

Adaptive Aggregation and Chirality Recognition
of Neuroactive Substances and their Building Blocks:
A Vibrational Spectroscopic and Microscopic Study

Dissertation
for the award of the degree
"Doctor rerum naturalium"
of the Georg-August-Universität Göttingen

submitted by
Marija Nedić
from Hamburg

Göttingen 2012

Prof. Dr. Martin A. Suhm (Referee)

Georg-August-Universität Göttingen/ Institute of Physical Chemistry

Prof. Dr. Sarah Köster (Co-Referee)

Georg-August-Universität Göttingen/ Institute for X-Ray Physics

Prof. Dr. Philipp Vana

Georg-August-Universität Göttingen/ Institute of Physical Chemistry

Date of the oral examination: 06th of June 2012

I (Marija Nedić), hereby confirm that I completed my dissertation independently and without any unauthorized support.

Göttingen,

Acknowledgments

I would like to give my sincere thanks to all the people who contributed to this dissertation in any professional or personal way. Your help and support were invaluable to the success of this work.

I would like to thank my advisor Prof. Dr. Martin A. Suhm for the interesting project and time for discussions. I would also like to thank Prof. Dr. Sarah Köster and Prof. Dr. Philipp Vana for being members of my thesis committee.

I would like to thank the mechanical workshop of the Institute of Physical Chemistry for constructing the sublimation cell. I would also like to thank the electric and glass workshops as well as Milo W. Noack for their helpfulness. I would also like to thank Birger Dittrich from the Institute of Inorganic Chemistry for solving the crystal structures of the three methyl mandelate forms, Ralf Tonner from Philipps-University Marburg for crystal calculations on methyl mandelate (still in progress), and Reinhard Machinek from the Institute of Inorganic Chemistry for recording the NMR data of methyl- d_3 mandelate.

I would like to thank the GGNB for their financial support (GGNB bridging fund, DFG Grant GSC 226/1) and the opportunity to take part in various seminars, excursions, and conferences. I would also like to thank the Graduiertenkolleg 782 for the chance to participate as a guest student.

I would like to say thank-you to the entire Suhm Group for creating an enjoyable working atmosphere, their interest and advice, as well as the small distractions during and after work. Special thanks also go to Tobias N. Wassermann who contributed to the alcohol-water project, to Alexandra Domanskaya who gave the decisive hint for the methyl mandelate project, and to Fabian Ziegler who wrote his Bachelor thesis on sublimated methylxanthines.

I would like to thank Amy Henslin, Nils Lüttschwager, Alexandra Domanskaya, and Julia Zischang for proofreading.

Finally, I would especially like to thank my parents, my brother, my boyfriend, and my extended family for their personal support over the years: Danke, Kiitos, and Hvala!

1. Introduction

The effectiveness of neuroactive substances, the activity of drugs as well as our olfactory sense are based on the chirality and conformation of the receptor and the molecules themselves [1]. The molecular recognition of such complexes is also known as the lock-and-key principle [2]. The discrimination between two enantiomeric molecules which differ like image and mirror image is called chirality recognition [3–6]. The receptors in the human body are chiral and are thus open for chirality recognition phenomena. The conformation of a molecule describes its spatial arrangement and influences its energy. The energetical order of conformations is determined by intramolecular interactions but also by interactions with the surrounding e.g., intra- and intermolecular hydrogen bonds, respectively [7–9]. The change of the preferred monomer conformation as a response to the surrounding may be called adaptive aggregation [10–12]. In this work chirality recognition phenomena and adaptive aggregation in hydrogen bonded crystals are investigated. Their high degree of long-range three-dimensional internal order of the molecules leads to more complexity than in molecular complexes, but also opens powerful options for the characterization [13]. Small hydrogen bonded clusters, which are also investigated within this work, serve as a model case for adaptive aggregation [11, 14].

There is a variety of methods to characterize molecular crystals [15]. Diffraction methods such as single-crystal X-ray or neutron diffraction are frequently used to solve the structure of crystals [13]. Vibrational spectroscopy provides information on the local interactions and couplings between the molecules [16], as well as on the driving forces for conformational rearrangements during crystal packing which can lead to polymorphism as a function of crystal preparation. Though Raman microspectroscopy has the advantage of a better spatial resolution due to a lower diffraction limit [17], IR microspectroscopy can be the method of choice. IR microspectroscopy provides a better signal-to-noise ratio and can be used for imaging purposes, while only stepwise mapping is possible with Raman microspec-

troscopy [17]. Anisotropic media such as crystals are available for polarization studies which provide information about the direction of the vibrational transition dipole vector.

