseudoumbilicus* and *Umbilicosphaera rotula*, which suggest biozone NN5 or younger, i.e. at least Langhian age.

In other Central Dalmatian localities examined, either an abundant but monotonous and poorly preserved nannoflora occurs displaying Middle to Late Eocene age (the larger pit of the Jadro quarry, TD236), or solely a poor Eocene assemblage is encountered. Such extremely scarce nannoflora was found at several localities over larger along-strike distances (80 km): in the town of Solin in the Voljaka Street section (TD248), a laminated pelite sample in the large abandoned quarry of Omiš (TD55), road cut at Porat near Živogošće (TD52) and in a metre-sized, grey, angular marl block included in thick limestone debrite at Gizdići near Klis (TD246).

#### *5.5.6. Dalmatian-Herzegovinian Zone*

In the densely imbricated thrust belt of the Dinaride carbonate platform in Southern Herzegovina, a single sample was analyzed from Crnići village near the Neretva valley (TD140). The diverse, reworked Cretaceous nannofossil association hints at an Upper Cretaceous source older than Maastrichtian. A scarce Lower to Middle Eocene nannoflora is also present. Indication for the Neogene age of the rocks is

provided by several specimens of *Calcidiscus leptoporus* ranging from the Early Miocene to recent (NN2-21).

Further to the SE, a narrow flysch zone is exposed in front of the Kuči Thrust that stretches NW-SE from the Nevesinjsko Polje to Podgorica. Two samples were taken close to Podgorica; from a fault-bounded block standing out from the Zeta Valley 3 km NW of Spuž village (TD100), and in Medun village, 2 km ENE of Podgorica (TD109).

Both profiles contain reworked Upper Cretaceous taxa; age ranges can be probably narrowed to Campanian-Maastrichtian at Spuž. Here the relatively rich nannoflora is Lower to Middle Eocene and consists of several taxa with overlapping stratigraphic ranges (Table 2). *Discoaster lodoensis* and *Discoaster septemradiatus* are markers of zones NP12-14 indicating Late Ypresian to Early Lutetian age. Important is a single specimen of *Discoaster* cf. *sublodoensis*, which marks the base NP14, the base of the Lutetian. The Ypresian *Tribrachiatulus orthostylus* (NP11-12) is also part of the assemblage. Such a complexity is best explained by a multiple reworking history and will be discussed later.

In Medun profile (TD109) the Palaeogene assemblage is scarce but *Tribrachiatulus orthostylus* occurs here as well, the Ypresian index species of the zones NP11-12.

#### 5.5.7. Southern Adriatic Zone

A common feature of the seventeen flysch samples taken in the Southern Adriatic Zone is their paucity of Cretaceous forms. In two samples they are entirely absent (Ulcinj, TD99; Stari Bar, TD116). Nevertheless, reworked Upper Cretaceous index forms are identified in some cases and they preferentially occur in the southern part of the zone. *Eiffellithus eximius* and *Uniplanarius gothicus* are characterized by the shortest range of all, and indicate reworking from Turonian-Campanian and Santonian-Maastrichtian strata, respectively. Two samples bear *Nannoconus steinmanni* hinting at reworking from Lower Cretaceous sediments (TD125, TD136).

In all samples Eocene forms are predominant, albeit different in origin. Often the zones NP16-17 were registered (Uppermost Lutetian and Bartonian) but in other cases merely a longer interval could be given (NP16-20 or NP16-21).

Three, partly overlapping biozones can be proven at the base of the Klezna profile (TD125) from the Upper Palaeocene to the Lutetian (range of *Discoaster multiradiatus*

is NP9-11, that of *Tribrahiatus orthostylus* is NP11-12 and that of *Discoaster lodoensis* and *Discoaster septemradiatus* is NP12-14). This peculiar overlap offers a wide range of interpretations with respect to the age and recycling history of the sediment and will be discussed in the subsequent part.

A variety of reworked Palaeogene zone markers have been encountered throughout the Southern Adriatic Zone. Specimens of *Discoaster multiradiatus* (NP9-11; Palaeocene) occur in sample TD49 (Dubravka). The NP12-14 zones are proven from the Zaljevo profile (TD43) corresponding to Upper Ypresian and earliest Lutetian. In addition, sample TD45 yielded *Nannotetrina* sp., a marker for NP15 (Mid-Lutetian). In TD51 an Upper Eocene zonal marker was encountered, *Chiasmolithus oamaruensis* (NP18-22). Oligocene marker taxa are extremely rare in the entire flysch belt, thus the finding of *Reticulofenestra lockeri* (NP23-NN1; Middle Rupelian to Lower Aquitanian) in sample TD43 and *Sphenolithus conicus* (NP25-NN3; Chattian to Middle Burdigalian) in sample TD49 is of particular importance.

Thirteen out of seventeen samples Miocene forms are sufficiently represented, whereas in TD93 they are missing, in TD51 there is one specimen and in TD45 and TD136 there are two specimens. Miocene species characteristic of zones NN4-6 indicate depositional ages not older than Late Burdigalian. In Zaljevo (TD43), occurrence of two specimens of *Helicosphaera ampliapertura* (range NN2-4) are of particular importance as together with other Neogene species (*Calcidiscus leptoporus*, *C. premacintyreii* and possibly also six-rayed *Discoaster* spp.) the stratigraphic position can be ascertained to the zone NN4 (Upper Burdigalian to Lower Langhian).

## **5.6. Nannofossil preservation**

Our results reveal that the Neogene calcareous nannofossil assemblages are surprisingly low both in abundance and diversity. Accurate dating of the Outer Dinaride Neogene successions awaits further bio- and chronostratigraphic control.

Physical and chemical processes operating during flysch formation and diagenesis influence the composition of the nannoflora (disintegration, dissolution, recrystallisation) and likely account for the observed overall scarcity of the nannoflora (e.g. Thierstein 1980; de Kaenel and Villa 1996). High degree of reworking of older species, together with evidence for diagenetic processes as indicated by carbonate-cemented tur-

bidite beds, carbonate veinlets dissecting the turbidites, bent mica plates and severely etched surfaces of susceptible heavy mineral grains (amphibole, staurolite, garnet) are in accordance with the poor preservation of the nannoflora. Indeed, samples from pelite clasts, embedded in breccias or well-cemented sandstones and presumably preserved from corrosive solutions, proved to yield more diverse Neogene assemblages than those found in laminated pelites (e.g. samples MOM-3, KSG-1, PIC-2, TD253, TD255, TD234, TD56; see Table 2).

### 5.7. Cretaceous to Palaeogene nannofloral elements

Most nannofossil assemblages are mixed, with evidence for recycling of specimens from pre-existing sediments. Cretaceous forms commonly occur together with the Cenozoic ones. Common long-lived Cretaceous species, e.g. *Watznaueria barnesae* are ubiquitous. Among the shorter-range taxa *Nannoconus steinmanni* indicates Lower Cretaceous, and several Upper Cretaceous markers occur as well (*Arkhangelskiella* sp., *Microrhabdulus* sp., *Eiffelithus turriseiffelii*). A limited number of characteristic taxa prove the availability of Lower Palaeogene sediments to erosion: *Heliolithus kleinPELLI*, *Discoaster multiradiatus*, *Discoaster lenticularis* (Palaeocene), *Tribachiatus orthostylus* (Lower Eocene), *Discoaster lodoensis* (Ypresian to lowermost Lutetian). All these Lower Palaeogene species are large in size and, according to our experience, fairly resistant against dissolution.

In spite of reworking, an attempt was made to identify characteristic Palaeogene assemblages preserved in the entire sample material. The most frequent Middle Eocene forms can, in several localities, be placed into the NP16 zone. Often, NP16 zone was recognized using the FO of *Reticulofenestra placomorpha* and the LO-s of *Sphenolithus furcatolithoides* and *Chiasmolithus solitus*. Whenever the latter species were not registered, the possible age of that assemblage could only be bracketed with lower precision, which might then extend from the NP16 upward into NP17 or even longer to the Late Eocene or Early Oligocene. We used the LO of *Chiasmolithus grandis* for the end of NP17, that of *Discoaster saipanensis* and/or *Discoaster barbadiensis* for the NP20/NP21 boundary (close to the Eocene/Oligocene boundary), and that of *Cyclococcolithus formosus* and *Reticulofenestra placomorpha* for the end of NP 21 and NP 22 zones, respectively, in the Early Oligocene. As for Late Eocene, a single, poorly pre-

served specimen of *Chiasmolithus oamaruensis* occurred in the entire studied material, as previously reported from Oprtalj, Istria (Benić 1991), Split (Jerković and Martini 1976) and Hvar (Marinčić 1981) in Central Dalmatia, and the North Mozura section in the Southern Adriatic Zone as well (de Capoa *et al.*, 1995). *Isthmolithus recurvus* (NP20-22), which indicates Late Priabonian to Middle Rupelian, was found at Omiš (sample TD54).

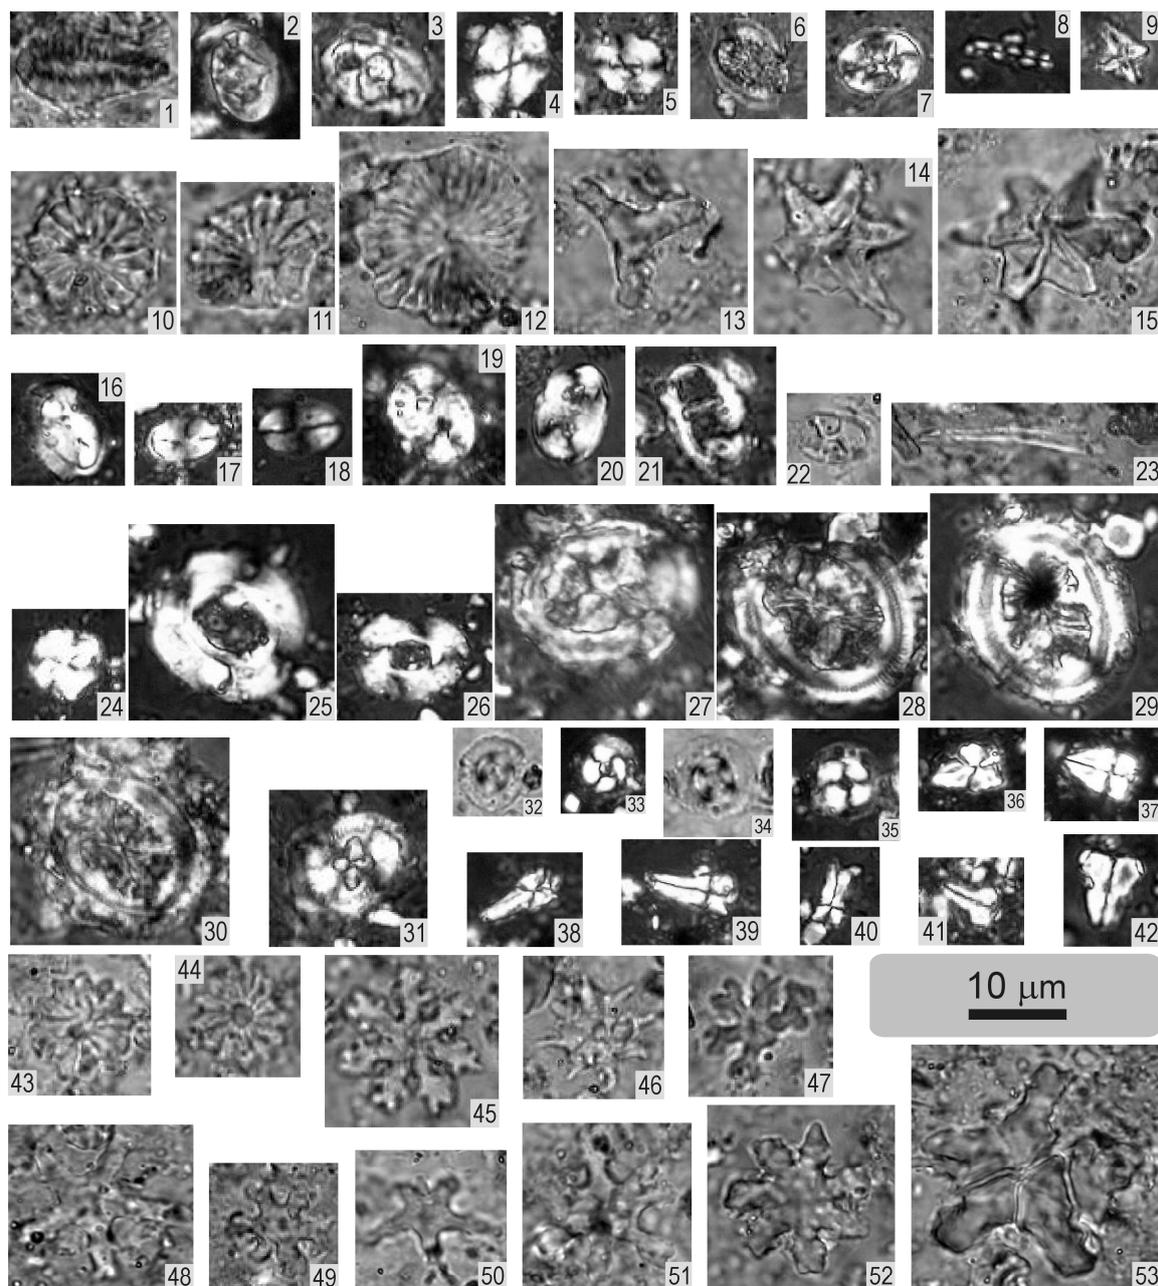

Species of even longer ranges spanning from the Middle Eocene to various levels in the Miocene include the ubiquitous and highly abundant *Cyclicargolithus floridanus* and *Coccolithus pelagicus*. Also *Sphenolithus moriformis*, *Helicosphaera euphratis*, *H. intermedia*, *Discolithina* div. sp., and *Transversopontis* sp. appear in a number of samples. It is evident that among them there may exist specimens indistinguishably that lived in a given part of the Eocene, Oligocene or Miocene.

In the Oligocene nannofossil zonation there are only a few markers to appear, due to the global cooling trend following the terminal Eocene events (e.g. Pomerol 1985). These few FO-s are typically represented by the low latitude forms of *Sphenolithus*. Of them, *Sphenolithus conicus*, ranging from NP25 to NN3 have been found in Istria, Central Dalmatia and the Southern Adriatic Zone. Further short-range index species include *Cyclicargolithus abisectus* and *Reticulofenestra lockeri*, and in this study both species have been encountered on Pag Island and in the Southern Adriatic Zone.

The scarcity of Palaeocene nannofloral elements is probably due to the unavailability of Palaeocene sediments for the reworking processes. Normally, both the diversity of Palaeocene zonal markers and their resistance would permit them to be well-represented in Cenozoic flysch sediments.

### **5.8. Distribution of nannofossil age ranges and sediment recycling**

Apart from significant Upper Cretaceous and Middle Eocene nannofloral components, and the presence of Lower to Middle Miocene nannoflora, there are index species of Palaeocene, Lower and Upper Eocene and Oligocene present, too (Fig. 3). Unusual composition of some assemblages depicts characteristic age distribution patterns, whether or not Neogene forms are recognized in that sample (Fig. 2). We can discern two types.

**Fig. 3.** Cretaceous (1-9), Palaeocene (10-12), Lower Eocene (13-15) and diverse Palaeogene (15-53) nannoplankton in the Outer Dinaride flysch. Abbreviations refer to light types used: PP, plane-polarized; SX, slightly cross-polarized; XP: cross-polarized. **1**, *Nannoconus steinmanni* (Sample TD43, SX); **2-3**, *Zeugrhabdotus embergeri* (2: TD16, XP; 3: TD123, XP); **4-5**, *Watznaueria barnesae* (4: TD16, XP; 5: TD262, XP); **6**, *Cribrosphaerella ehrenbergii* (TD123, SX); **7**, *Eiffellithus turriseiffelii* (TD43, XP); **8**, *Microrhabdulus* sp. (TD18, XP); **9**, *Micula* sp. (TD123, XP); **10-11**, *Discoaster multiradiatus* (10: TD262, PP; 11: TD123, PP); **12**, *Discoaster lenticularis* (TD43, PP); **13**, *Tribrachiatus orthostylus* (TD262, PP); **14-15**, *Discoaster lodoensis* (14: TD16, PP; 15: TD43, PP); **16**, *Helicosphaera compacta* (TD43, XP); **17-18**, *Discolithina plana* (17: TD261, XP; 18: TD16, XP); **19**, *Transversopontis pulcher* (TD262, XP); **20**, *Transversopontis* sp. (TD15, XP); **21**, *Lophodolithus nascens* (TD262, XP); **22**, *Neococcolithes dubius* (TD253, PP); **23**, *Blackites* sp. (TD123, PP); **24**, *Reticulofenestra bisecta* (PIC-2, XP); **25-26** *Reticulofenestra placomorpha* (25: TD16, XP; 26: TD18, XP); **27-30**, *Chiasmolithus grandis* (27: TD16, XP; 28: TD16, XP; 29: TD15, XP; 30: TD262, SX); **31**: *Chiasmolithus* sp. (TD43, XP); **32-35** *Cyclococcolithus formosus* (32-33: TD43, PP and XP resp.; 34-35: TD16, PP and XP resp.); **36-39**, *Sphenolithus radians* (36: TD123, XP; 37: TD123, XP; 38: TD16, XP; 39: TD16, XP); **40**, *Sphenolithus furcatolithoides* (TD16, XP); **41-42** *Zygrhablithus bijugatus* (41: TD261, XP; 42: TD16, XP); **43-44**, *Discoaster barbadiensis* (43: TD262, PP; 44: TD262, PP); **45**, *Discoaster mirus* (TD262, PP); **46**, *Discoaster saipanensis* (TD262, PP); **47** and **49**, *Discoaster deflandrei* (both TD262, PP); **48** and **50-51**: *Discoaster tanii* (48: TD123, PP; 50: TD123, PP; 51: TD123, PP); **52-53**, *Discoaster nodifer* (52: TD262, PP; 53: TD18, PP).

(1) Joint occurrence of Palaeogene species with no overlapping age ranges. We observe this in Istria (TD11, TD171), Northern Kvarner area (TD37), Pag Island (TD272) at Mravince in Central Dalmatia (TD227), and in the Southern Adriatic Zone (TD38, TD43, TD45).

(2) A blurred, consecutive overlap pattern of several index species: *Discoaster multiradiatus* (NP9-11), *Tribrachiatus orthostylus* (NP11-12), *Discoaster lodoensis* and *D. septemradiatus* (NP12-14) and *Discoaster* cf. *sublodoensis* (NP14-15) occur together, in addition to Lower and Upper Cretaceous markers. Such mixed assemblages were encountered both in the Zeta Valley in the Dalmatian-Herzegovinian Zone (TD100) and in the Southern Adriatic Zone (TD125). Evidently, the partly overlapping ranges of these species can be combined to a number of species coexistence patterns, but recycling remains necessary to explain overall species composition. The resulting maximum time span for the Early Palaeogene „cascade” alone may cover ca. 9 Ma, but presence of further non-overlapping taxa suggests a more or less continuous and by all means cannibalistic sedimentation. Both types of age distribution provide an insight into the progressive Cretaceous to Cenozoic sediment reworking history. Actual sedimentation ages of the flysch likely become younger towards the foreland, along with the increasing number of reworked “fossil” biozones. During thrusting, the deposited flysch was off-scraped, reworked, its material acting as a source for the yet younger flysch deposits.

We need to stress that the few, comparatively thick flysch profiles available (e.g. Brkini, Šopot, Skradin, Split, Petrovac) all display a limited thickness (ca. 300-500 m), which is not enough to accommodate the time represented by the full nannofossil age spectrum assuming typical flysch sedimentation rates (50-2000 m/Ma; Einsele 1992, p. 389). De Capoa *et al.*, (1995) documented the nannofossils of the 140 metres thick Petrovac profile in the Southern Adriatic. With nearly equidistant sampling they obtained successively younger assemblages upsection from the Upper Thanetian to the Langhian, which spans ca. 40 Ma implying a sedimentation rate of only ca. 3.5 m/Ma, which is not realistic for submarine fan depositional setting. Judging from their data, at Petrovac there are either undiscovered, short-lived unconformities or, more likely, most of the older ages come from reworked nannofossils due to extensive dilution.

### 5.9. Miocene nannofossils

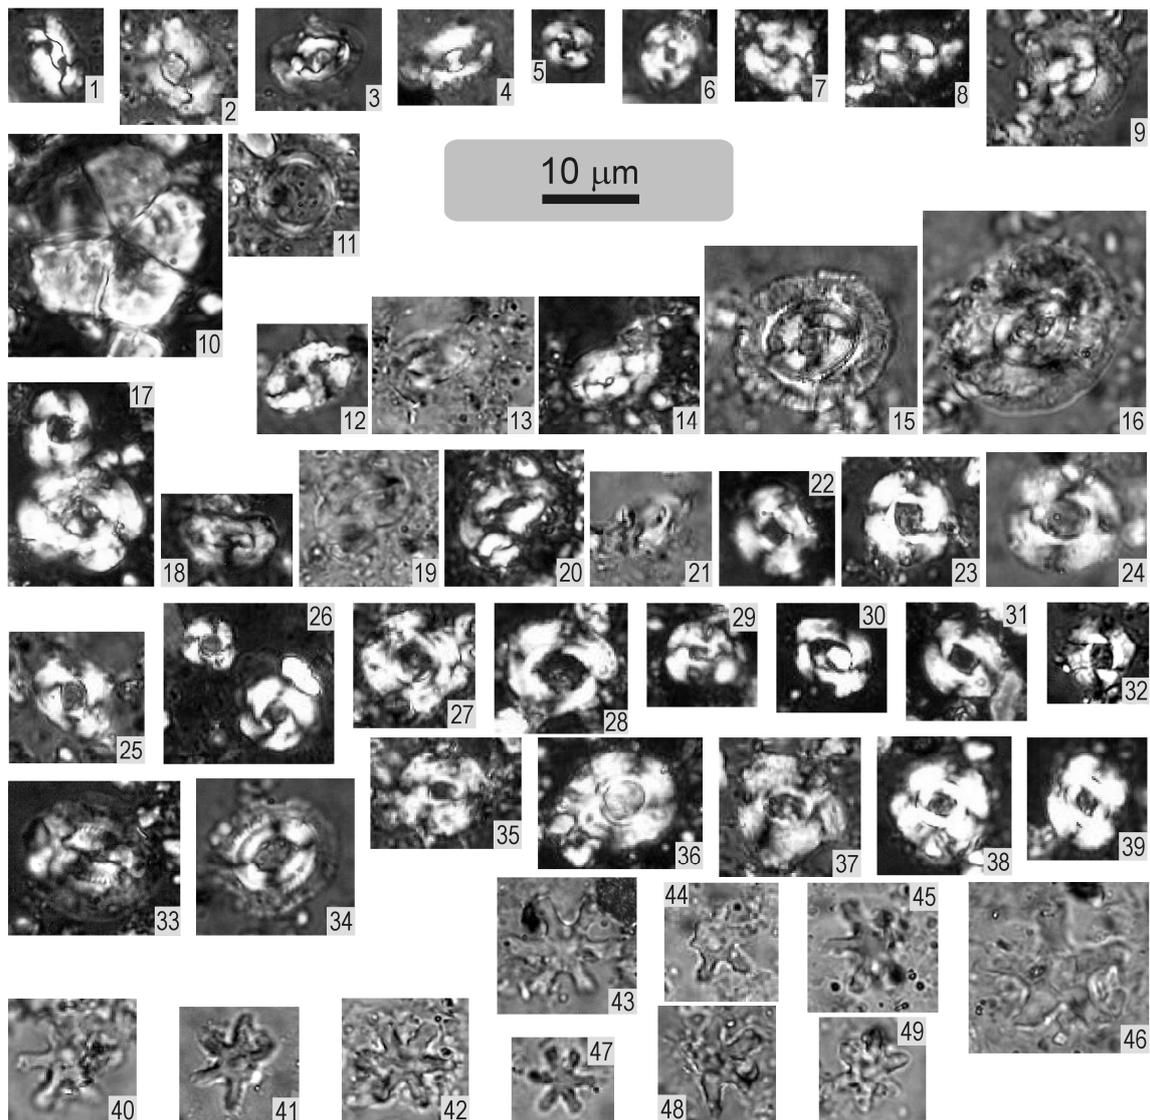

The majority of samples contains nannofossils suggesting Miocene age. In the NW portion of the Dinaride foreland basin, this paper reports such fossils for the first time from onshore outcrops. Unfortunately, these crucial forms are small, very rare, often poorly preserved and tend to comprise morphologically variable species.

In our experience however, most standard flysch nannofossil stratigraphic studies typically ignore or overlook such “inconvenient” forms. As they have outstanding importance in Dinaride flysch stratigraphy, they have to be discussed in more detail.

The most common placolith species encountered in the Outer Dinarides are species of the *Calcidiscus* group, *Reticulofenestra pseudoumbilicus*, *Reticulofenestra haqii* and *Coccolithus miopelagicus*. As demonstrated by Young (1998), however, these often exhibit a wide variety in shape and size, hampering exact taxonomic identification. In fact, morphologically related forms do occur in the Palaeogene, albeit a very rare phenomenon, e.g. *Reticulofenestra dictyoda* (Deflandre in Deflandre and Fert) Stradner in Stradner and Edwards (see Varol 1998). The comparatively high frequency of this type of placoliths met in the Dinaride samples strongly argues for their Miocene rather than Eocene age. Among these species, *Reticulofenestra pseudoumbilicus* >7 µm is the most common one. Regarding the *Calcidiscus* species, *C. leptoporus* and *C. macintyreii* are of very low frequency, only a few specimens were found in the entire material. On the contrary, *Calcidiscus premacintyreii* has been often registered, even though it occurs in its less typical varieties. The occurrence of *Coccolithus miopelagicus* is well demonstrated (Fig. 4).

The genus *Helicosphaera* is represented by several species, two of them have a Miocene FO; *Helicosphaera carteri* and *Helicosphaera ampliapertura*. Unfortunately, *Helicosphaera* is just moderately resistant to dissolution and overcalcification, resulting in poor preservation. This makes *H. carteri* difficult to identify, but the flange and the central area with the two pores are visible (Fig. 4). A third species of *Helicosphaera* is characterized by prominent central openings and a conjunct central bar which suggests Neogene age despite the poorly preserved flange at the rim of the coccolith (Photo 12 in Fig. 4).

Among the *Discoaster* species a rather frequent type occurs with five or six narrow rays. Their preservation is always very poor, with heavily overcalcified specimens, and ends of their arms mostly broken off. Although this type exists also in the Eocene, *Dis-*

**Fig. 4.** Palaeogene to Neogene (1-11) and Neogene (12-46) nannoplankton of the Outer Dinaride flysch. Designations as in Fig. 3. **1-2**, *Helicosphaera euphratis* (1: Sample TD43, XP; 2: Sample TD262, XP); **3-4**, *Helicosphaera intermedia* (3: TD127, XP; 4: TD43, XP); **5-7**, *Cyclicargolithus floridanus* (5-6: PIC-2, XP; 7: TD261, XP); **8-9**, *Coccolithus pelagicus* (8: TD261, XP; 9: TD262, SX); **10**, *Braarudosphaera bigelowi* (TD127, XP); **11**, *Coronocyclus nitescens* (TD262, SX); **12**, *Helicosphaera* sp. (flange poorly preserved but note prominent central openings and the conjunct central bar, TD127, XP); **13-14**, *Helicosphaera carteri* (13: TD15, PP; 14: TD15, XP); **15-16**, *Coccolithus miopelagicus* (15: TD262, PP; 16: TD16, XP); **17**, *Reticulofenestra pseudoumbilicus* >7 $\mu$ m (above; together with the Palaeogene *Reticulofenestra placomorpha*, below, TD15, XP); **18-20**, *Helicosphaera carteri* (18: TD16, XP; 19: TD262, PP; 20: TD262, XP); **21**, *Helicosphaera obliqua* (TD262, SX); **22-26**, *Reticulofenestra haqii* (22: TD16, XP; 23: TD18, XP; 24: TD262, XP; 25: TD123, XP; 26: TD43, XP, 2 specimens); **27-32**, *Reticulofenestra pseudoumbilicus* >7 $\mu$ m (27: TD261, XP; 28: TD261, XP; 29: TD261, XP; 30: TD251, XP; 31: TD16, XP; 32: TD15, XP); **33-34**, *Coccolithus miopelagicus* (33: TD16, SX; 34: TD16, SX); **35-37**, *Calcidiscus premacintyreii* (35: TD261, XP; 36: TD262, XP; 37: TD261, XP); **38-39**, *Calcidiscus* sp. (38: TD15, XP; 39: TD261, XP); **40-44** and **48-49** *Discoaster* spp. 6-ray (40: PIC-2, PP; 41: TD15, PP; 42: TD18, PP; 43: TD123, PP; 44: TD253, PP; 48 and 49: TD18, PP); **45-46**, *Discoaster* spp. 5-ray (45: TD15, PP; 46: TD123, PP); **47**, *Discoaster* sp. 7 $\mu$ m, 6-ray (TD261, PP).

*coaster tani* and similar forms are generally very rare. In fact, in the Miocene the most frequent *Discoaster* spp. are 5- or 6-rayed with bifurcations at the end of their arms, represented by a wide variety of species. Among them the *Discoaster exilis* group is the most probable candidate (e.g. with *Discoaster aulakos* Gartner 1967 in Young 1998, p. 257), but they bear close resemblance to *Discoaster variabilis* Martini and Bramlette 1963 as well. If bifurcation is not visible it is either broken off or it is a primary characteristic (such as that of *Discoaster bellus* Bukry and Percival 1971, for example). With respect to decisive specific characteristics, the central area (with or without knob), the inter-ray area (rounded or rather V-shaped), the arms (with the sides tapering, parallel or curving) and the ending of the arms (bifurcating or not) were considered. In spite of poor preservation of the *Discoaster* spp. under discussion, their characteristics suggest Miocene age.

Overall, the identified Miocene nannofossil species correspond to the zones NN4-6 (based on *Calcidiscus premacintyre*), but they are probably not older than NN5 as *Reticulofenestra pseudoumbilicus* >7 µm occurs first in this zone. Consequently, whenever Neogene taxa are present, the age of clastic sedimentation in the Adriatic onshore area is likely not older than Langhian.

As a result of the surprisingly rare occurrence and poor preservation of the nannofossils and occasionally wide specific morphological variability, the Neogene age of deposition cannot be unambiguously confirmed. Noticeably, the observed problematic forms are unknown in the Bakony Eocene Basin in Hungary although it exhibits rather comparable Middle Eocene nannofossil assemblages to those in the Outer Dinarides (Báldi-Beke 1984; Báldi-Beke and Báldi 1991).

Research is in progress to further address this stratigraphic problem by looking at the roles of hydraulic, diagenetic and weathering processes being suspect to exert a fundamental control on the assemblage compositions.

## **5.10. Implications for palaeoenvironment**

### *5.10.1. Pelagic environment with neritic influence*

Despite sediment mixing and reworking, it is evident that the most frequent forms pertain to a Middle Eocene assemblage. The species composition is rather complex and

exhibits common placoliths. Some species possess a specific habitat and are thus of ecologic importance, such as the nearshore taxa *Neococcolithes dubius*, *Pemma* sp., *Discolithina*, *Transversopontis* and holococcoliths, e.g. *Zygrhablithus bijugatus* (e.g. Perch-Nielsen 1985b). Although abundance of these nearshore taxa is low in all samples, as many of them are at the same time particularly susceptible to dissolution, it can be assumed that their initial abundance was higher in the sediment, which in turn calls for a remarkable neritic influence on sedimentation in the Eocene. The scarce Neogene assemblage does not provide useful environmental information.

#### *5.10.2. Neogene: Absence of planktonic foraminifera, presence of nannofossils*

Preliminary examination of our samples containing Miocene nannofossils did not yield any planktonic foraminifera younger than Middle Eocene in Istria and Kvarner or younger than Early Oligocene in the Southern Adriatic (V. Čosović, pers. comm. 2006; F. Rögl, pers. comm. 2007). To our knowledge, no such data have been published from onshore localities, either (Table 1).

The characteristic depth habitat of several planktonic foraminifer species can preclude their survival in relatively shallow waters. Most species require oceanic salinities near 35-36 ‰, a few of them can tolerate salinities down to 30.5 ‰ and can thus only penetrate coastal waters if sufficiently clear and lacking in turbidity (Haynes 1981, p. 330). Nannoplankton, in contrast, tolerates reduced salinity although diversity can be reduced in brackish water under elevated freshwater input (e.g. Olszewska and Garecka 1996; Schulz *et al.*, 2005).

In places, the Outer Dinaride flysch deposits rapidly grade into shallow marine deposits. Sand-rich shallow shelf environments influenced by nearby river mouths have been described from the Islands of Rab and Pag and from Northern Dalmatia (Zupanič and Babić 1991; Babić *et al.*, 1993; Babić and Zupanič 1998). Facies architecture of clastic deposits in Northern and Central Dalmatia is also well documented (e.g. Postma *et al.*, 1988; Mrinjek 1993; Marjanac 1996), and show fan deltas prograding on the flysch succession. The increasing proximity of the alluvial environments implies significant freshwater input which could have a profound effect on salinity and thus adversely influenced foraminifer distribution.

### 5.10.3. Heterochronous redeposition

As a prominent feature, debrites of several metres of thickness that intercalate the turbiditic flysch successions of the Outer Dinarides often contain isolated tests of Eocene larger foraminifera. In spite of attempts to date the depositional age by means of such fossils (Pavić 1970) they are evidently allochthonous in submarine fan setting. Pavlovec (2003) noted that *Nummulites* assemblages found in flysch deposits Dinarides-wide were in fact no true biocoenoses but rather mixed in composition with unusual species proportion as compared to those in the limestones. Indeed, derived fossils may occur in a state of preservation as good as or better than that of the original rock, and the reworked fauna may be more diverse and contains a much higher proportion of planktonics than that of the source rock (Curry 1982).

Ample examples from the Outer Dinarides and from comparable settings in the surrounding areas show that larger, smaller and also pelagic foraminifer tests can survive diagenesis in unconsolidated sediment and be reworked into younger strata: (i) Lower Eocene (Upper “Cuisian”) flysch of Trnovo, SW Slovenia contains Lower to Middle Cuisian larger foraminifera: *Nummulites subdistans* (Pavlovec 2006); (ii) Planktonic foraminifera in the flysch of Pićan are uniformly Middle Lutetian in age but if examined in detail, they belong to various biozones (Pavlovec *et al.*, 1991); (iii) Lower Oligocene (NP21-22) calcareous turbidites in Budapest, Hungary contain Upper Eocene (Priabonian) larger foraminifera: *Chapmanina gassinensis* and *Nummulites fabianii* (Varga 1982, 1985; Nagymarosy 1987); (iv) Lower Oligocene flysch in the Carpathians yielded Eocene *Nummulites* (Kulka 1985). (v) The Frazzanò Flysch of the Calabria-Peloritani arc previously dated by Upper Eocene foraminifera yielded Upper Oligocene calcareous nannofossils (de Capoa *et al.*, 1997); (vi) Similarly, flysch of the Sicilian Maghrebids containing Lower Oligocene planktonic foraminifera were dated by means of calcareous nannofossils to be at least Aquitanian (de Capoa *et al.*, 2000); (vii) Microfossils of Lower Miocene strata of the Zawada Formation in the Carpathians are dominated by reworked Middle Eocene planktonic foraminifera and calcareous nannoplankton (Oszczypko *et al.*, 1999); (viii) Flysch of the Ionian Zone in the Hellenides, to the SE of the Outer Dinaride flysch basins, is Early Miocene in age and contains abundant reworked Cretaceous and Eocene nannofossils (Piper *et al.*, 1978; Bellas 1997). Evidence for a considerable time gap between foraminifer and nannofossil ages arises also from our new results. For instance, isolated Lower to Middle Eocene *Nummulites* tests from

various biozones occur together with older, massive Palaeogene and Cretaceous carbonate lithoclasts (Hagn *et al.*, 1979) as well as with Middle to Upper Eocene planktonic foraminifera and Cretaceous to Palaeogene nannofossils from a number of biozones (Drobne *et al.*, 1979) and with Upper Oligocene palynomorphs, nannofossils and larger foraminifera (Šparica *et al.*, 2005) in the Pićan flysch profile on Istria. These strata have been dated herein to be not older than Late Burdigalian. Table 1 and Fig. 2 illustrate the contradiction of microfossil age data from the entire Outer Dinaride flysch.

#### *5.10.4. Weak early-stage diagenesis*

Redeposition of micro- and macrofossils such as larger, smaller and planktonic foraminifera without intense signal of wearing or abrasion can be attributed to subaqueous mud volcanoes linked to dewatering, in what might be a dynamic, accretionary wedge-type environment (e.g. Kohl and Roberts 1994). Probably, high water content of sediment prevented diagenesis initially, and allowed easy removal of carbonate particles from the siliciclastic matrix downslope the submarine fans, over a longer time span. Such a mechanism for a continuous redeposition and accumulation of Eocene foraminifera until at least Middle Miocene is very likely to have taken place in the imbricated frontal thrust belt of the Dinarides, interpreted as an accretionary wedge (Tari-Kovačić 1998).

### **5.11. Implications for palaeogeography**

We have demonstrated that our new calcareous nannofossil data from the Outer Dinaride Cenozoic prove the presence of a wide range of Lower Cretaceous, Upper Cretaceous, Palaeocene, several non-overlapping Eocene, Oligocene and Miocene species in these strata.

The significance of our results is twofold. On the one hand, they indicate that the Cretaceous platform carbonate nappes have been covered by pelitic sediments, connected with progressive sediment reworking during the Cenozoic. It is essential to assume that before, during, and after the deposition of the Eocene foraminiferal lime-

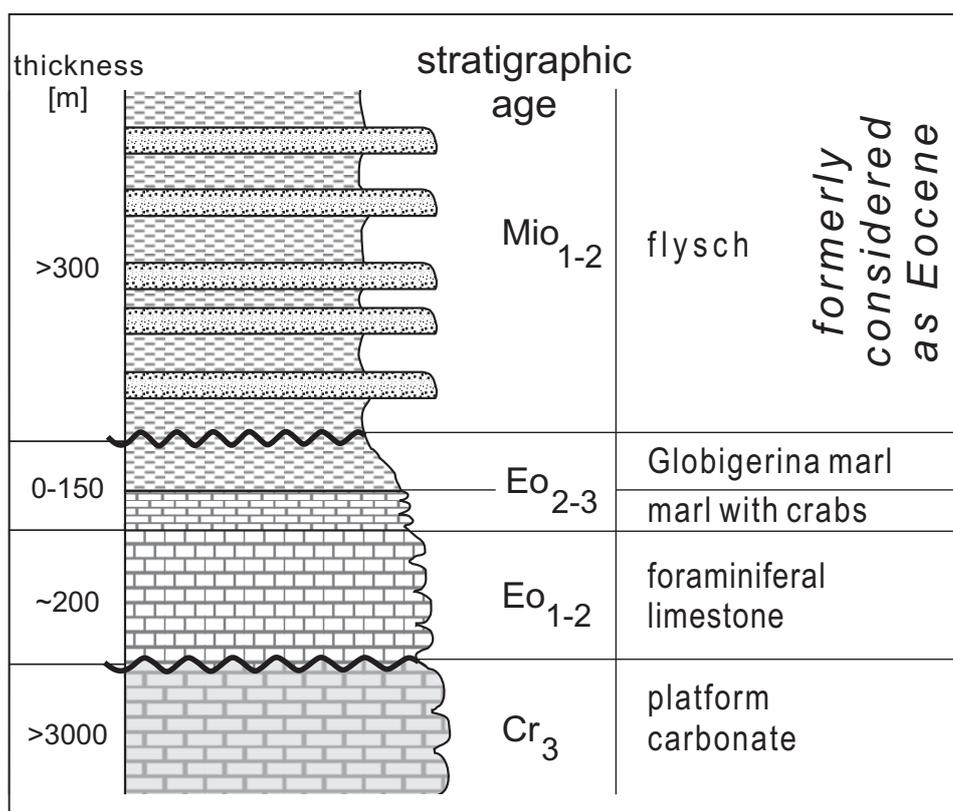

stones in the present-day Outer Dinaride coastal range, there existed widespread marine environments, covering the Cretaceous platform carbonates in the inner imbricate belt, where the nannofossils can be derived from.

On the other hand, the data strongly suggest a considerably younger, at least Burdigalian sedimentation age throughout the onshore flysch deposits, with clear implications on Outer Dinaride tectonics. Overall, this picture is best explained by a series of wedge-top basins (see DeCelles and Giles 1996) progressively migrating towards the Apulian foreland.

The flysch develops from the underlying "*Globigerina* Marl" (Marjanac and Ćosović 2000). These shelf to shallow bathyal deposits are dated by means of micro- and macrofauna and by calcareous nannofossils (Muldini-Mamužić 1965; Benić 1991; Drobne and Pavlovec 1991; Pavšič and Premec-Fuček 2000; Schweitzer *et al.*, 2005) ranging in age from Palaeocene in the NW to Upper Eocene in the SE.

Biostratigraphic results obtained in our study for Central Dalmatia and the Southern Adriatic Zone agree well with the findings of Puškarić (1987), Radoičić *et al.*, (1989, 1991), de Capoa *et al.*, (1995), and de Capoa and Radoičić (1994*a, b*, 2002) who first demonstrated Neogene nannofossil age in a number of flysch localities of the SE part of the basin system. Further to SE, flysch in the Ionian Zone in the Hellenides is likewise dated to be Lower Miocene (Piper *et al.*, 1978; Bellas 1997). Our new data, however, lead us to extend the Miocene sedimentation ages to other portions of the coastal onshore localities as well, from Northern Dalmatia through Pag Island till the Istrian Peninsula. As a consequence, proposing SE-directed diachroneity along the Outer Dinaride front (Piccoli and Proto Decima 1969) is no longer reasonable. Furthermore, superposition of Neogene flysch onto the Eocene "Marl with crabs" or *Globigerina* marl implies a widespread, basin-scale regional unconformity, but hitherto this issue has not received much attention. In fact, the thickness of the *Globigerina* marl varies extremely from 10 to 150 m (Marjanac and Ćosović 2000), and contacts with angular (Marjanac 2000) or erosional (Marjanac *et al.*, 1998) unconformity to the overlying flysch both exist. Šikić (1963; 1968) also argued that deposition of the both units was interrupted by a deformational event and suggested the existence of a basin-wide unconformity. An abrupt change in the composition of the planktonic foraminifer fauna above a carbonate debrite horizon separating the *Globigerina* marl and the flysch was noted by Muldini-Mamužić (1965). De Capoa *et al.*, (1995) noted that a hardground is developed on top of the "Marl with crabs", directly overlain by flysch. All these data suggest a

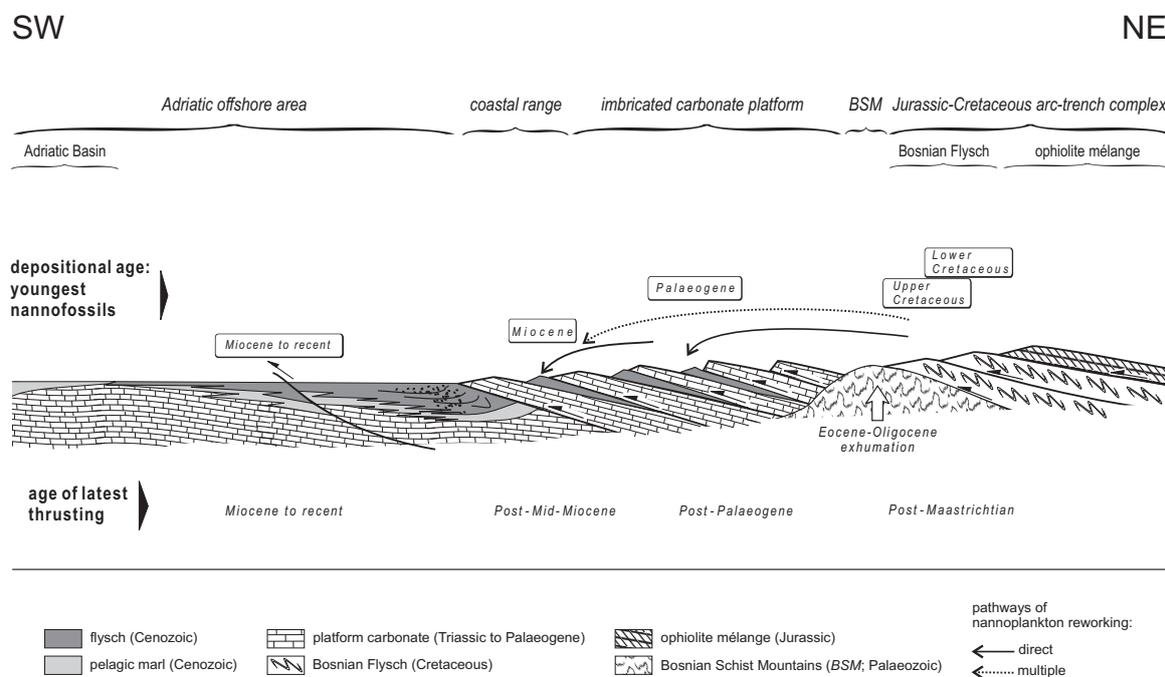

break in sedimentation and possibly slight submarine erosion as well, in spite of the classical view dealing with the progressive transition of the *Globigerina* marl to the flysch (see review in Marjanac and Ćosović 2000). Although remnants of Palaeogene flysch can exist in the coastal range, our data clearly imply that, at most localities in the basin, the flysch is of Neogene age and separated from the *Globigerina* marl or from older flysch strata by unconformity (Fig. 5).

**Fig. 5.** Schematic stratigraphic setting of the Outer Dinaride flysch in the coastal range according to the new nannofossil age data. As it directly overlies well-dated Eocene *Globigerina* marls, their relationship requires the presence of a major, basin-wide unconformity separating them. At places however, also small erosional remnants of older, Palaeogene flysch may still exist in the same orogenic strike.

The heavy mineral composition of the flysch (Magdalenić 1972; Mikes *et al.*, 2004, 2005) and especially the nannofossil "age spectra" both exhibit a remarkable degree of basinwide homogenization. In the course of wedge-top deposition, a series of small, relatively shallow basins could have been developed on and in front of the advancing thrust sheets. The "smoothing" is interpreted as a result of multiple reworking from the

precursor flysch slices and sediment dispersal that occurred within the westward-propagating, complex thrust wedge (Fig. 6).

**Fig. 6.** Schematic sketch showing the implications of biostratigraphic data. With progressive nappe propagation towards Apulia, shallow foredeeps develop at the actual nappe front. Continuous thrusting and associated sediment off-scraping result in consecutive reworking of planktonic fossils into younger strata. Flysch remnants preserved at the base of thrust sheets become progressively younger towards Apulia. This process lasted until at least late Early Miocene in the present-day Outer Dinaride coastal range, as indicated by deformed flysch sediments yielding Neogene calcareous nannoplankton. In the offshore Adriatic basin, clastic sedimentation has lasted until recent time. Age of the Bosnian Flysch taken from Hrvatović (1999) and Christ (2007). In the upper nappe unit of the Bosnian Flysch, an Albian deformation phase is also supposed (Petri 2007). Thermal history of the Bosnian Schist Mountains after Pamić *et al.* (2004).

## 5.12. Implications for Cenozoic deformation history

Flysch remnants are typically sandwiched between thrust sheets, and occur in different structural position in the Outer Dinaride nappe pile. The Bosnian Flysch is in uppermost position, and ranges in age up to Turonian to Palaeocene (Dimitrijević 1997 p. 38, Hrvatović 1999; Christ 2007). Turbiditic sequences of comparable age are found in the same structural position along orogenic strike in isolated outcrops near Zagreb, Bosanski Novi and Bihać (Jelaska *et al.*, 1969; Babić 1974; Babić and Zupanić 1976;

Crnjaković 1981) and in the Slovenian Trough (e.g. Buser 1987). These units are thrust on the AdCP, an imbricated pile of Mesozoic carbonates, the detachment surfaces being marked by a series of extremely narrow slices of Cenozoic flysch. Here, limited evidence suggests Early Eocene age of deposition (samples TD100 and TD109; planktonic foraminifer data of Krašeninnikov *et al.*, 1968). In the thrust slices below, available biostratigraphic and sedimentological data suggest a foreland-directed migration of clastic facies zones in the Palaeogene (e.g. Bignot 1972; Engel 1974; Chorowicz 1977; Drobne 1977; Cadet 1978; Marinčić 1981; Košir 1997).

Our new biostratigraphic data imply post-Mid-Miocene deformation in the Outer Dinaride coastal range. Older thrusting events to the NE are recorded by the Lower and Upper Cretaceous units of the folded Bosnian Flysch (Dimitrijević 1997; Hrvatović 1999; Christ 2007; Petri 2007) and by Lower Eocene flysch slices thrust by Mesozoic carbonates (Krašeninnikov *et al.*, 1968). On the other hand, to the SW of our sample sites, deformed Pliocene sediments and GPS measurements indicate ongoing shortening along the coastal range (Tari-Kovačić 1998; Pribičević *et al.*, 2002; Picha 2002; Tari 2002; Prelogović *et al.*, 2003; Altiner *et al.*, 2006; Mantovani *et al.*, 2006; Vrabc and Fodor 2006). Therefore, the new Miocene nannofossil depositional age of most flysch units and their structural position indicate that both sedimentation and deformation have been a long-lived continuous process in the Dinarides. The formation, subsidence and inversion of the subbasins and thus sediment cannibalization are well-documented by the high proportion of recycled nannofossils.

### **5.13. Conclusions**

Sixty-nine samples taken along the 700-km onshore sector of the Outer Dinaride flysch belt were analyzed for calcareous nannofossils. Most of them yielded mixed nannoflora with Cretaceous, Palaeogene and Neogene species.

In the light of the new nannofossil data presented herein, we suggest that the flysch sedimentation lasted at least up to Mid-Miocene all along the Dinaride coastal range. In spite of disagreement with existing planktonic foraminifer biostratigraphic data, our results are well in line with recently published nannofossil data from a number of localities within the flysch basin.

Majority of the nannoflora consists of Middle Eocene taxa, together with less abundant Cretaceous, Palaeocene and Oligocene nannofossils. Wherever Neogene species have been discovered, all these older floras are implied to be recycled from older flysch units of the Outer Dinaride accretionary wedge.

Cretaceous platform carbonate nappes of the Outer Dinarides were extensively covered by Cenozoic marine sediments. Remnants are preserved at the base of thrust sheets while the reworked microfossils also testify to the existence of Cenozoic basins on top of the accretionary wedge.

The stratigraphic relation of well-dated Eocene *Globigerina* marls lacking evidence for reworked fossil content and the Neogene flysch allows us to propose a working hypothesis on a major, widespread, hitherto largely ignored unconformity along the entire Dinaride coastal range, which requires further field evidence.

The Miocene onshore Outer Dinaride flysch suffered severe compressional deformation and is typically preserved below the imbricate thrust sheets of the Dinaride carbonate platform. Along the coastal zone, the deformation postdates Middle Miocene. This compressional phase provides evidence for the continuity of deformational events between the more internal, older Late Cretaceous to Palaeogene compressional phases and the ongoing thrusting at the Adriatic front.

# Double dating of detrital zircon from the Dinarides by fission-track and LA-ICPMS U/Pb analysis

---

This chapter contains a manuscript that is currently under preparation:  
"Double dating of detrital zircon from the Dinarides by fission-track and LA-ICPMS U/Pb analysis"  
for publication in *Chemical Geology*.  
authored by:  
Tamás Mikes, Teresa E. Jeffries, István Dunkl, Raimon Tolosana-Delgado and Hilmar von Eynatten

# **Double dating of detrital zircon from the Dinarides by fission-track and LA–ICPMS U/Pb analysis**

Tamás Mikes, Teresa E. Jeffries, István Dunkl, Raimon Tolosana-Delgado and Hilmar von Eynatten

## **Abstract**

In sedimentary provenance analysis, a fundamental question is the age of a crystalline source rock and the timing of subsequent thermotectonic events that affected crystalline terrains prior to exhumation and erosion. Zircon is a useful detrital mineral which carries a wealth of information about the petrogenesis, geochronology, alteration, and cooling history of its source rocks, but only few attempts were made so far to combine such data from single grains. We present an approach combining fission track (FT) and in-situ LA–ICPMS U/Pb isotopic analyses from the same grain. Detrital zircons were dated by the FT method, and grain interiors were imaged by SEM-CL to avoid ablation of inherited or other unsuitable domains. Precise and accurate U/Pb isotopic compositions were determined by a simple setup consisting of a 213 nm Nd:YAG laser source, coupled to a quadrupole ICPMS instrument. Our results are significant for at least two reasons: (1) The U/Pb analytical protocols provide an excellent trade-off between analysis quality and a high, cost-effective sample throughput (70–100 zircon grains per day). Figures of merit include a sensitivity of >2100 cps/ppm for  $^{207}\text{Pb}$  in case of a 55  $\mu\text{m}$  nominal pit diameter. Within-run U/Pb elemental fractionation remains below 1%, rendering correction for it unnecessary. CL-control and a good spatial resolution aid in reducing age bias, as judged from the notably high proportion (>90%) of concordant ( $\pm 5\%$ ) grain ages. (2) The double dating approach yields valuable insights into the thermal history of source terrains of Dinaride synorogenic sediments. Several clusters of age-pairs can be isolated that identify Alpine tectonostratigraphic units. The results can be effectively used for building a more realistic model of hinterland erosion and sediment dispersal patterns than normally achieved by using the two dating techniques separately.

## 6.1. Introduction

Zircon is a prime U/Pb geochronometer for igneous and high-grade metamorphic rocks, due to its broad occurrence, high stability and retentivity for radiogenic Pb. It remains rather stable in the sedimentary cycle and, hence, is extensively used in detrital U/Pb geochronology as a tool for provenance analysis, in constraining maximum depositional ages, and in stratigraphic correlation. The U/Pb single grain ages are used to constrain high-temperature events such as magmatic crystallization and high-grade metamorphism (Davis *et al.*, 2003; Fedo *et al.*, 2003)

Zircon also retains a diverse range of further chronological, petrogenetical and thermal information about its metamorphic, igneous and sedimentary host rocks. Many single-grain techniques have been implemented to examine zircon genetical aspects, such as crystal structure (Nasdala *et al.*, 2005), external and internal morphology (Dunkl *et al.*, 2001; Vavra, 1990) trace element signatures (e.g. Hoskin and Schaltegger, 2003), O isotope composition (Valley, 2003), Hf isotopic systematics (Gerdes and Zeh, 2006), Li isotopic signature (Ushikubo *et al.*, 2008) and cooling ages both by fission track (FT) analysis (Hurford *et al.*, 1984; Carter, 1999) and (U-Th)/He analysis (Reiners, 2005).

In sedimentary provenance studies, a fundamental question is the age and petrogenesis of a crystalline source rock and the timing of subsequent thermotectonic events that affected crystalline terrains prior to exhumation and erosion (e.g. Weltje and von Eynatten, 2004). Single detrital grains lend themselves favourably to address this question, although attempts to combine the above techniques in the same grain have been limited so far.

Carter and Moss (1999) were the first to couple U/Pb and FT ages of detrital zircon. They used aliquots of the same detrital sample sets, and compared the principal U/Pb and FT age components from them using the statistical method of Sambridge and Compston (1994), in order to constrain the age signature of the source units of Mesozoic sediments in Thailand. For the first time, however, these authors also attempted to perform the U/Pb analyses on the same grains previously dated by the FT method, although the approach they followed was rather time-consuming; it consisted of identifying and removing the FT-dated grains from the Teflon mount, remounting them in epoxy and repolishing for in-situ U/Pb analysis. The U/Pb ages were derived in both types of experiments by sensitive high-resolution ion microprobe (SHRIMP). Recently,

Bernet *et al.* (2006) presented a combined U/Pb–FT study of detrital zircon from Neogene (Siwalik Group) to recent sediments from the Himalayan foreland basin. They also used ion microprobe techniques (secondary ion mass spectrometry – SIMS) to derive the U/Pb ages. However, in the lack of direct textural control, and due to the prevalence of old polymetamorphic rocks in the source area, their U/Pb ages potentially represent mixtures from zircon domains of different isotopic composition, revealing only limited geological information.

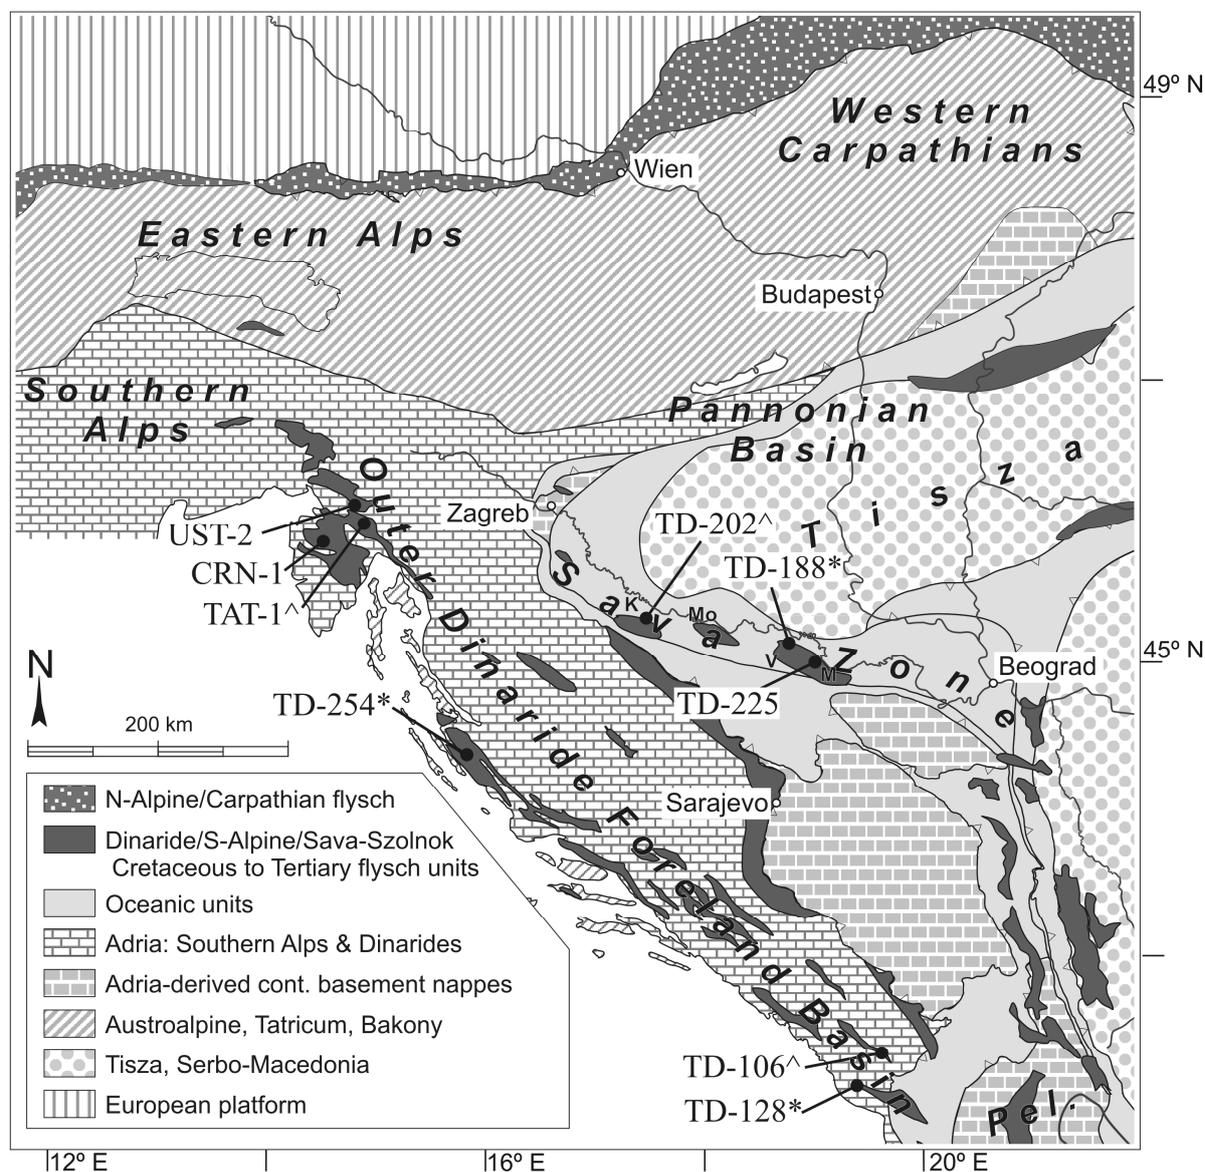

Whereas ion-probe techniques yield precise and accurate results (SIMS and especially SHRIMP), measurement times and analytical costs per isotopic datum are rather high. Furthermore, there is a risk of obtaining a biased isotope ratio due to contamination by recent common Pb at the sample surface, which even increases by the etching of fission tracks. Finally, these techniques require a high quality of the analyzed surface; this is difficult to realize in the case of etched zircon grains that have been embedded in a low-adhesion material such as PFA Teflon. Such grains exhibit an irregular, rugged surface if the density of the etched tracks is high and, in our experience, repolishing such FT mounts can not be accomplished without losing a significant proportion of grains. For the reasons above, we consider the ion-probe techniques to be of limited use in zircon U/Pb–FT double dating studies.

Recent advances in laser ablation–inductively coupled plasma mass spectrometry (LA–ICPMS) have made it a tool now challenging SIMS and SHRIMP in accuracy, precision and also spatial resolution (Günther *et al.*, 1999; Horn *et al.*, 2000; Horstwood *et al.*, 2003; Jeffries *et al.*, 1998, 2003; Košler *et al.*, 2002). Moreover it can offer a high throughput, capable of providing as many as 1000 single-grain U/Pb isotopic analyses per day (Frei and Gerdes, 2008). Laser ablation would typically remove a 10 to 30  $\mu\text{m}$  thick layer within the analyzed area and, hence, it does not require a particularly high quality for the polished sample surface. Time-resolved analysis of the laser ablation signal allows to isolate the signal portion that is no longer affected by potential surface contamination.

In double dating studies (less than 10 publications so far), LA–ICPMS U/Pb analysis has been already utilized in conjunction with (U-Th)/He thermochronology of the grains (Rahl *et al.*, 2003; Reiners *et al.*, 2005; Campbell *et al.*, 2005).

Here we present the results of a study combining FT and cathodoluminescence-controlled LA–ICPMS U/Pb geochronology from the same detrital zircon grains, from synorogenic sedimentary deposits in the Dinarides; one of the most complex and least

understood part of the European Alps. We use the data to develop a scheme for constraining major tectonic units in the sedimentary source area, many of them possessing a characteristic age-signature.

**Fig. 1.** Tectonic setting of the Dinarides with sampling locations shown. Map compiled after FGI, (1970), Aubouin (1973) and Schmid *et al.* (2008). *Star*, U/Pb dating was performed also on a handpicked zircon aliquot from that sample; *circumflex*, FT analysis alone, without U/Pb geochronology on the same grains. *Pel.*: Pelagonian Unit. ## 6.2. Geologic background

The samples chosen for this study were collected in two Tertiary basins of the Dinarides, each characterized by an entirely different geodynamic setting. Our previous work (Mikes *et al.*, 2005, 2006b) has revealed that these sedimentary sequences share many similarities in terms of their heavy mineral spectra, which are dominated by Cr-spinel, garnet and the very stable zircon + tourmaline + rutile assemblage.

### 6.2.1. Tectonic outline of the Dinarides

The Dinarides are an integral part of the European Alpine chain, located between the Southern Alps and the Hellenides (Fig. 1). An impressive SW-vergent pile of Alpine tectonostratigraphic units, they are characterized by Jurassic ophiolites thrust onto the distal passive margin of the Adriatic plate (Dimitrijević, 1982; Pamić *et al.*, 2002, Karamata, 2006; Schmid *et al.*, 2008). The latter is built up of sedimentary to low-grade metamorphic Lower Palaeozoic basement and its Permo-Mesozoic cover. The Early Cretaceous thrusting involved several Adria-derived units passively carrying the ophiolites previously thrust onto them, and gave rise to the formation of a vast clastic wedge in front of the continental-ophiolite thrust sheet complex (Aubouin 1973; Schmid *et al.*, 2008; Chapter 2 of this Thesis). The Outer Dinaride structural units are dominated by the elements of the large Mesozoic Adriatic Carbonate Platform (Vlahović *et al.*, 2005). Individual tectonic units of the platform are often separated by imbricated slices of Tertiary flysch which shows mixed carbonate–siliciclastic composition (Chorowicz, 1977; Chapter 5 of this Thesis), hinting at a major sediment source outside the platform. Thrusting in the Outer Dinarides was accompanied by the formation of a retrowedge at the NE margin of the Dinarides – the Sava Zone – that formed the collisional zone of the Dinarides with the Tisza Unit in the Tertiary (Pamić 1993, 1998, 2002; Tari, 2002; Schmid *et al.*, 2008).

### 6.2.2. Sava Zone

The Sava Zone is an elongated, highly complex tectonic zone located at the northern margin of the Inner Dinarides, separating them from the Tisza Unit further in the north (Fig. 1). It forms isolated outcrops, while a great part of the zone is covered by

Neogene sediments of the Pannonian Basin. The Sava Zone consists of Late Cretaceous ophiolites overlain by Late Cretaceous to Eocene mixed siliciclastic–carbonatic flysch-like sediments. Their deposition started in a forearc basin setting, created by the Late Cretaceous to Early Paleogene northward-directed subduction of remnant oceanic lithosphere – off the distal margin of the Adriatic plate – beneath the Tisza Unit (Pamić 1993; Pamić *et al.*, 2002, Schmid *et al.*, 2008). Whereas obduction of the Neotethys onto the Adriatic margin went to completion in the latest Jurassic already, (see Chapters 2–4 of this Thesis for details) biostratigraphic and geochronologic results revealed the existence of Campanian to Early Maastrichtian oceanic crust as well, which was thrust southwards onto the Jurassic ophiolites (Pamić and Šparica 1983; Karamata *et al.*, 2005, Ustaszewski *et al.*, in press). Geochemical data from the Cretaceous ophiolites in the Sava Zone are most consistent with an active back-arc extension behind the – already obducted – leading edge of the Neotethyan oceanic slab, with this back-arc magmatism thus considerably post-dating the onset of the obduction (Pamić *et al.*, 2002; Ustaszewski *et al.*, in press). Meanwhile, according to the interpretation of Tari (2002), around the Cretaceous/Tertiary transition the Sava Zone was converted to a retrowedge, developing behind the main thrust-wedge complex of the SW-vergent Dinaride orogen.

Siliciclastic flysch is underlain by Upper Cretaceous pelagic sediments ranging in age up to Late Campanian–Early Maastrichtian (Babić and Zupanić 1976; Bulić *et al.*, 1978; Jelaska 1978). Siliciclastic components found in the very rare intercalations of the pelagic sequence of the Banija–Kordun area (the westernmost part of the Sava Zone) comprise quartz, feldspar, chlorite, muscovite, tourmaline and rounded quartz grains and indicate a mature continental source area to the NE of the basin (Babić and Zupanić, 1976). In many occurrences a Maastrichtian age seems likely for the onset of flysch deposition, probably lasting until the Middle Eocene (Motajica Mts.: Pantić and Jovanović, 1970; Majevisa Mts.: Bulić *et al.*, 1978; Trebovac Mts.: Jelaska, 1978). In the Kozara Mts., the age of flysch deposition can be bracketed by the Campanian age of the underlying ophiolites (Karamata *et al.*, 2005; Ustaszewski *et al.*, in press) and the age of overprinting of the flysch at anchizonal conditions, based on K/Ar data from the shale sample TD207;  $63.2 \pm 1.4$  Ma and  $55.6 \pm 0.8$  Ma from the  $<2 \mu\text{m}$  and  $<0.2 \mu\text{m}$  fractions, respectively (K. Wemmer, pers. comm. 2007). These data are consistent with a Paleocene calcareous nannofossil assemblage identified in the same sample (M. Báldi-Beke, pers. comm. 2007), with the Late Paleocene age of intercalated shallow

marine limestone debris (Ustaszewski *et al.*, in press), and with Middle Eocene planktonic foraminifera from marls unconformably overlying the deformed and overprinted flysch (V. Čosović, pers. comm. 2006).

Siliciclastic components of the flysch were sourced from a composite source area made up of ophiolites, granitoids and metamorphic units (Jelaska *et al.*, 1970; Mikes *et al.*, 2006b; Ustaszewski *et al.*, in press). The geochemistry, textural patterns and (Th-U)/Pb geochronology of detrital monazite suggest that these rock suites included Late Permian A-type granitoids and Jurassic to Early Cretaceous metamorphic rocks (Krenn *et al.*, 2008). Palaeocurrent indicators suggest sediment transport from NE to E relative to the Sava Zone at present directions (Jelaska *et al.*, 1970, Babić and Zupanić 1976; Jelaska 1978), or from E to SE if the Tertiary counter-clockwise rotation in the Sava Zone that exceeds 30° is also taken into account (Márton *et al.*, 2005).

Sediments of the Sava Zone and their ophiolitic or continental basement underwent deformation and Alpine regional metamorphism due to the collision of the Tisza Unit with the Inner Dinaride continental margin (Pamić, 1993). The degree of metamorphism shows large regional variations, ranging up to amphibolite facies, and is dated mostly as Late Cretaceous to Early Paleogene (Pamić 1993, 1998; Balen *et al.*, 2003; Starijaš *et al.*, 2006; Krenn *et al.*, 2008). The sedimentary–metamorphic sequence is intruded by Late Cretaceous to Oligocene granitoids and bimodal volcanic series (Pamić and Šparica 1983; Pamić 1997, 2002; Pamić *et al.*, 2000; Starijaš *et al.*, 2005; Ustaszewski *et al.*, in press).

### 6.2.3. Outer Dinaride foreland basin

Flysch-like sediments in the Outer Dinarides form part of a large foreland basin system at the front of the SE-directed Dinaride thrust wedges (Fig. 1). Basin remnants can be traced along the orogenic strike from the Southern Alps to the Hellenides. Stratigraphic position of the flysch is described in terms of a Palaeogene to Neogene marine sequence overstepping Cretaceous platform carbonates, that are locally overlain by coarse-grained delta deposits draining Outer Dinaride carbonate nappes. The flysch overlies well-dated Lower to Upper Eocene *Globigerina* marls; their contact is conformable at places, but angular or erosional unconformities have been often reported (e.g. Marinčić, 1981; Marjanac, *et al.*, 1998; Marjanac, 2000). Due to repetitive thrusting, flysch profiles are tilted, usually truncated at their base and less than 100-

400 m thick. Turbidite beds are dominantly composed of siliciclastics, with a highly variable amount of carbonate admixture. In the NW part of the basin system, palaeocurrent data indicate largely SW-directed primary, and SE-directed deflected (longitudinal) flows (Magdalenić, 1972; Babić and Zupanić, 1983; Orehek, 1991). Radial current directions are commonly found in Central Dalmatia, resulting from complex basin floor topography and multiple flow reflection (Marjanac 1990). Based mostly on paleocurrent indicators and heavy mineral analyses in the NW, two different hypotheses exist for the provenance of the siliciclastic material. Magdalenić (1972) suggested a dual, Alpine-Dinaride source, whereas Marinčić (1981) and Marinčić *et al.* (1996) proposed derivation from the Dinaride units to the NE of the basin.

The flysch sandstones are lithic wackes to calcilithites, with their main framework components averaging at  $Q_{60-85}F_{5-15}L_{10-25}$ , corresponding to a recycled orogenic provenance (Mikes *et al.*, 2006a). Major and trace element geochemistry as well as heavy mineral analysis indicate provenance mixing of mature, quartzose sedimentary rocks and ophiolitic sequences. Locally however, especially in the central and SE part of the basin, the heavy mineral spectra comprise higher amounts of unstable metamorphic species (hornblende, tremolite, epidote, chloritoid), whereas Cr-spinel, garnet, rutile, zircon, tourmaline and apatite as well as minor amounts of staurolite and glaucophane characterize most of the heavy mineral assemblages elsewhere in the entire basin system (Woletz, 1962; Pavičić *et al.*, 2003; Mikes, 2003; Mikes *et al.*, 2005). Regional distribution of new calcareous nannofossil depositional ages reveals an increasing preservation for the Neogene part of the sequence towards the SE (Chapter 5). This pattern is well in line with a recent kinematic reconstruction by Ustaszewski *et al.* (2008), proposing that the amount of post-Early Miocene shortening increases in this direction. The above data suggest increased relief and exhumation in the SE Dinarides in the Late Tertiary, and westerly-directed drainage towards the foreland basin system.

### 6.3. Sampling, analytical techniques and data treatment

Fresh, medium-grained sandstones were selected for this study; three from the Sava Zone and six from the Outer Dinaride foreland basin. Of them, double dating was performed on two and four samples, respectively (Table 1). Samples TD-188, TD-254 and TD-128 were chosen for preparing a second, handpicked zircon aliquot to perform

a systematic comparison of the U/Pb ages obtained on fission-track etched and unetched aliquots.

**Table 1.** Sample set used in this study for zircon FT and U/Pb analyses. The lower number of U/Pb analyses from fission track dated grains is mostly due to a loss of some crystals from the FT mount during the steps of transfer to the LA cell; only less than 2 % of all analyses were rejected due to a severe age bias. From sample UST-2, only one out of the two FT mounts (n=30) was used for U/Pb dating. *SZ*, Sava Zone; *ODFB*, Outer Dinaride foreland basin. Stratigraphic ages are as compiled in Ustaszewski *et al.* (in press) and from V. Čosović (pers. comm), M. Bálđi-Beke (pers. comm), and Chapter 5; chronostratigraphic assignment according to Gradstein *et al.* (2004).

sample	locality	depositional age (Ma)	ZFT analysis		U/Pb geochronology			
				<i>n</i>	<i>grain-matched with ZFTA</i>	<i>n</i>	<i>on unetched aliquot</i>	<i>n</i>
TD-188	SZ, Vucjak Mt.	<70.6	x	60	x	48	x	10
TD-225	SZ, Majevisa Mt.	<65.5	x	55	x	46		
TD-202	SZ, Kozara Mt.	65.5–48.6	x	60				
UST-2	ODFB, NW	<55.8	x	60	x	30		
TAT-1	ODFB, NW	<55.8	x	60				
CRN-1	ODFB, NW	<33.9	x	60	x	46		
TD-30	ODFB, NW	<55.8					x	58
TD-254	ODFB, central	<18.2	x	60	x	53	x	131
TD-128	ODFB, SE	<18.2	x	60	x	53	x	142
TD-106	ODFB, SE	<53.6	x	50			x	71

### 6.3.1. Sample preparation

Zircon grains were recovered from about 2 to 5 kg samples of sandstones, following dry sieving (<0.250 mm), hydraulic pre-concentration using a Wilfley-table, dissolution of the carbonate component by cold 5% acetic acid, gravity separation by hot LST heavy liquid ( $\rho=2.88 \text{ gcm}^{-3}$ ), and electromagnetic separation.

### 6.3.2. Fission track analysis

Crystals were embedded in PFA Teflon with two mounts made from each sample. Spontaneous tracks were revealed by etching in NaOH-KOH eutectic melt at 225°C (Gleadow *et al.*, 1976) for 23 to 74 hours. Neutron irradiations were performed at the research reactor of Oregon State University. The external detector method was used (Gleadow, 1981) and, after irradiation, the induced fission tracks in the mica detectors were revealed by etching in 40% HF for 30 min. Track counts were made with a Zeiss

Axioskop microscope at  $\times 1000$  magnification combined with a computer-controlled stage system (Dumitru, 1993). The FT ages were determined by the zeta method (Hurford and Green 1983) using the age standards listed in Hurford (1998). See Dunkl *et al.* (2001) for further details.

### 6.3.3. Grain referencing

Following FT analyses, grains were documented by reflected light photomicrographs in all samples selected for the double dating. Grain co-ordinates were exported from the FT stage system and transferred to the stage control softwares of both the scanning electron microscope and the laser ablation instrument. This facilitated a rapid and easy re-identification of the grains.

### 6.3.4. Cathodoluminescence (CL) imaging

The FT-dated grains were imaged by CL prior to laser ablation. An Oxford Instruments CL system was used, interfaced to a JEOL 8900 RL electron microprobe operated at 15 kV accelerating voltage and 30 nA beam current. Images were less contrasty than those normally acquired by routine zircon imaging. We attribute this to the combined effects of the (1) rather uneven surfaces of the sectioned crystals resulting from the etching procedure (cf. Fig. 13), and (2) the unusually low beam current (chosen to reduce evaporation of the thermally unstable PFA teflon surrounding the grain in the rastered area) was not sufficient for the CL detector to produce a more brilliant image of the CL intensity contrasts.

### 6.3.5. LA-ICPMS U/Pb geochronology

U/Pb isotopic composition was determined on carefully selected crystal domains by laser ablation – inductively coupled plasma mass spectrometry (LA-ICPMS). The instrumental setup used consists of a single-collector Agilent 7500cs ICPMS equipped with a quadrupole mass filter, and a New Wave UP213 Nd:YAG UV laser system ( $\lambda = 213$  nm) operated in dynamic ablation mode. Analytical parameters are listed in Table 2. Off-line reduction of raw data was made by LAMTRACE (Jackson, 2008) and PapiAGE (Dunkl *et al.*, in prep.), with no correction for any common Pb present. Age

calculations were made using Isoplot 3.0 (Ludwig, 2003). Results of analysis and age calculation are listed in Appendices 6-1 and 6-2.

**Table 2.** LA-ICPMS instrumental parameters and measurement protocol used in this study.

<i>ICP-MS instrument operating conditions</i>	
Instrument	Agilent 7500 cs
Forward power	1500 W
Coolant gas flow	13 lmin <sup>-1</sup> Ar
Auxiliary gas flow	0.8 lmin <sup>-1</sup> Ar
Carrier gas flow	0.9 lmin <sup>-1</sup> He
Sampling depth	6.9 mm
<i>ICP-MS data acquisition parameters</i>	
Analyzed masses	201; 204; 206; 207; 208; 235; 232; 238
Dwell time	10 ms (20 ms for masses 207 and 235)
Sweeps	1000
Background acquisition time	60 s
Total ablation time	75 s
Washout time	90–120 s
Ablation time taken for age calculation	10–40 s
<i>Laser ablation operating conditions</i>	
Instrument	New Wave Research UP213 Q-switched Nd:YAG
Wavelength	213 nm
Pulse width	3 ns
Fluence at surface	2.5–3.5 Jcm <sup>-2</sup>
Pulse energy at surface	0.01–0.1 mJ per pulse
Energy distribution	Homogenized flat beam, aperture imaged
Repetition rate	10 Hz
Laser focus	fixed to target surface
Sampling scheme	ablation along short line rasters
Raster scan speed	5 μm <sup>s</sup> -2
Nominal pit diameter	55 μm (standard); 30–55 μm (unknowns)
Ablation cell	New Wave's standard circular design (V~9 cm <sup>3</sup> )
Length of tubing	1.5 m
<i>Standardization and data reduction</i>	
External standard used	Nancy 91500 zircon
Standard-sample bracketing sequence	...-[4-12-4]-[4-12-4]-...
Reference used for quality control	Plešovice zircon
Data reduction software used	LAMTRACE (primary) / PepiAGE (test phase)

### 6.3.6. Integrated processing of U/Pb and FT age data

The fact that contrasting amounts of error associate single-grain U/Pb and FT ages requires a rigorous statistical treatment of the data, in order to identify geologically meaningful age clusters. First, marginal age distributions were constructed using a variable bandwidth kernel density estimation, where a so-called normal kernel was attributed to each grain age; the standard deviation of the kernel was set equal to the standard error of that particular analysis (see details in Sircombe and Hazelton, 2004). For creating the age-pair plots presented in Fig. 10, a two-dimensional version of the same variable bandwidth kernel density estimation was used, assuming no correlation between the two standard errors. Clusters on the age-pair plots were defined by iso-density levels of the 2D variable bandwidth kernel density estimate. A higher density, i.e. a more probable grain clustering, is achieved whenever more grains plot together and/or if they have low analytical error.

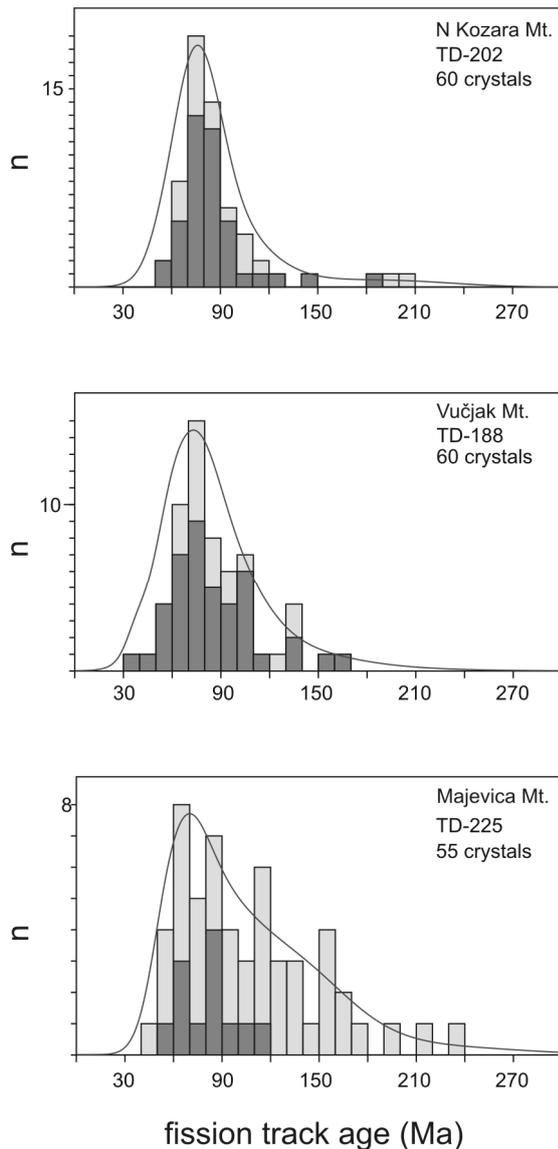

## 6.4. Results

### 6.4.1. Fission track analysis

The track counting results are listed in Appendix 1. The  $\chi^2$ -test (Green, 1981) and the dispersion (Galbraith and Laslett, 1993) indicate that most samples represent mixtures from multiple sources having different cooling ages. The PopShare software (Dunkl and Székely, 2002) was used to deconvolute the age spectrum in up to 3 age components. Table 3 contains the best fitting results.

#### 6.4.1.1. Sava Zone

Three samples from the Sava Zone are all dominated by a Late Cretaceous age component (Fig. 2; Table 3). In the Kozara (TD-202) and Vučjak Mts. (TD-188), the age distribution is dominated by a Late Cretaceous mode around 75 Ma, and in the latter a less significant age component of 90 Ma is also present. The majority of single-grain ages is connected to glass-clear, euhedral crystals with intact crystal edges and

**Fig. 2.** Distribution of single grain zircon fission track ages in three flysch sandstone samples of the Sava Zone. *Dark grey bars*, glass-clear, euhedral zircon crystals; *light grey bars*, all crystals. Composite age spectra (continuous lines) were computed according to Hurford *et al.* (1984).

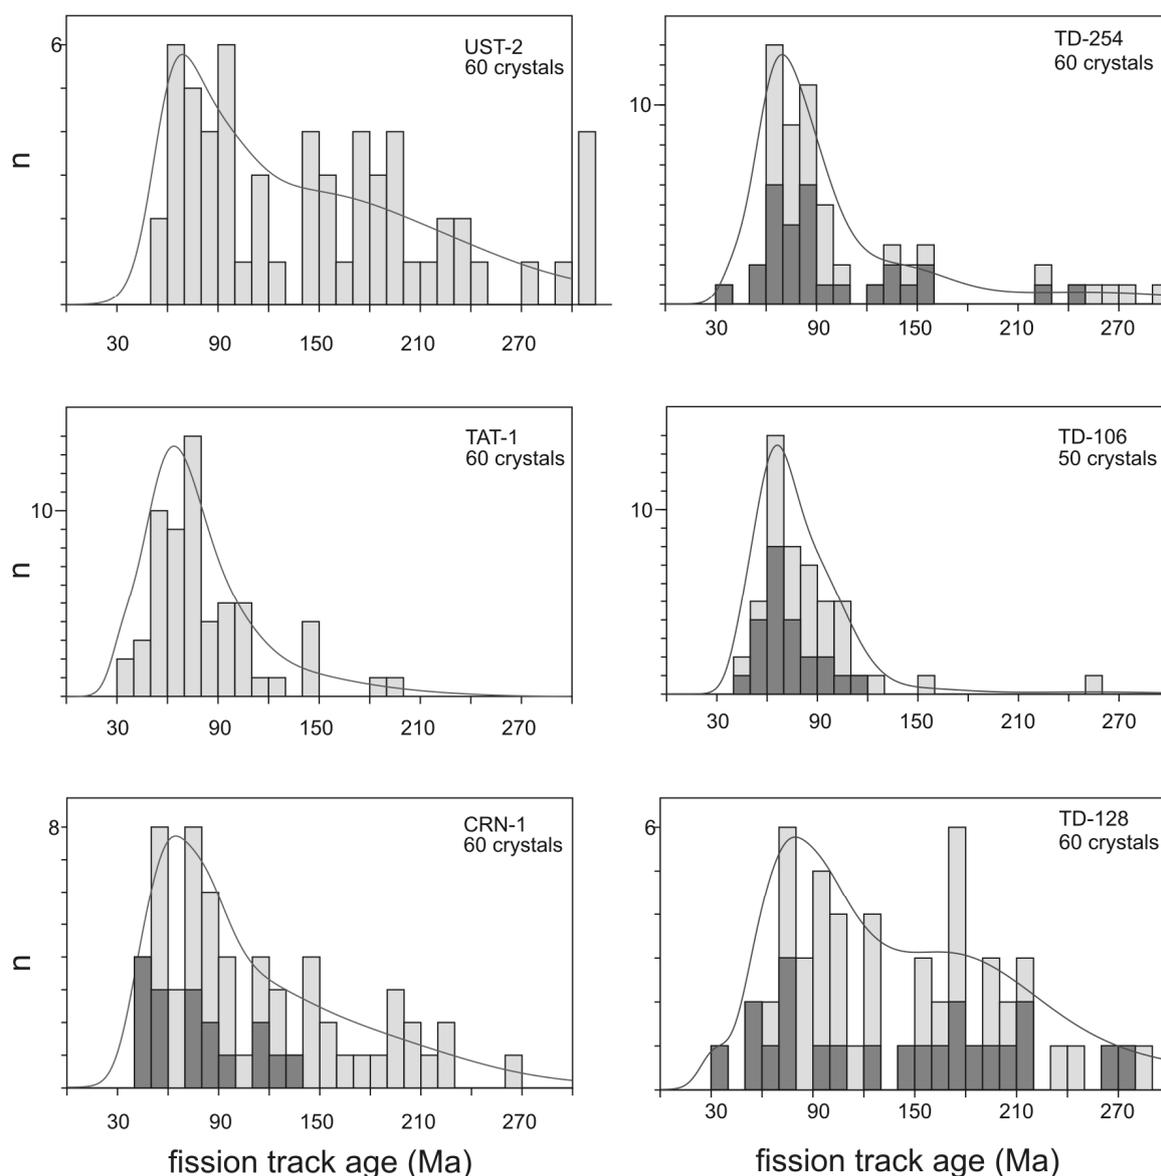

#### 6.4.2. U/Pb geochronology – assessment of data quality

We performed 276 U/Pb age determinations by LA-ICPMS on zircon single grains that were previously dated by FT analysis. In order to test the possible effects of (1) the etching on the U-Pb isotopic systematics of the grains and (2) the FT operator bias on the underlying U/Pb age structure of the FT dated grains, we also analyzed an unetched aliquot from three samples (see details in Table 1).

faces, suggesting a direct derivation from a magmatic and/or volcanic source in the Cretaceous. Sample TD-225 (Majevisa Mts.) shows the broadest age distribution; about one half of the grains is derived from a different source that experienced a last cooling event in the Jurassic-Early Cretaceous (Fig. 2; Table 3).

#### 6.4.1.2. Outer Dinaride foreland basin

FT age distributions in six samples are invariably dominated by a Late Cretaceous age population, with their modes ranging between 69 and 88 Ma, comparable to the results in the Sava Zone. They all emerge from a broad distribution of older single-grain ages (except for sample TD-106). There, a Jurassic-Early Cretaceous group with a mode around 143 Ma and a Permo-Triassic group with a mode around 247 Ma can additionally be isolated (Fig. 3; Table 3).

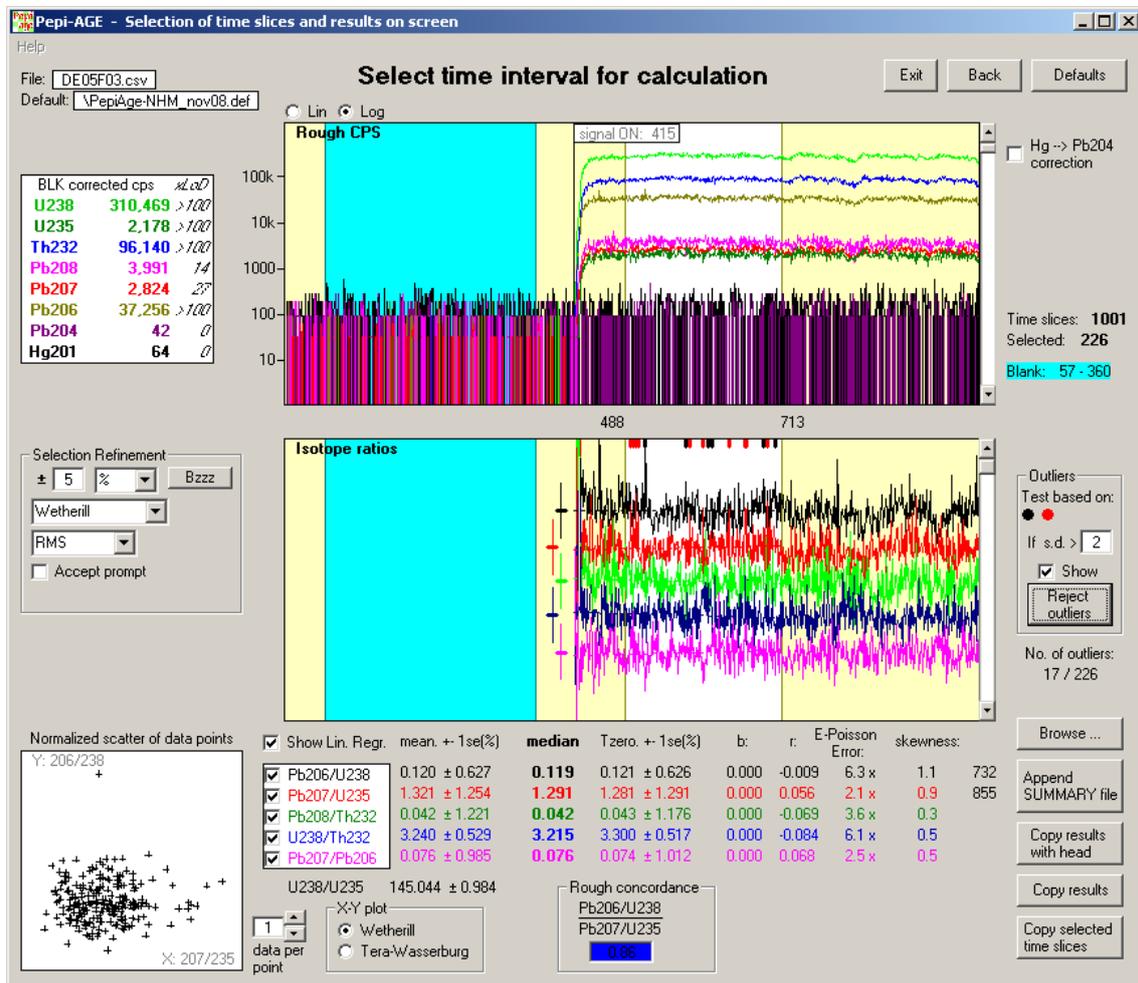

**Fig. 3.** Distribution of single grain zircon fission track ages in six flysch sandstone samples of the Outer Dinaride foreland basin. *Dark grey bars*, glass-clear, euhedral zircon crystals; *light grey bars*, all crystals (morphology was not registered in samples UST-2 and TAT-1). Composite age spectra (continuous lines) were computed according to Hurford *et al.* (1984).

Due to our unusual sample material (i.e. etched surfaces) we briefly assess data quality to ensure a meaningful geological interpretation of the U/Pb geochronologic results.

The amount of isotope ratio drift encountered during the laser ablation was minimal. This phenomenon is partly attributed to chemical fractionation caused by non-stoichiometric sampling by the laser pulses (e.g. Hergenröder, 2006), and necessitates several labour-intensive correction steps, e.g. the use of a thallium tracer solution aspirated into the plasma and employing a fractionation law that relates laser fluence and

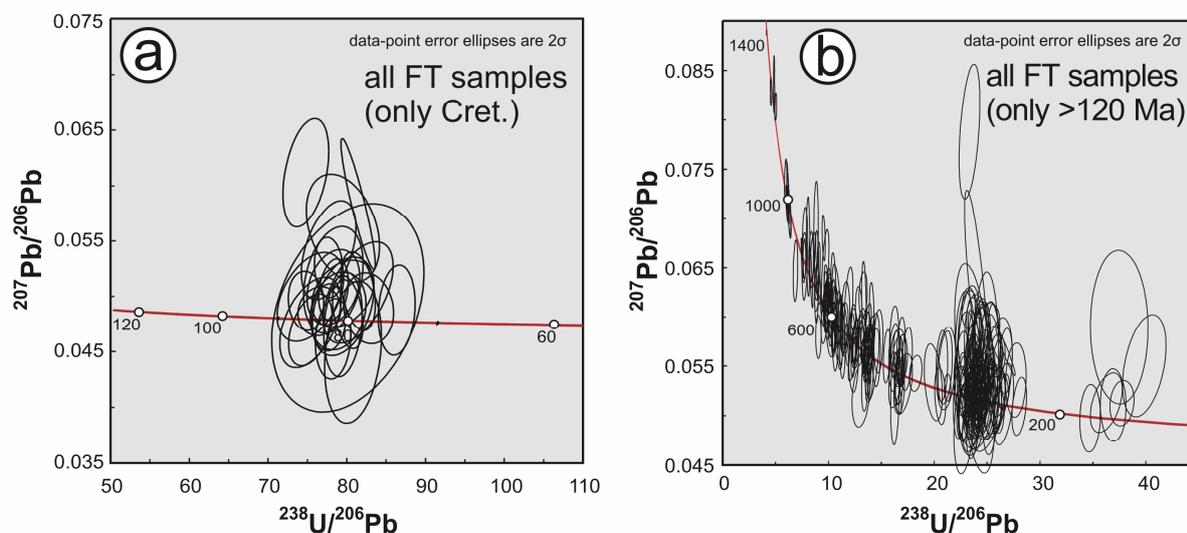

crater aspect ratio to the rate of Pb/U fractionation during ablation (Horn *et al.*, 2000) or an off-line mathematical correction of the drifted dataset (Sylvester and Ghaderi, 1997). These additional measures are both a source of additional error that (1) needs to be propagated into the uncertainties of the final isotope ratio results, and (2) adversely affects the accuracy. We used the ratio of the y-intercept of the linear regression of the  $^{206}\text{Pb}/^{238}\text{U}$  signal to the median of the individual, time-resolved  $^{206}\text{Pb}/^{238}\text{U}$  ratios in order to quantify the ablation-induced within-run drift. In most cases this value remained below 1%, which enabled us to take the median isotope ratios for the age calculation without performing a drift correction additionally (Fig.4).

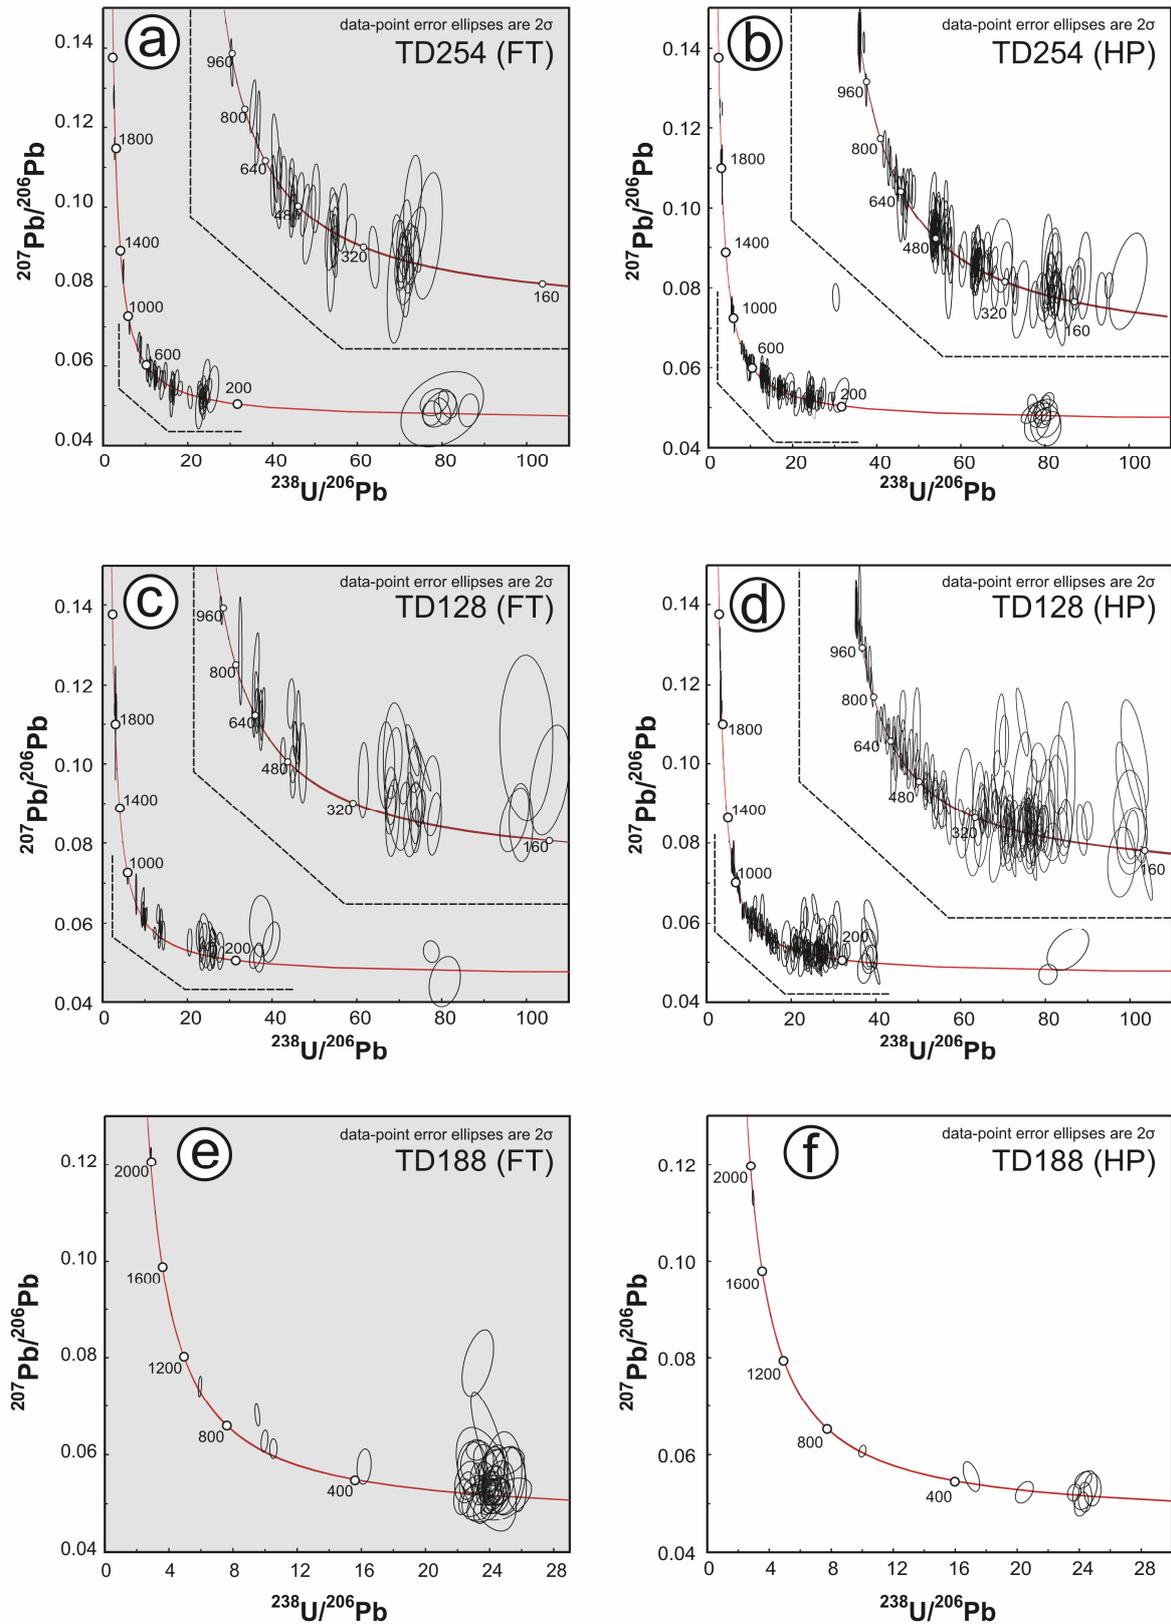

**Fig. 4.** Time-resolved isotope ratio analysis by laser-ablation ICPMS of the 91500 zircon reference material. The background-corrected analyte intensity ratios  $^{207}\text{Pb}/^{235}\text{U}$  and  $^{206}\text{Pb}/^{238}\text{U}$  show no significant time-dependent drift away from the initial value at the begin of the experiment, which rendered any correction for within-run drift unnecessary.

Preliminary assessment of the possible incorporation of the common Pb component was made using Tera-Wasserburg concordia plots (Figs. 5 & 6; Tera and Wasserburg, 1972). For the majority of the analyses, the  $2\sigma$  error ellipses are within the concordia, pointing to no significant amounts of common Pb component in the analyzed zircon volumes. This is corroborated by the conventional Wetherill concordia plots, showing a good agreement of the  $^{207}\text{Pb}/^{235}\text{U}$  and  $^{206}\text{Pb}/^{238}\text{U}$  ages (Figs. 7 & 8). On the basis of this pattern, no common Pb correction procedure was applied to our detrital datasets.

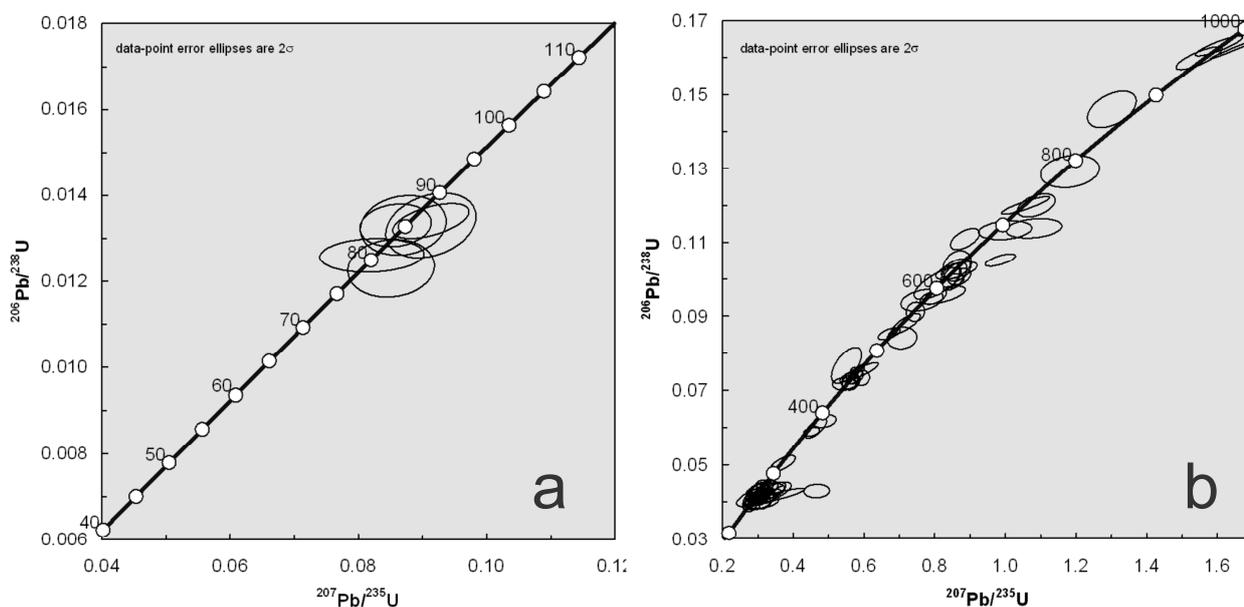

The data show several major cluster of concordant U/Pb age data at: 630 to 610, 460, 270 and 80 Ma in the Sava Zone, and at 500, 470 to 450, 370, 270, 240 and 80 Ma in the Outer Dinaride foreland basin. Most of the ages can reflect magmatic or volcanic crystallization events, based on the prevalence of grains with a euhedral to subhedral character and a well-defined oscillatory zoning pattern throughout the imaged surface.

**Fig. 5.** Tera-Wasserburg concordia for all double dated grains. **a:** ages around 80 Ma; **b:** ages older than ca. 120 Ma.

**Fig. 6.** Tera-Wasserburg concordia of three double dated zircon samples (left) for which additional U/Pb analyses were performed on their unetched aliquots (right). Both the overall age distributions and the common Pb levels of crystals in the FT mounts are fairly comparable to those in the epoxy mounts.

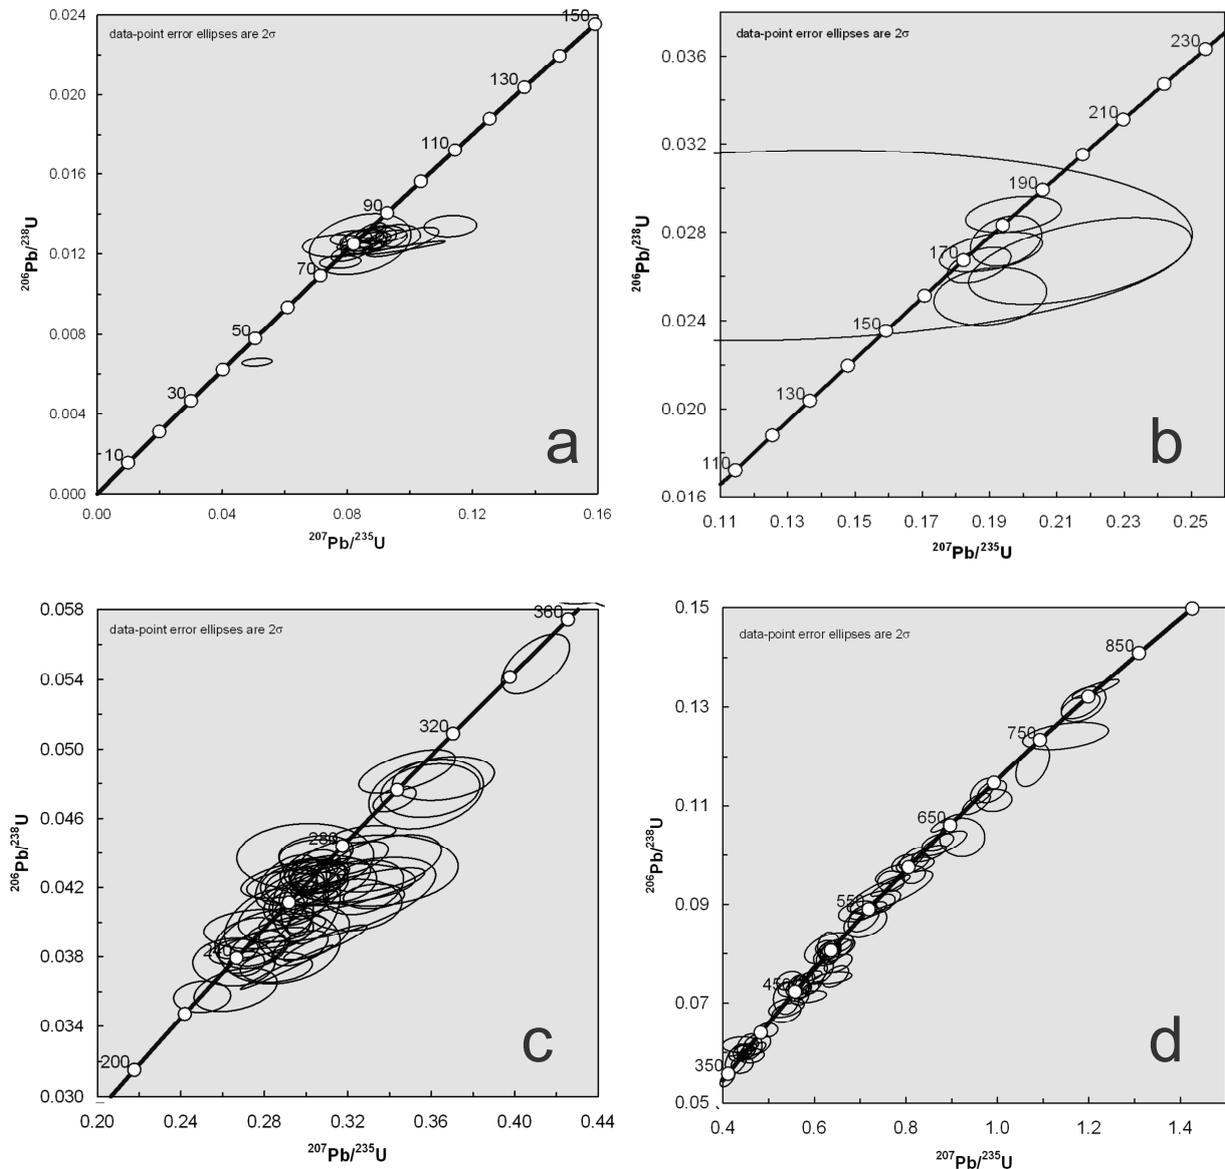

**Fig. 7.** Wetherill concordia of the double dated zircon grains in the Sava Zone. **a:** Cretaceous age group; **b:** older, Phanerozoic to Late Proterozoic grains. A few, largely concordant grains >1000 Ma plot outside the diagram.

## 6.5. Discussion

### 6.5.1. Capability of quadrupole LA-ICPMS for zircon U/Pb geochronology

The analytical setup and parameters used in this study (Table 2) enabled us to acquire precise and accurate isotopic ratios for zircon U/Pb geochronology. In concordant Phanerozoic zircons,  $^{207}\text{Pb}$  is the least abundant isotope of the U-Pb system, thus the success of the analyses largely depends on the ability to detect this analyte. Table 4 shows the typical performance of the Agilent 7500cs ICPMS instrument in terms of sensitivity for the 207 and other masses. We used the  $^{207}\text{Pb}$  sensitivity values to determine the instrumental limits of U/Pb dating at the laser beam diameters employed, taking the typical range of U concentrations encountered in the Dinaride zircon grains (Fig. 9). The calculations show that the intersection of the age-intensity function with the ca. 90 cps limit of detection (grey band) yields an estimate for the actual instrumental "limit of dating". Knowing the U concentrations in advance – derived from the fission track chronology – is helpful to decide if an adjustment of ablation parameters is necessary prior to analysis of that particular grain.

**Fig. 8.** Wetherill concordia of the double dated zircon grains in the Outer Dinaride foreland basin. **a:** Cretaceous age group; **b:** Jurassic age group; **c:** Permo-Triassic age group; **d:** Phanerozoic to Late Proterozoic grains. A few, largely concordant grains >1000 Ma plot outside the diagram.

### 6.5.2. Double dating: implications for sedimentary provenance

We combined the  $^{206}\text{Pb}/^{238}\text{U}$  geochronological and FT thermochronological results for each grain in order to obtain a two-dimensional distribution of ages, which highlights several important provenance characteristics.

**Table 3.** Deconvolution of composite zircon FT age spectra for all samples that failed the  $\chi^2$ -test, i.e. shows a broad age distribution suggesting a composite source. Calculations were based on the Simplex algorithm (Cserepes, 1989) implemented by Popshare software (Dunkl and Székely, 2002); fittings were performed by iteratively minimizing the root mean square. Tect: tectonic unit (S – Sava Zone; D – Outer Dinarides); M1, M2, M3: mean of the isolated age components; SD1, SD2, SD3: standard deviations of the components (Ma); %C1: proportion of the youngest component (%); RMS: root mean square.

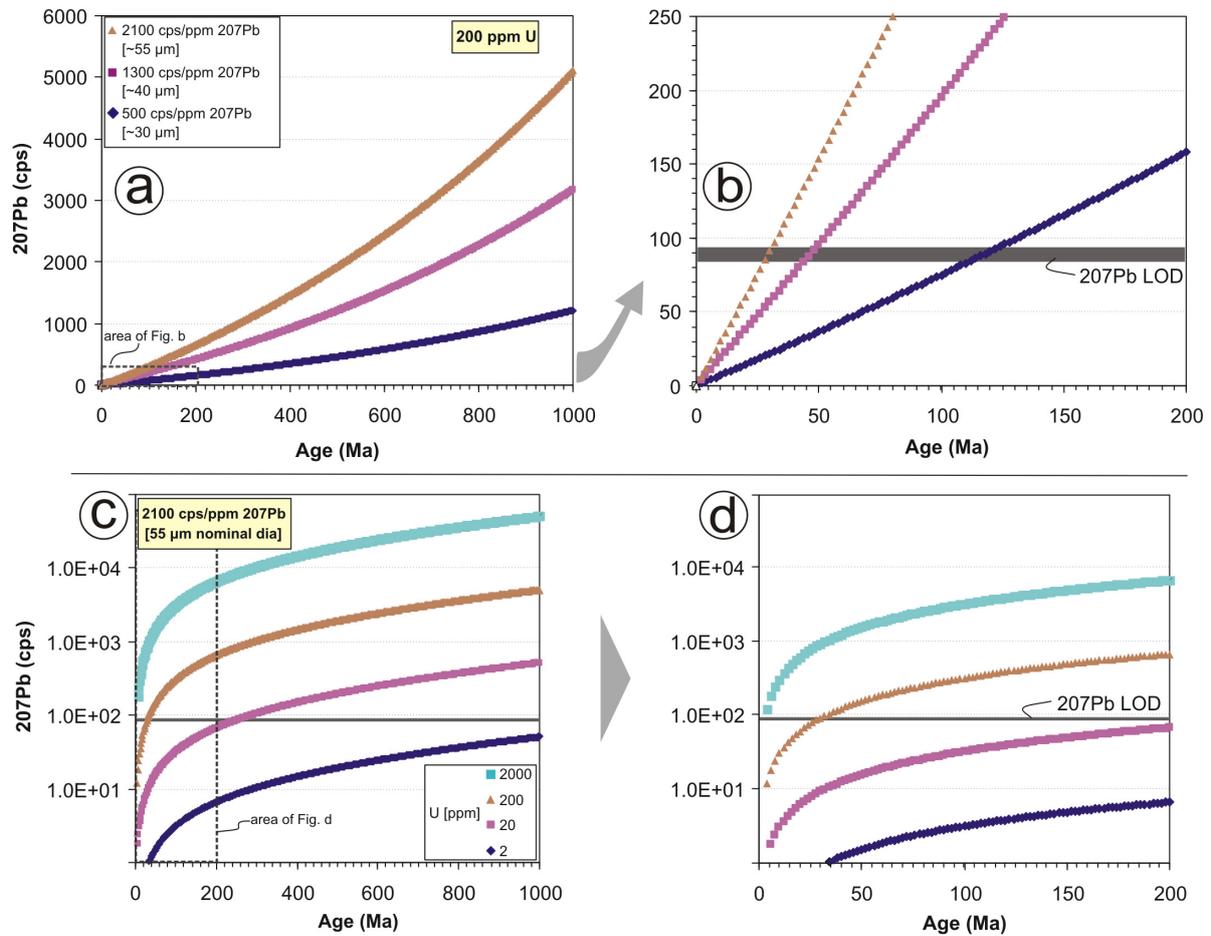

sample	tect	comp.	n	M1	SD1	%C1	M2	SD2	M3	SD3	RMS
TD-188	S	2	60	74	9	39	91	29	-	-	0.023
TD-225	S	3	55	72	16	44	118	24	187	24	0.021

**Table 4.** Typical instrument sensitivities for selected analytes as determined here on the Nancy 91500 zircon reference material, using background corrected count rates from experiment #no30b18. Recommended isotope concentrations are as reported in the GeoRem database (Jochum *et al.*, 2005). Sensitivities in case of pit diameters other than 55  $\mu\text{m}$  are calculated from the ratios of the different ablated volumes. All sensitivities are corrected for the difference between the nominal and the measured pit diameter which is usually around 10%.

**Fig. 9.** Modelled ICPMS instrument response on mass 207 in the laser ablation experiments, as a function of various parameters. **a** and **b** (blow-up of framed area in **a**): a zircon with a typical U concentration of 200 ppm, as a function of the geological age, assuming only single-component radiogenic Pb in the lattice. Three cases are shown; for 500, 1300 and 2100 cps/ppm sensitivities, which correspond to nominal pit diameters of 30, 40 and 55 μm, respectively, most frequently chosen in this work. **c** and **d** (blow-up of framed area in **c**): instrument response on mass 207 at a sensitivity of 2100 cps/ppm as a function of geological age, for zircons with four different U concentrations. These calculations show the limits (and capabilities) of the instrumental setup for the purposes of U/Pb age dating. Intersection of any curve with the ca. 90 cps limit of detection (grey line) would yield an estimate for the actual "limit of dating". Knowing the U concentrations in advance – derived from the neutron irradiations – is helpful to decide if an adjustment of ablation parameters is necessary prior to analysis of that particular grain.

In the Sava Zone (Fig. 10a), well isolated groups of Late Cretaceous (86 to 79 Ma), late Early to Late Permian and Ordovician to Early Silurian crystallization ages occur. Probably, a Late Proterozoic group of ages between 640 to 600 Ma also forms a less pronounced cluster. The Ordovician to Early Silurian group and a minor fraction of the Permian group were derived from source units experiencing no major thermal event after Jurassic to Early Cretaceous times. However, the majority of the Permian crystals

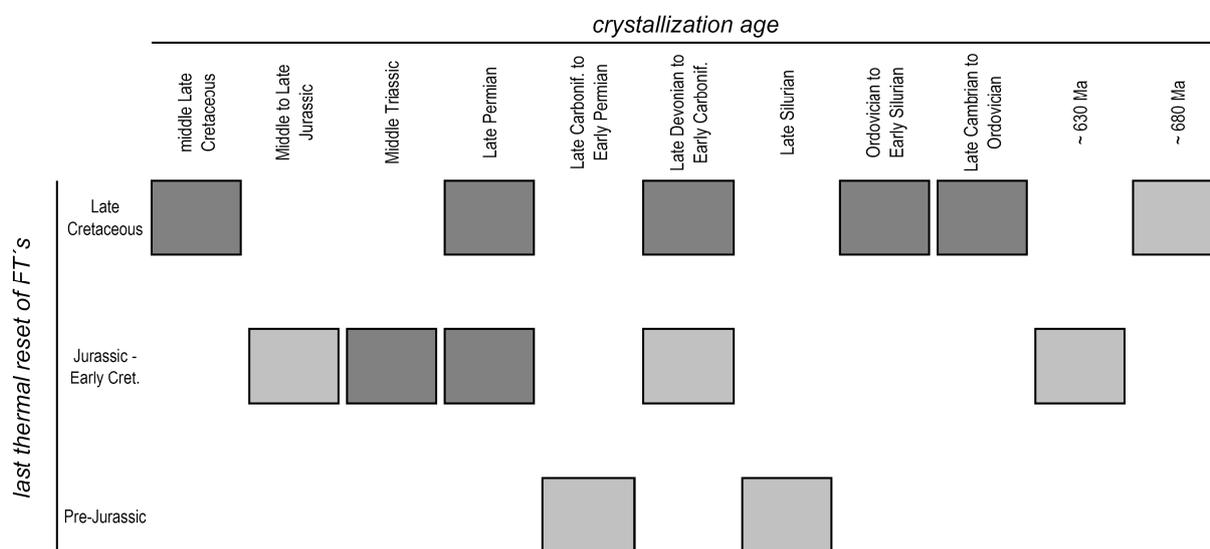

**Fig 10.** Age-pair plots portraying the relationship of U/Pb and FT ages on a single-grain level, reflecting the ages of crystallization and of cooling below mid-crustal levels, respectively. **a:** Sava Zone; **b:** Outer Dinaride foreland basin. Individual kernel density estimates for the marginal distribution of both sorts of ages are displayed as well. Characteristically, standard error is low with the U/Pb ages ( $1\sigma$ : 0.5-1.5%), and high with the FT ages ( $1\sigma$ : 15-30%), which explains the contrasting age distribution types. In this two-dimensional combination of the age distributions, the clusters are defined by isodensity levels of a variable bandwidth 2D kernel density estimate (as described in Section 6.3.6.). See text for discussion.

is derived from units that cooled below the thermal zone of zircon track instability only in the Late Cretaceous. The youngest cluster of identical U/Pb and FT ages of ca. 80 Ma clearly represent a first-cycle source. Their magmatic (probably volcanic), rather than metamorphic origin is supported by oscillatory zoning with faint but straight zone boundaries, and their rather uniform U concentration (colour coding in Fig. 10a). It is possible that grains of this group represent a single source.

Age distributions in the Outer Dinaride foreland basin reveal essentially the same clusters, but several additional ones occur here as well (Fig. 10b). These include a Late Cambrian (c. 500 Ma), a Late Devonian (c. 380 Ma) and a Triassic (c. 240 Ma) component; however only the two former are characterized by Late Cretaceous cooling ages. Small but coherent groups of further Late Devonian to Early Carboniferous (380 to 340 Ma) as well as Late Carboniferous to Early Permian ages (310-290 Ma) may reflect a Triassic thermal event affecting their source rocks. As in the Sava Zone, a fraction of the Permian grains shows no effective thermal reset in the source units after their Jurassic/Early Cretaceous cooling. A striking feature is that none of the Triassic grains indicates dominant Late Cretaceous cooling event, but they belong to the same Late Mesozoic FT age population as the Permian grains noted above. Finally, a small age cluster of Jurassic crystals documenting an Early Cretaceous cooling event also occurs. A part of these peculiar crystals exhibits an unusually large size (up to 200  $\mu\text{m}$ ), typically low U contents, and large regular and homogeneous CL domains indicative of magmatic zoning, altogether suggesting a gabbroid origin (Vavra, 1990; Grimes *et al.*, 2007).

The age clusters isolated herein match typical Alpine tectonostratigraphic units. Given that basement geochronology is known in detail, several source terranes can be pinpointed with such a confidence that is normally not achieved by using the two dating techniques separately. We preliminarily conclude that a majority of the grains indicating Late Cretaceous overprint is derived from the Austroalpine and/or Tisza Units as this thermal event is not recorded in the Central and Northern Dinarides (see discussion in Chapter 2 of this Thesis). Our results clearly demonstrate the mixing of sediments derived from exhumed source areas that previously underwent fundamentally different thermal histories (Fig. 11). In summary, the double dating technique has the potential to discriminate among detrital grains (1) derived from several sources characterized by different thermal evolution but an identical U/Pb age signature, or (2)

derived from units sharing a uniform cooling history but comprising rocks with a variety of zircon U/Pb ages.

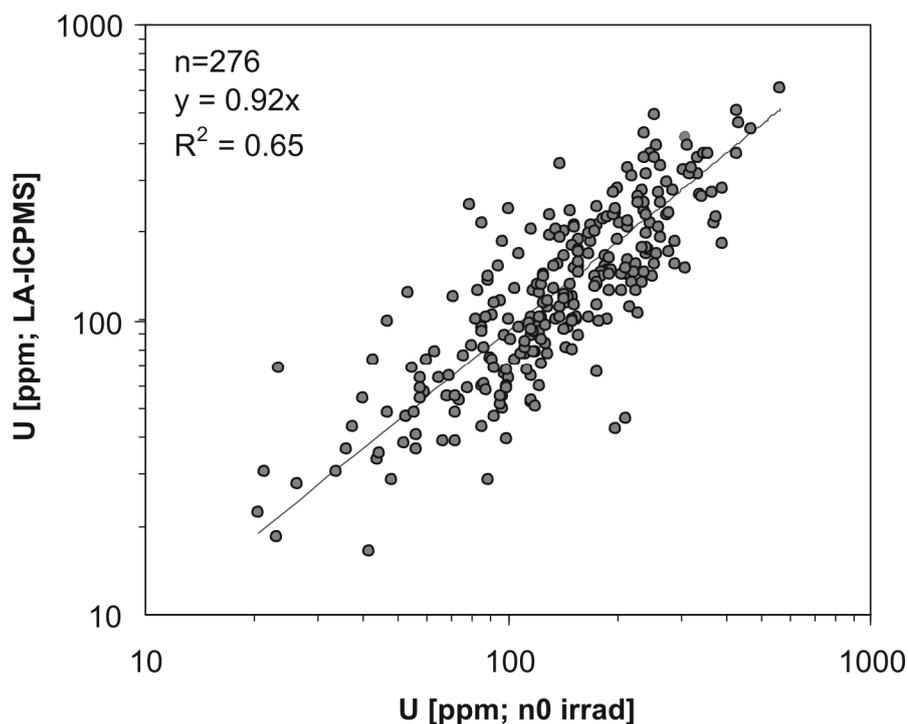

**Fig. 11.** Schematic representation of the zircon double-datum clusters which have been isolated by the two-dimensional statistical treatment, for the case of the Outer Dinaride foreland basin (Fig. 10b). The double dating technique has the potential to discriminate detrital grains from sources with an identical U/Pb age signature if the tectonic units comprising these rocks underwent different thermal histories; this is normally not achieved by using the two dating techniques separately. The remarkable mixed FT age character of the Permian grains along with the lack of a Late Cretaceous thermal imprint on the Middle Triassic age population strongly suggest the mixing of Dinaride and Austroalpine/Tisza-derived detritus in the sediment dispersal system; a Late Cretaceous regional thermal overprint is not typical for the Dinaride basement as its last main cooling occurred in the Jurassic-Early Cretaceous (see discussion in Chapter 2 of this Thesis).

### 6.5.3. Implications for U concentration determination

With conventional FT analysis, the U concentration is determined by irradiating the sample with thermal neutrons. This will induce a fission of the  $^{235}\text{U}$  atoms, which is then recorded by an external detector placed directly onto the crystals. The induced tracks are used to derive the U concentration distribution in the crystal, exactly on those areas where the spontaneous tracks were counted (e.g. Hurford and Green, 1982; Tagami and O'Sullivan, 2005). Although unparalleled in spatial resolution, still a number of limitations remain with this technique that are related both to the quality of irradiation (affecting U concentration data quality), and also to the serious hindrance of the need to ship the samples to a suitable research reactor (resulting in long turn-

around times, serious safety issues related to the treatment of low-activity materials, and the ever-decreasing number of suitable reactors).

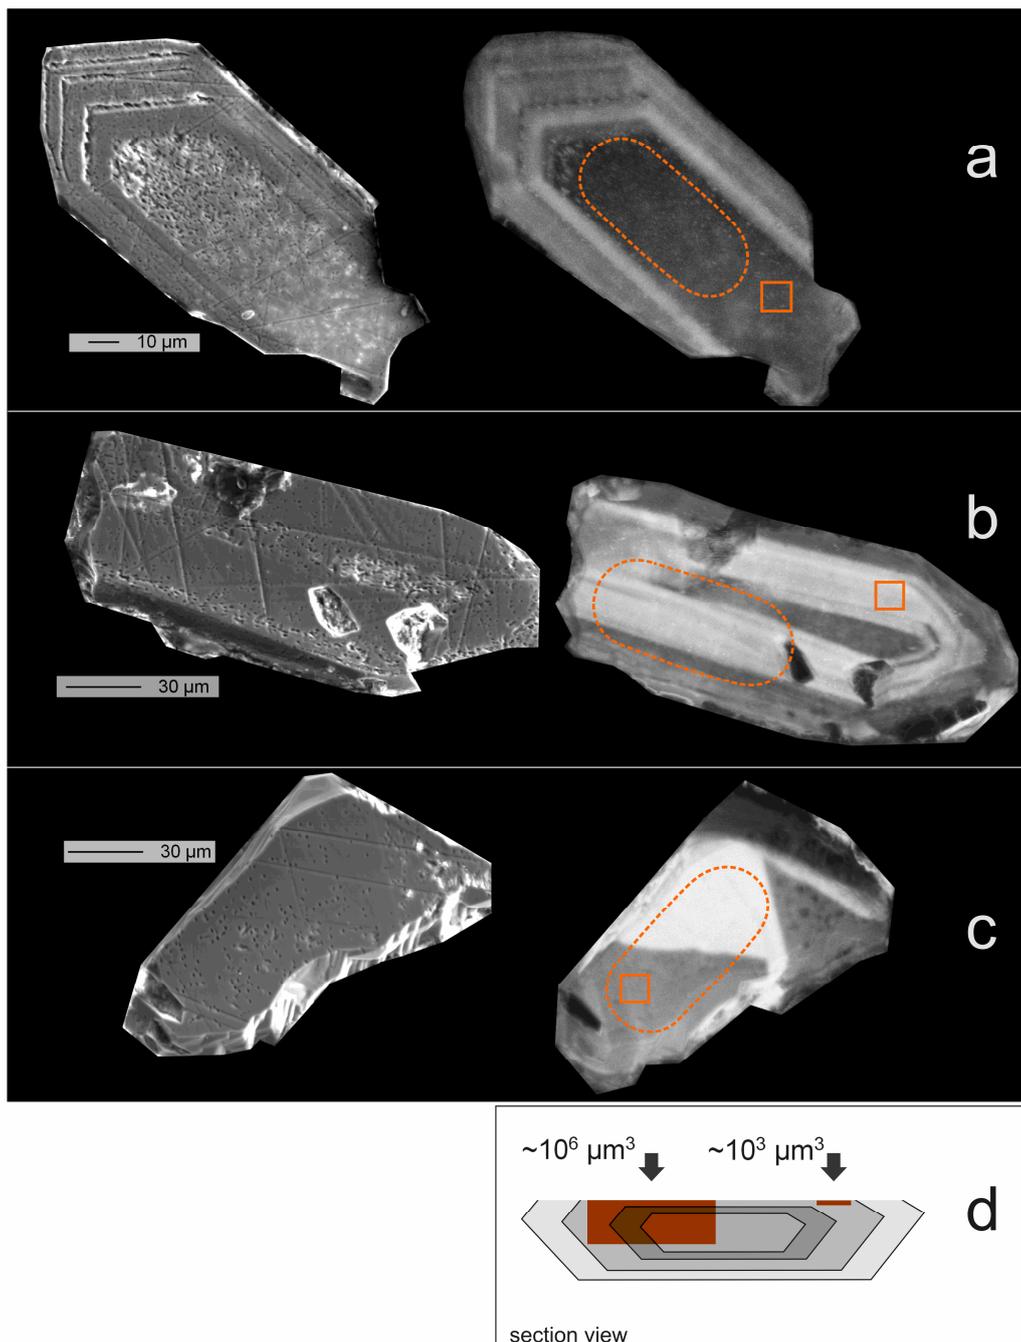

Recent efforts focused on overcoming these issues by utilizing LA-ICPMS to derive the U concentration of zircon for FT age calculation (Cox *et al.*, 2000; Svojtka and Košler, 2002; see also Hasebe *et al.*, 2004, for apatite).

**Fig. 12.** Cross-plot of zircon U concentrations determined by neutron irradiation and subsequently by LA-ICPMS. The data are only moderately correlated, accounted for by the different sampling area and depth of the techniques used, together with the three-dimensional extension of U heterogeneity in zircon (see also Fig. 13).

Although LA-ICPMS instrument tuning parameters and the analytical protocol were optimized for U/Pb age determination (Table 2), we made an attempt in this study to determine the U concentrations. Comparing the results to the U concentrations derived from the neutron irradiations (Fig. 12), a moderate correlation is obtained. We attribute the deviation to four possible factors; (1) the considerable difference in the spatial resolution of the two techniques clearly shows that U concentrations integrated over different volumes (Fig. 13) pose a serious source of inconsistency in case of U heterogeneity; (2) the geometry of the ablation cell used features a large (ca. 10 mm) distance between the sample grains and the 91500 zircon

standard, which is unfavourable due to different efficiency in aerosol transport in these regions of the cell (Bleiner and Bogaerts, 2007); (3) the heterogeneous distribution of U in the 91500 standard ( $\pm 17\%$ ; Belousova *et al.*, 2002); (4) the uncertainty inherent to the neutron irradiation. We consider (1) to be the most dominant factor and future work should focus on developing ablation protocols that converge the ablated volume to that used in the FT analysis.

---

**Fig. 13 (previous page):** SEM (left) and CL (right) images of zircon grains illustrating U zoning. Zones rich in U are characterized by a higher track density and darker CL than U-poor zones. Note the inherent volume difference of the dating approaches, which at the same time provide the U concentrations as well. Track counting is performed in the square area; the induced tracks counted in the external detector reflect the average U concentration in the topmost 7  $\mu\text{m}$  thick layer of the zircon grain, whereas laser ablation integrates U concentration from a ca. three orders of magnitude larger volume. The examples are arranged in a downward increasing order of expected disagreement between the both concentration values.

## 6.6. Conclusions

The zircon FT–U/Pb double dating approach as developed and described in this study yields valuable insights into the thermal history of source terrains of Alpine synorogenic sediments, demonstrated by case studies from the peripheral and rethrow-edge foreland basins of the Dinarides. The "age-pairs" clearly match typical Alpine tectonostratigraphic units and the results can be effectively used for building a more realistic model of hinterland erosion and sediment dispersal patterns than normally achieved by using the two dating techniques separately. In the Tertiary basins of the Dinarides, a major sediment contribution from the adjacent Tisza, Austroalpine and Pelagonian Units is highly probable.

## *Chapter 7*

### Conclusions

## Conclusions

This work presents the results of a sedimentary provenance study undertaken in Cretaceous to Tertiary basins of the Dinarides. The major objective has been to put new constraints on the orogenic evolution of this integral, yet one of the least known segment of the European Alpine chain. We have taken on the approach of in-depth characterizing the detritus derived from major tectonostratigraphic units, focusing on information extracted via the geochemistry, geochronology and fission-track thermochronology of single detrital grains. We used these results to describe the paleogeology and understand sediment dispersal patterns which are all dependent on the large-scale crustal and surface processes involved in the Alpine orogeny.

The Bosnian Flysch forms a *c.* 3000 m thick, intensely folded stack of Upper Jurassic to Cretaceous mixed carbonate and siliciclastic sediments in the Central Dinarides, sandwiched between the Adriatic Carbonate Platform and the Dinaride Ophiolite Zone. Rich in ophiolite- and continental-derived detritus, its detailed study revealed important tectonic events related to the closure and obduction history of the Neotethys Ocean. Middle Jurassic intraoceanic subduction was shortly followed by exhumation of the overriding oceanic plate. Trench sedimentation was controlled by a dual sediment supply from the sub-ophiolitic high-grade metamorphic soles and from the distal continental margin of the Adriatic plate. Following the obduction onto Adria, from the Jurassic–Cretaceous transition onwards a vast clastic wedge (Vranduk Formation) was developed in front of the leading edge, fed by continental basement units of Adria that experienced Early Cretaceous synsedimentary cooling, by the overlying ophiolitic thrust sheets and by redeposited elements of coeval Urganian facies reefs grown on the thrust wedge complex.

Erosion of the ophiolitic thrust sheets provides important evidence for Late Jurassic acid magmatism at the intraoceanic convergent margin, inferred from detrital monazite (Th-U)/Pb and zircon U/Pb geochronology in the Vranduk Fm., as well as from apatite fission-track (FT) analysis of a unique tephra horizon preserved at the basin margin. The dominant monazite and zircon age components of  $164 \pm 3$  Ma and  $152 \pm 10$  Ma, respectively, as well as the apatite FT age of  $148 \pm 11$  Ma consistently indicate that leucocratic melt generation culminated in Middle to Late Jurassic times, coeval with and slightly post-dating sub-ophiolitic sole metamorphism. Monazite

growth and explosive volcanism call for supra-subduction zone processes at the convergent intraoceanic plate margin of the Neotethys. Extensive compilation of geochronological data demonstrates that such Jurassic felsic rocks are widespread also in the entire Dinaride-Hellenide orogen.

To characterize the eroded ophiolitic lithologies in more detail, we determined the chemical composition of detrital Cr-spinel grains by electron microprobe in several further Cretaceous sedimentary units in the same orogenic strike. These rocks occur in isolated exposures in the uplifted basement units of Medvednica, Ivanščica, Žumberak and Samobor Mountains near Zagreb. Evidence of the early Alpine evolution of the Dinarides in this area is less clear due to intense Tertiary strike-slip tectonics and the Neogene sedimentary cover of the Pannonian Basin. Cr-spinel geochemistry from the Oštrc Formation reveals that in the Early Cretaceous the ophiolitic source area was predominantly composed of harzburgite peridotites and associated cumulate rocks, probably developed in a supra-subduction zone setting. The supply of Cr-spinel with comparable chemical signatures remained dominant until the end of the Cretaceous, suggesting that exposed remnants of the same ophiolite belt persisted through the Cretaceous and/or that recycling was significant. Similarities with the Bosnian Flysch and data reported from the Northern Calcareous Alps and the Transdanubian Central Range imply a rather extensive harzburgitic ophiolite belt extending along the Adriatic margin during the Early Cretaceous.

Following mid-Cretaceous deformation and thermal overprint of the Vranduk Formation and the Adria-derived basement nappes, the depozone migrated further towards SW and received increasing amounts of redeposited carbonate detritus released from the Adriatic Carbonate Platform margin (Ugar Formation). Subordinate siliciclastic source components indicate changing source rocks on the upper plate, with ophiolites becoming subordinate. The zone of the continental basement previously affected by the Late Jurassic–Early Cretaceous thermal imprint has been removed; instead, the basement mostly supplied detritus with a wide range of pre-Jurassic cooling ages. However, a c. 80 Ma, largely synsedimentary cooling event is also recorded by the Ugar Formation, that contrasts the predominantly Early Cretaceous cooling of the Adriatic basement and suggests, at least locally, a fast exhumation.

In the Outer Dinarides, the Cenozoic thrust fronts are associated with flysch deposits. They overlie Eocene platform carbonate to bathyal marl successions that subsequently cover the Adriatic Carbonate Platform. Planktonic foraminifer

biostratigraphy indicates Eocene age of flysch sedimentation. New calcareous nanofossil data reveal that several assemblages are present; besides the dominant Mid-Eocene species, Cretaceous, Palaeocene, Oligocene and Miocene taxa were also identified throughout the entire flysch belt. Widespread occurrence of nanofossil species of zone NN4-6 indicate that flysch deposition lasted up to at least Mid-Miocene. Ubiquitous occurrence of various pre-Miocene taxa demonstrate that extensive, possibly submarine sediment recycling has occurred in the Cenozoic. As flysch remnants are typically sandwiched between thrust sheets, these new stratigraphic ages give a lower bracket on deformation age of the coastal range. The data provide a link between Cretaceous compression in the Bosnian Flysch and recent deformation in the Adriatic offshore area.

Using detrital zircon grains from the Outer Dinaride flysch and from the Sava Zone, we developed an approach to combine fission track (FT) and in-situ LA-ICPMS U/Pb isotopic analyses from the same grain. Detrital zircons were dated by the FT method, and grain interiors were imaged by cathodoluminescence (CL) to avoid ablation of inherited or other unsuitable domains. Precise and accurate U/Pb isotopic compositions were determined by a simple setup consisting of a 213 nm Nd:YAG laser source, coupled to a quadrupole ICPMS instrument. Our double dating study of detrital zircon shows that: (1) The U/Pb analytical protocols provide an excellent trade-off between analysis quality and a high, cost-effective sample throughput (70-100 zircon grains per day). Figures of merit include a sensitivity of >2100 cps/ppm for  $^{207}\text{Pb}$  in case of a 55  $\mu\text{m}$  nominal pit diameter. Within-run U/Pb elemental fractionation remains below 1%, rendering correction for it unnecessary. CL-control and a good spatial resolution aid in reducing age bias, as judged from the notably high proportion (>90%) of concordant ( $\pm 5\%$ ) grain ages; (2) The double dating approach allows several clusters of age-pairs to be isolated, that identify Alpine tectonostratigraphic units. In the Outer Dinaride flysch basin, a remarkably mixed FT age character of the Permian grains is observed, with a dominant Late Cretaceous FT age component. This, along with the lack of the same Late Cretaceous thermal imprint on the Middle Triassic age population strongly suggest the mixing of Dinaride and Austroalpine/Tisza-derived detritus in the sediment dispersal system. Zircon double dating can be effectively used for building a more realistic model of hinterland erosion and sediment dispersal patterns than normally achieved by using the two dating techniques separately.

# APPENDIX

## **List of Appendices**

### **Appendices of Chapter 2:**

Appendix 2-1: Geographic position of sampling localities and overview of the performed analyses

Appendix 2-2: Stratigraphic range and distribution of calcareous nannofossils in the Bosnian Flysch. See table notes

Appendix 2-3: Instrument setup and measurement conditions of the EMP and LA-ICP-SF-MS analyses

Appendix 2-4: Major and trace element X-ray fluorescence geochemical analyses of the DOZ mélange and the Bosnian Flysch sediments

Appendix 2-5: Microprobe analyses of detrital tourmaline in the Bosnian Flysch sediments

Appendix 2-6: Microprobe analyses of detrital rutile in the DOZ mélange and the Bosnian Flysch sediments

Appendix 2-7: Microprobe analyses of detrital Cr-spinel in the DOZ mélange and the Bosnian Flysch sediments

Appendix 2-8: Microprobe analyses of detrital garnet in the DOZ mélange and the Bosnian Flysch sediments

Appendix 2-9: Results of U/Pb LA-ICP-SF-MS dating of detrital zircon from the DOZ mélange and the Bosnian Flysch sediments

Appendix 2-10: Results of detrital zircon fission track thermochronology from the Bosnian Flysch sediments. Refer to text for the principal age components

### **Appendix of Chapter 3:**

Appendix 3-1. Electron microprobe analyses of Cr-spinel from Cretaceous clastic sediments in the NW Dinarides

#### **Appendices of Chapter 4:**

- Appendix 4-1. Analytical parameters used for electron probe microanalysis of monazite grains in this study
- Appendix 4-2. Chemical composition of detrital monazite grains of the Lower Cretaceous Vranduk Formation, determined in-situ by electron probe microanalysis
- Appendix 4-3. New U/Pb age results of detrital zircon grains of the Lower Cretaceous Vranduk Formation, determined in-situ by laser-ablation ICP-SF-MS
- Appendix 4-4. Geographic position of the sampling localities.
- Appendix 4-5. Description of the electron microprobe total (Th-U)/Pb chemical dating method of detrital monazite
- Appendix 4-6. Details of age spectrum deconvolution of detrital monazite and zircon

#### **Appendices of Chapter 5:**

- Appendix 5-1 List of all calcareous nannofossil taxa cited in the text and figures of Chapter 5
- Appendix 5-2 Geographic position of sampling localities treated in Chapter 5

#### **Appendices of Chapter 6:**

- Appendix 6-1 Analytical results of the detrital zircon FT – LA-ICPMS U/Pb double dating experiments
- Appendix 6-2 Analytical results of detrital zircon LA-ICPMS U/Pb geochronology, performed on unetched aliquots of the double dated samples on conventional polished epoxy mounts

**Geographic position of sampling localities and overview of the performed analyses**

Observed nannofossil abundance per 1000 fields of view

□ present  
 ■ very rare  
 ♦ rare  
 □ frequent  
 ▲ common

1-2 specimens observed  
 <10 specimen  
 10-100  
 >100  
 >>100

?: questionable occurrence. In case of entries "cf" and "?" 1-2 specimens were observed  
 Samples BO127b and TD148 were barren of calcareous nannofossils

**Instrument setup and measurement conditions of (a) EMP and (b) LA-ICP-SF-MS analyses**

**(a) Electron microprobe analyses**

Analyzed mineral	<b>Tourmaline</b>				
Acceleration voltage	20 kV				
Beam current	15 nA				
Probe diameter	7 µm				
Data correction	ZAF (including a fixed value of 10.2 wt% B <sub>2</sub> O <sub>3</sub> to account for boron matrix)				
Element	Spectrometer	X-ray line	Counting time peak (s)   bgd (s)		Standard
Si	1 TAP	Kα	15	5	Wollastonite; Willsboro (NY, USA)
Ti	3 PETJ	Kα	30	15	TiO <sub>2</sub> (synthetic)
Al	1 TAP	Kα	15	5	Al <sub>2</sub> O <sub>3</sub> (synthetic)
Fe	4 LIF	Kα	15	5	Haematite; Elba (Italy)
Mn	4 LIF	Kα	30	15	Rhodonite; Broken Hill (Australia)
Mg	2 TAP	Kα	15	5	MgO (synthetic)
Na	2 TAP	Kα	15	5	Albite; Amelia (VA, USA)
Ca	3 PETJ	Kα	15	5	Wollastonite, Willsboro (NY, USA)
K	3 PETJ	Kα	15	5	Sanidine; Weibern (Germany)
Zn	5 LIFH	Kα	30	15	Gahnite (USNM 145883)
V	5 LIFH	Kα	30	15	metallic V
Analyzed mineral	<b>Garnet</b>				
Acceleration voltage	15 kV				
Beam current	15 nA				
Probe diameter	3 µm				
Data correction	ZAF				
Element	Spectrometer	X-ray line	Counting time peak (s)   bgd (s)		Standard
Si	1 TAP	Kα	15	5	Pyrope; Kakanui (New Zealand)
Ti	3 PETJ	Kα	30	15	TiO <sub>2</sub> (synthetic)
Al	1 TAP	Kα	15	5	Al <sub>2</sub> O <sub>3</sub> (synthetic)
Fe	5 LIFH	Kα	15	5	Haematite; Elba (Italy)
Mn	5 LIFH	Kα	15	5	Rhodonite; Broken Hill (Australia)

Ni	5 LIFH	Kα	30	15	NiO (synthetic)
Si	2 TAP	Kα	30	15	Wollastonite; Willsboro (NY, USA)

**(b) LA-ICP-SF-MS analyses**

*ICP-SF-MS: instrument operating conditions*

Instrument	Thermo Element 2
Forward power	1100 - 1350 W
Coolant gas flow	16 l min <sup>-1</sup> Ar
Auxiliary gas flow	1 l min <sup>-1</sup> Ar
Carrier gas flow	0.8 l min <sup>-1</sup> He
Make-up gas flow	0.3 l min <sup>-1</sup> Ar

*ICP-SF-MS: data acquisition parameters*

Scan mode	E-scan
Scanned masses	202; 204; 206; 207; 208; 235; 232; 238
Mass resolution	low
Detector dead time	18 ns
Dwell time	4 ms
Settling time	1 ms
Number of scans	1000
Detector mode	analogue for mass 238, pulse for all other masses
Background acquisition time	30 s
Total ablation time	60 s
Ablation time taken for age calculation	15-45 s

*Laser ablation: operating conditions*

Laser type	New Wave UP213 Nd:YAG
Wavelength	213 nm
Laser mode	Q switched
Laser fluency	3.5 Jcm <sup>-2</sup>
Repetition rate	10 Hz
Sampling scheme	single spot static ablation
Nominal pit diameter	30 µm
Ablation cell	teardrop-shaped, low volume (V~3 cm <sup>3</sup> )
Length of tubing	1 m

*Standardization and data reduction*

External standard used	GJ-1 zircon
Reference used for quality control	Plešovice zircon
Data reduction software used	PEPITA

**Electron microprobe analyses of detrital rutile from the Dinaride Ophiolite Zone mélange and the Bosnian Flysch**

**Results of detrital zircon fission track thermochronology from the Bosnian Flysch**

Sample ID	Stratigraphy	Cryst.	RhoS	[Ns]	RhoI	[Ni]	RhoD	[Nd]	P ( $\chi^2$ )	Disp.	FT age* $\pm 1\sigma$ [Ma]
BO-117	Ugar Fm.	60	138.9	[6474]	26.3	[1226]	6.60	[4859]	0	0.42	212.4 $\pm$ 13.9
TD-154	Vranduk Fm.	60	83.3	[7456]	21.0	[1880]	5.49	[2652]	0	0.24	136.9 $\pm$ 6.5

Cryst: number of dated zircon crystals.

Track densities (Rho) are as measured ( $\times 10^5$  tr/cm<sup>2</sup>); number of tracks counted (N) shown in brackets.

P ( $\chi^2$ ): probability obtaining Chi-square value for n degree of freedom (where n = no. crystals-1).

Disp.: Dispersion, according to Galbraith and Laslett (1993).

\*: Central ages calculated using dosimeter glass: CN 2 with  $z_{CN2} = 127.8 \pm 1.6$  for zircon. See text for principal age components.

**Electron microprobe analyses of detrital Cr-spinel  
from Cretaceous siliciclastic sediments in the Croatian NW Dinarides**

[analyses in wt%. bdl=below detection limit]

## **Electron microprobe total (Th-U)/Pb chemical dating of detrital monazite**

Monazite crystals were handpicked from the non-magnetic mineral fraction under the binocular microscope and verified using EDS and SE imaging. They are transparent, colourless to pale yellow, lack severe surface etch figures, and contain virtually no mineral inclusions, whereas tiny droplets of silicate melt is trapped in some of them. Grains were mounted in epoxy, polished and carbon-coated. Chemical analyses were performed using a JEOL JXA-8900RL electron microprobe at the Geoscience Center Göttingen, equipped with five wavelength-dispersive spectrometers, operated at 20 kV accelerating voltage, 80 nA probe current, and a nominal spot size of 5  $\mu\text{m}$  (20 nA and 10  $\mu\text{m}$  in case of the REE glass standards). Although advantageous for an increased count rate and better precision (e.g. Williams *et al.*, 2006), the choice of a probe current higher than 80 nA was rendered impractical in this study due to possible beam damage effects and the dimension of the monazite grains (partly <50  $\mu\text{m}$ ) being surrounded by the thermally unstable epoxy resin. Spectrometer conditions and the primary standards used for element concentration calculation are listed in Appendix 4-4. Spectral line interferences of Th  $M_\gamma$  on U  $M_\beta$ , U  $M_\zeta$  on Pb  $M_\beta$ , Ce  $L_\beta$  on Nd  $L_\alpha$ , and Ce  $L_\beta$  on Sm  $L_\alpha$  were carefully corrected. Primary standards were measured routinely after each run of c. 90 minutes to assess analysis quality. Monazite fragment #18 of the Variscan granite DVT-303 (Dunkl *et al.*, 2008) was also included in the standard batch, due to its limited chemical zoning and apparent homogeneity in (Th-U)/Pb ages, in order to monitor the consistency of sample age results.

In total, 496 spot analyses were performed on 79 grains: 123 spots on 17 grains of sample BO-12, 315 spots on 54 grains of sample BO-72 and 58 spots on 8 grains of sample BO-95. DVT-303 was analyzed in 41 spots which yielded a pooled date of  $314.9 \pm 4.7$  Ma (2 $\sigma$  s.e.), in good agreement with preliminary zircon U/Pb ages from this granite (c. 320 Ma; Dunkl *et al.*, 2008).

Net intensities were corrected using the ZAF algorithm provided by JEOL following correction for detector dead time and background subtraction. Achieved detection limits within  $\pm 3\sigma$  confidence interval were approximately 165 ppm for Th and U, and 90 ppm for Pb as quantified by Eq. 1:

$$I_{PK} - I_{BG} \geq 3\sigma \sqrt{\frac{I_{BG}}{t_{BG}}} \quad (1)$$

where

$I_{PK}$  : peak intensity [cps];

$I_{BG}$  : total (lower + upper) background intensity [cps];

$t_{BG}$  : total (lower + upper) background count time [s].

Achieved instrumental sensitivity for Pb translates to a c. 87 and 29 Ma age of "limit of dating" for a monazite having 2 and 6 wt% of ThO<sub>2</sub>, respectively, given a UO<sub>2</sub>/ThO<sub>2</sub> ratio of 0.1.

Apparent ages were calculated for each spot analysis according to Montel *et al.*, (1996), assuming a concordant isotopic system in the monazite (e.g. Cocherie *et al.*, 1998). In this study, age uncertainty calculation was based on the analytical uncertainties of the Th, U and Pb measurements:

$$\sigma(c_i) = \sqrt{c_i^2 \cdot \left( \frac{\frac{I_{PK}}{t_{PK}} + \frac{I_{BG-} + I_{BG+}}{2(t_{BG-} + t_{BG+})}}{[I_{PK} - (I_{BG-} + I_{BG+})]^2} \right)} \quad (2)$$

where

$t_{PK}$ ;  $t_{BG-}$ ;  $t_{BG+}$  : peak, lower and upper background measurement times, respectively [s];

$I_{PK}$ ;  $I_{BG-}$ ;  $I_{BG+}$  : peak, lower and upper background intensities [cps];

$c_i$  : concentration of element i in the sample.

Analytical uncertainties derived from Eq. 2 were propagated through the age equation of Montel *et al.*, (1996) to obtain age uncertainties for each spot analysis.

Spot ages  $x_j$  together with their analytical error (standard deviation,  $\sigma_j$ ) were assessed in each grain by Grubbs-test (Grubbs, 1969) to exclude outlier spot ages. Spots

passing the test were pooled together to estimate the grain weighted mean age,  $\overline{x^*}$  (with weights being inversely proportional to the square of analytical error,  $\frac{1}{\sigma_j^2}$ ):

$$\overline{x^*} = \sum_{j=1}^N \frac{1}{\sigma_j^2} \cdot \frac{1}{\sum_{j=1}^N \frac{1}{\sigma_j^2}} \cdot x_j \quad (3)$$

where  $N$  is the number of non-outlying spots within a grain.

The standard error of this mean age,  $Q$ , accounts for both the average spot analytical errors and the spread of the spot ages within that grain.  $Q$  is thus taken as the total grain age error:

$$Q = \frac{1}{N} \left[ \sum_{j=1}^N \sigma_j^2 \right] + \frac{1}{N} \left[ \sum_{j=1}^N (x_j - \overline{x^*})^2 \right] \quad (4)$$

The spread of the individual grain ages with their standard errors was visualized through a kernel density estimation, constructed as the sum of Gaussian curves centered on each grain age and its error (mean =  $\overline{x^*}$ , s.d. =  $Q$ ). This one-dimensional variable bandwidth kernel density estimation was carried out in *R* environment using the method of Sircombe and Hazelton (2004).

### **Details of age spectrum deconvolution of monazite and zircon**

The existence of several distinct age populations was tested independently with two softwares (Popshare – Dunkl and Székely, 2002; Isoplot – Ludwig, 2003) in both cases assuming a mixture of Gaussian distributions. The programs yielded estimates of the average ages ( $\mu_p$ ) for each age population, together with their spreads ( $\sigma_p$ ) and their proportion in the whole sample ( $q_p$ ). From these, the most probable age for each isolated population was determined as

$$\mu_p \pm \frac{2\sigma_p}{\sqrt{Gq_p}}$$

where G is the total number of grains, and p is the population index (i.e. the number of pre-set populations). The two softwares gave consistent results (Table 2 in Chapter 4).

**List of all calcareous nannofossil taxa cited in the text and figures of Chapter 5**

<i>Arkhangeliskiella cymbiformis</i> Vekshina 1959	Campanian – Maastrichtian
<i>Arkhangeliskiella</i> sp.	Upper Cretaceous
<i>Blackites creber</i> (Deflandre 1954) Roth 1970	Eocene
<i>Blackites</i> sp.	
<i>Braarudosphaera bigelowi</i> (Gran & Braarud 1935) Deflandre 1947	Cretaceous – recent
<i>Braarudosphaera</i> sp.	
<i>Broinsonia</i> sp.	Albian – Maastrichtian
<i>Calcidiscus leptoporus</i> (Murray & Blackman 1898) Loeblich & Tappan 1978	NN2-21
<i>Calcidiscus macintyreii</i> (Bukry & Bramlette 1969) Loeblich & Tappan 1978	NN7-19
<i>Calcidiscus premacintyreii</i> Theodoridis 1984	NN4-6
<i>Calcidiscus tropicus</i> Kamptner 1956 <i>sensu</i> Gartner 1992	NN4-10
<i>Chiasmolithus grandis</i> (Bramlette & Riedel 1954) Radomski 1968	NP11-17
<i>Chiasmolithus modestus</i> Perch-Nielsen 1971	NP16
<i>Chiasmolithus oamaruensis</i> (Deflandre 1954) Hay, Mohler & Wade 1966	NP18-22
<i>Chiasmolithus solitus</i> (Bramlette & Sullivan 1961) Locker 1968	NP10-16
<i>Chiasmolithus</i> sp.	
<i>Chiastocyclus</i> sp.	
<i>Clausiococcus fenestratus</i> (Deflandre & Fert 1954) Prins 1979	Palaeogene – NN1
<i>Coccolithus eopelagicus</i> (Bramlette & Riedel, 1954) Bramlette & Sullivan 1961	Eocene
<i>Coccolithus miopelagicus</i> Bukry 1971	?NN5-8
<i>Coccolithus pelagicus</i> (Wallich 1871) Schiller 1930	Eocene – Recent
<i>Coronocycclus nitescens</i> (Kamptner 1963) Bramlette & Wicoxon 1967	Eocene – Miocene
<i>Cribricentrum reticulatum</i> (Gartner & Smith 1967) Perch-Nielsen 1971	NP16-20
<i>Cribrosphaerella ehrenbergii</i> (Arkhangel'sky 1912) Deflandre <i>in</i> Piveteau 1952	Albian – Maastrichtian
<i>Cyclagelosphaera reinhardtii</i> (Perch-Nielsen 1968) Romein 1977	Cretaceous – Palaeocene
<i>Cyclicargolithus abisectus</i> (Müller 1970) Wise 1973	NP24-NN1
<i>Cyclicargolithus floridanus</i> (Roth & Hay <i>in</i> Hay et al. 1967) Bukry 1971	Middle Eocene – NN7
<i>Cyclicargolithus luminis</i> (Sullivan 1965) Bukry 1971	Middle Eocene – Oligocene
<i>Cyclicargolithus</i> sp.	
<i>Cyclococcolithus formosus</i> Kamptner 1963	Eocene – NP21
<i>Discoaster aster</i> Bramlette & Riedel 1954	Miocene
<i>Discoaster barbadiensis</i> Tan 1927	NP10-20
<i>Discoaster binodosus</i> Martini 1958	Lower to Middle Eocene
<i>Discoaster deflandrei</i> Bramlette & Riedel 1954	Eocene – Oligocene
<i>Discoaster distinctus</i> Martini 1958	NP12-14
<i>Discoaster exilis</i> Martini & Bramlette 1963	NN4-9
<i>Discoaster lenticularis</i> Bramlette & Sullivan 1961	NP9-10
<i>Discoaster lodoensis</i> Bramlette & Riedel 1954	NP12-14
<i>Discoaster mirus</i> Deflandre <i>in</i> Deflandre & Fert 1954	?NP13-14
<i>Discoaster multiradiatus</i> Bramlette & Riedel 1954	NP9-11
<i>Discoaster nodifer</i> (Bramlette & Riedel, 1954) Bukry 1973	NP15-22
<i>Discoaster saipanensis</i> Bramlette & Riedel 1954	NP15-20
<i>Discoaster septemradiatus</i> (Klumpp 1953) Martini 1958	NP12-14
<i>Discoaster sublodoensis</i> Bramlette & Sullivan 1961	NP14-15
<i>Discoaster tani</i> Bramlette & Riedel 1954	NP16-22
<i>Discoaster</i> sp.	
<i>Discolithina multipora</i> (Kamptner 1948) Martini, 1965	Eocene – Miocene
<i>Discolithina plana</i> (Bramlette & Sullivan, 1961) Perch-Nielsen 1971	?Palaeogene
<i>Discolithina</i> sp.	
<i>Eiffellithus eximius</i> (Sover 1966) Perch-Nielsen 1968	Turonian – Campanian
<i>Eiffellithus</i> sp.	
<i>Eiffellithus turriseiffelii</i> (Deflandre <i>in</i> Deflandre & Fert 1954) Reinhardt 1965	Upper Albian – Maastrichtian
<i>Helicosphaera ampliaptera</i> Bramlette & Wilcoxon 1967	NN2-4
<i>Helicosphaera carteri</i> (Wallich 1877) Kamptner 1954	NN1 – recent
<i>Helicosphaera compacta</i> Bramlette & Wicoxon 1967	Middle Eocene – NP24
<i>Helicosphaera euphratis</i> Haq 1966	Middle Eocene – Miocene
<i>Helicosphaera intermedia</i> Martini 1965	Middle Eocene – Miocene
<i>Helicosphaera obliqua</i> Bramlette & Wilcoxon 1967	NP24 – NN6
<i>Helicosphaera seminulum</i> Bramlette & Sullivan 1961	Lower – Middle Eocene
<i>Heliolithus kleinpellii</i> Sullivan 1964	NP6-9
<i>Isthmolithus recurvus</i> (Deflandre <i>in</i> Deflandre & Fert 1954)	NP 20-22 (marker of base NP20; Martini, 1971)
<i>Lanternithus minutus</i> Stradner 1962	NP16-22
<i>Lophodolithus nascens</i> Bramlette & Sullivan 1961	NP9-15
<i>Markalius inversus</i> (Deflandre <i>in</i> Deflandre & Fert 1954) Bramlette & Martini 1964	Cretaceous – Eocene
<i>Marthasterites</i> sp.	Upper Cretaceous
<i>Micrantholithus vesper</i> Deflandre 1954	Eocene – Miocene
<i>Microrhabdulus</i> sp.	Cenomanian – Maastrichtian
<i>Micula</i> sp.	Coniacian – Maastrichtian
<i>Nannoconus steinmanni</i> Kamptner 1931	Uppermost Jurassic – Lower Cretaceous
<i>Nannoterrina</i> sp.	NP15
<i>Neococcolithes dubius</i> (Deflandre <i>in</i> Deflandre & Fert 1954) Black 1967	NP13-16 (?17-18)
<i>Pemma papillatum</i> Martini 1959	Middle Eocene
<i>Pemma rotundum</i> Klumpp 1953	Middle Eocene
<i>Pemma</i> sp.	Middle Eocene
<i>Reticulofenestra bisecta</i> (Hay, Mohler & Wade 1966) Roth 1970	NP16-25 (or NN1)
<i>Reticulofenestra haqii</i> Backman 1978	NN2-15
<i>Reticulofenestra lockeri</i> Müller 1970	NP23 rare, NP24 – ?NN1
<i>Reticulofenestra placomorpha</i> (Kamptner 1948) Stradner <i>in</i> Stradner & Edwards 1968 [actual valid synonym: <i>R. umbilica</i> (Levin 1965) Martini & Ritzkowski 1968]	NP16-22
<i>Reticulofenestra pseudoumbilicus</i> (Gartner 1967) Gartner 1969	NN4-15 (<7µm occurs from NN5 in the Mediterranean)
<i>Rhabdolithus</i> sp.	
<i>Sphenolithus conicus</i> Bukry 1971	NP25 – NN3
<i>Sphenolithus furcatolithoides</i> Locker 1967	NP15-16
<i>Sphenolithus moriformis</i> (Brönnimann & Stradner 1960) Bramlette & Wilcoxon 1967	Lower Eocene – Miocene
<i>Sphenolithus radians</i> Deflandre <i>in</i> Deflandre & Fert 1954	Lower to Middle Eocene (rare in Upper Eocene)
<i>Sphenolithus</i> sp.	
<i>Sphenolithus</i> sp. (? <i>calyculus</i> : Bukry 1985)	<i>S. calyculus</i> : Palaeogene – NN1
<i>Sphenolithus spiniger</i> Bukry 1971	Middle Eocene

<i>Transversopontis pulcher</i> (Deflandre in Deflandre & Fert 1954) Hay, Mohler & Wade 1966	Eocene – Oligocene
<i>Transversopontis</i> sp.	
<i>Tribrachiatulus orthostylus</i> Shamrai 1963	NP11-12 (?13-14)
<i>Umbilicosphaera rotula</i> (Kamptner 1956) Varol 1982	NN2-16
<i>Uniplanarius gothicus</i> (Deflandre, 1959) Hattner & Wise, 1980	Santonian – Maastrichtian
<i>Watznaueria barnesae</i> (Black 1959) Perch-Nielsen 1968	Bajocian – Maastrichtian
<i>Zeughrabdotos embergeri</i> (Noël 1958) Perch-Nielsen 1984	Tithonian – Maastrichtian
<i>Zeughrabdotos</i> sp.	
<i>Zygrhablithus bijugatus</i> (Deflandre in Deflandre & Fert 1954) Deflandre 1959	Eocene – NP25

---

*Note:* Stratigraphic ranges of species taken from the following sources. Cretaceous: Burnett (1998) and Perch-Nielsen (1985a); Palaeogene: Perch-Nielsen (1985b) and Baldi-Beke (1977, 1984); Neogene: Fornaciari *et al.* (1996), Fornaciari & Rio (1996) and Young (1998).

*Geographic position of sampling localities for calcareous nannofossils (Chapter 5)*

Area	Sample	Locality	Latitude (N)	Longitude (E)

Appendix 6-1

[Table is two pages wide - note facing pages]

Detrital zircon FT-U/Pb double dating analytical results

Notes: Tect: tectonic position of the sample; D: Outer Dinaride foreland basin; S: Sava Zone. N<sub>s</sub>: spontaneous track count; ρ<sub>s</sub>: spontaneous track density (×10<sup>5</sup> tr/cm<sup>2</sup>); N<sub>i</sub>: induced track count; ρ<sub>i</sub>: induced track density (×10<sup>5</sup> tr/cm<sup>2</sup>). Peak: length of the laser ablation signal extracted for the isotope ratio calculation. p: error correlation of <sup>207</sup>Pb/<sup>235</sup>U and <sup>206</sup>Pb/<sup>238</sup>U ratios. Conco.: concordance expressed as [<sup>207</sup>Pb/<sup>235</sup>U age]/[<sup>206</sup>Pb/<sup>238</sup>U age] × 100. Peak: length of the laser ablation signal extracted for the isotope ratio calculation. N.dia: nominal pit diameter – measured diameters are c. 10% smaller at the sample surface.

Appendix 6-1

[Table is two pages wide - note facing pages]

Detrital zircon FT-U/Pb double dating analytical results

Notes: Tect: tectonic position of the sample; D: Outer Dinaride foreland basin; S: Sava Zone.  $N_s$ : spontaneous track count;  $\rho_s$ : spontaneous track density ( $\times 10^5$  tr/cm<sup>2</sup>);  $N_i$ : induced track count;  $\rho_i$ : induced track density ( $\times 10^5$  tr/cm<sup>2</sup>). Peak: length of the laser ablation signal extracted for the isotope ratio calculation. p: error correlation of <sup>207</sup>Pb/<sup>235</sup>U and <sup>206</sup>Pb/<sup>238</sup>U ratios. Conco.: concordance expressed as  $[\frac{^{207}\text{Pb}/^{235}\text{U age}}{^{206}\text{Pb}/^{238}\text{U age}}] \times 100$ . Peak: length of the laser ablation signal extracted for the isotope ratio calculation. N.dia: nominal pit diameter – measured diameters are c. 10% smaller at the sample surface.

Appendix 6-1

[Table is two pages wide - note facing pages]

Detrital zircon FT-U/Pb double dating analytical results

Notes: Tect: tectonic position of the sample; D: Outer Dinaride foreland basin; S: Sava Zone.  $N_s$ : spontaneous track count;  $\rho_s$ : spontaneous track density ( $\times 10^5$  tr/cm<sup>2</sup>);  $N_i$ : induced track count;  $\rho_i$ : induced track density ( $\times 10^5$  tr/cm<sup>2</sup>). Peak: length of the laser ablation signal extracted for the isotope ratio calculation. p: error correlation of <sup>207</sup>Pb/<sup>235</sup>U and <sup>206</sup>Pb/<sup>238</sup>U ratios. Conco.: concordance expressed as  $[\frac{^{207}\text{Pb}/^{235}\text{U age}}{^{206}\text{Pb}/^{238}\text{U age}}] \times 100$ . Peak: length of the laser ablation signal extracted for the isotope ratio calculation. N.dia: nominal pit diameter – measured diameters are c. 10% smaller at the sample surface.

Appendix 6-1

[Table is two pages wide - note facing pages]

Detrital zircon FT-U/Pb double dating analytical results

Notes: Tect: tectonic position of the sample; D: Outer Dinaride foreland basin; S: Sava Zone.  $N_s$ : spontaneous track count;  $\rho_s$ : spontaneous track density ( $\times 10^5$  tr/cm<sup>2</sup>);  $N_i$ : induced track count;  $\rho_i$ : induced track density ( $\times 10^5$  tr/cm<sup>2</sup>). Peak: length of the laser ablation signal extracted for the isotope ratio calculation. p: error correlation of <sup>207</sup>Pb/<sup>235</sup>U and <sup>206</sup>Pb/<sup>238</sup>U ratios. Conco.: concordance expressed as [<sup>207</sup>Pb/<sup>235</sup>U age]/[<sup>206</sup>Pb/<sup>238</sup>U age] × 100. Peak: length of the laser ablation signal extracted for the isotope ratio calculation. N.dia: nominal pit diameter – measured diameters are c. 10% smaller at the sample surface.

Appendix 6-2

Results of detrital zircon LA-ICPMS U/Pb geochronology on non-double-dated aliquots, in conventional epoxy mounts

page 1 of 4

Notes: Tect: tectonic position of the sample; D: Outer Dinaride foreland basin; S: Sava Zone. Peak: length of the laser ablation signal extracted for the isotope ratio calculation. p: error correlation of <sup>207</sup>Pb/<sup>235</sup>U and <sup>206</sup>Pb/<sup>238</sup>U ratios. Conco.: concordance expressed as [<sup>207</sup>Pb/<sup>235</sup>U age]/[<sup>206</sup>Pb/<sup>238</sup>U age] × 100. Peak: length of the laser ablation signal extracted for the isotope ratio calculation.

LA-ICPMS apparent ages

Appendix 6-2

Results of detrital zircon LA-ICPMS U/Pb geochronology on non-double-dated aliquots, in conventional epoxy mounts

page 2 of 4

Notes: Tect: tectonic position of the sample; D: Outer Dinaride foreland basin; S: Sava Zone. Peak: length of the laser ablation signal extracted for the isotope ratio calculation. p: error correlation of <sup>207</sup>Pb/<sup>235</sup>U and <sup>206</sup>Pb/<sup>238</sup>U ratios. Conco.: concordance expressed as [<sup>207</sup>Pb/<sup>235</sup>U age]/[<sup>206</sup>Pb/<sup>238</sup>U age] × 100. Peak: length of the laser ablation signal extracted for the isotope ratio calculation.

LA-ICPMS apparent ages

Appendix 6-2

Results of detrital zircon LA-ICPMS U/Pb geochronology on non-double-dated aliquots, in conventional epoxy mounts  
page 4 of 4

Notes: Tect: tectonic position of the sample; D: Outer Dinaride foreland basin; S: Sava Zone. Peak: length of the laser ablation signal extracted for the isotope ratio calculation. p: error correlation of  $^{207}\text{Pb}/^{235}\text{U}$  and  $^{206}\text{Pb}/^{238}\text{U}$  ratios. Conco.: concordance expressed as  $[\frac{^{207}\text{Pb}/^{235}\text{U age}}{^{206}\text{Pb}/^{238}\text{U age}}] \times 100$ . Peak: length of the laser ablation signal extracted for the isotope ratio calculation.

# Lebenslauf von Tamás Mikes

Geboren in Budapest, am 12. August 1980  
Eltern: Zsolt Mikes und Kornélia Rózsa  
Ungarischer Staatsbürger

## AKADEMISCHER WERDEGANG

- 2004–2008     **Promotion in Geowissenschaften**, Universität Göttingen  
*Thema der Dissertation: Late Mesozoic to Cenozoic erosion and sediment dispersal in the Dinaride orogen: a sedimentary provenance approach*  
Betreuer: H. von Eynatten & I. Dunkl
- 2004     **Diplom in Geologie** (Nostrifikation), Eötvös Universität Budapest  
2003     **Diplom in Geologie (Vertiefungsrichtung Sedimentgeologie)**, Univ. Tübingen  
*Diplomarbeit: Provenance analysis of Palaeogene flysch sandstones of the Northwestern External Dinarides.* Betreuer: I. Dunkl  
*Studienarbeit: Sedimentology and palaeoseismicity recorded in Quaternary fluvial sands of the Sárrét Basin, Hungary.* Betreuer: P. Bons, M. Kázmér  
Tag der Diplomhauptprüfung: 11. November 2003; Prüfer: W. Frisch
- 2002–2003     **Geologiestudium**, Universität Tübingen  
1998–2002     **Geologiestudium**, Eötvös Universität Budapest  
1998     **Abitur**, Budapest

## HOCHSCHULLEHRER

T. Báldi, L. Csontos, F. Horváth, M. Kázmér, M. Mindszenty, Cs. Szabó, O. Sztanó (*Budapest*); T. Aigner, G. Markl, W. Frisch (*Tübingen*); H. von Eynatten, I. Dunkl (*Göttingen*); J.F. Dewey (*Davis*); D. Günther (*Zürich*); L. Nasdala (*Wien*); A.M.C. Şengör (*Istanbul*); S.M. Schmid (*Basel*); M. Wagreich (*Wien*); G. Manby (*Greenwich*); M. Williams (*Massachusetts*)

## AUSZEICHNUNGEN

- 2005     'Kriván Pál'-Plakette für junge Wissenschaftler (*Ungarische Geologische Gesellschaft*)  
2002     Studentischer Preis der *MOL Ungarischer Erdöl- und Erdgas AG*  
2002     'Studentische Exzellenz'-Preis der Naturwiss. Fakultät, Eötvös Universität, Budapest

## MITGLIEDSCHAFTEN

- Mineralogical Society of America     seit 2004  
Society for Sedimentary Geology     seit 2003  
International Association of Sedimentologists     seit 2003  
Ungarische Geologische Gesellschaft (MFT)     seit 1998