Sublimation is a rather rare technique used in the crystallization process. Nevertheless, it is the conceptually cleanest way of crystal preparation since no solvent or further sample treatment is required [18, 19]. Here, adaptive aggregation and chirality recognition effects depend on the inherent interactions between equal molecules and not on molecule-solvent interactions. The crystal habit is only determined by the fastest growth directions [20] and reveals information about the relative strengths of the interactions present in the crystal. Comparison with gas phase measurements and quantum-chemical calculations are feasible. Kinetic control allows for the sublimation of sub-millimeter-sized crystals which are suitable for infrared measurements in transmission mode without further preparation. Measurement of different faces is possible by rotating the crystal on the substrate.

There is an enhanced propensity for complex crystal structures in sublimated crystals. The percentage of organic molecules in the Cambridge Structural Database (CSD) with more than one molecule in the asymmetric unit ($Z' > 1$) increases from 11% to 17% for sublimated crystals [21, 22]. A tendency to form complex crystal structures was also found for chiral molecules or molecules having directional intermolecular interactions, e.g., hydrogen bonds [23]. FTIR spectra of crystals, and especially of sublimated chiral crystals, are expected to show complex in-phase and antiphase coupling patterns for many molecular vibrations (factor group splittings) [16]. Additionally, quantitative differences in the molecular structures building the asymmetric unit may lead to further spectral splittings [24]. However, the increased complexity of crystal spectra compared to gas phase spectra may be turned into an assignment advantage by exploring crystal rotation, IR polarization, and monomer calculations. The facial and polarization dependence of vibrational bands gives information about the direction of the vibrational transition dipole vector within the macroscopic crystal.

FTIR polarization microscopy has been applied in the infrared before [25–27], mostly in reflection mode. Also, oriented single crystals and oriented films were investigated by polarized THz transmission spectroscopy [28–31]. Furthermore, polarized Raman spectroscopy has been used to assign molecular and phonon modes of single crystals [32, 33].

In the present work, polarized Fourier transform infrared (FTIR) microspectroscopy in transmission mode is primarily applied to the characterization of sublimated crystals. All investigated substances are chiral and are open for hydrogen bonding. Rotated crystal measurements support the assignment of spectra to different faces. In order to unravel the molecular orientation within the crystals a version of the oriented gas model approach [25, 34, 35] is adopted. Monomer calculations are used to simulate the intensities of fundamental modes according to the molecular orientation within the crystal and the applied polarization. Published crystal structures, if available, are used for the assignment of the molecular orientation based on the assumption that the same polymorph is present in the sublimated microcrystals. Crystal phase calculations of the vibrational spectra would be highly desirable, but meet formidable challenges due to the size of the molecules and of the unit cells. A cooperation was started with R. Tonner [36].

In Chapter 2, elementary aspects of the vibrational transition dipole vector are elucidated and the limits of the oriented gas model approach for the modeling of crystal IR spectra based on monomer calculations in the gas phase are explored. It is shown that the oriented gas model approach exhibits deficiencies in predicting red shifts and intensifications which are due to hydrogen bonds. Nonetheless, it is useful to predict the polarization behavior of a crystal.

The sublimation cell constructed for the vacuum sublimation and measurement of microcrystals is characterized in Chapter 3. The experimental and theoretical methods are described there as well.

Adaptive aggregation is investigated in Chapter 4 for the elementary case of small alcohol-water clusters in jet-expansions [11, 14]. It is shown that water acts as the proton donor in mixed dimers and that ethanol exhibits the less stable gauche conformation in the ethanol-water dimer. This serves as a model case for conformational switching in the more complex crystals.

Methyl mandelate was chosen as the test substance for the polarized transmission FTIR microspectroscopic studies on sublimated crystals because of its structural similarity to some neurotransmitters [37]. Results including the change of conformation and chirality recognition of a 1:1 and a 3:1 racemic crystal [38] are presented in Chapter 5. Quantum-chemical calculations, ATR-IR spectra, and isotope labeling are used for the vibrational assignment. The molecular orientation within the crystals is inferred through a comparison of experimental with oriented gas model spectra.

The polarized transmission FTIR microspectroscopic method is applied to mandelic acid [37] in Chapter 6 and to the neuroactive phenylpropanolamines norephedrine, pseudonorephedrine, ephedrine, and pseudoephedrine in Chapter 7. Chirality recognition effects are presented for norephedrine and pseudoephedrine. In the case of ephedrine a hydrate and an anhydrate are crystallized. The spectroscopic crystal studies are supported by quantum chemical calculations, ATR spectra, and deuteration experiments. Vibrational assignments are performed and the molecular orientation within the crystals are determined. Tentative molecular orientations are proposed for enantiopure norephedrine and racemic pseudoephedrine. In the case of the phenylpropanolamines the influence of hydrogen bonds and of the molecular conformation on the N-H stretching positions is investigated.

A summary of the results and an outlook are given in Chapter 8.

2. Basics

IR spectroscopy is a powerful tool standardly used for the investigation of vibrational modes and the analysis of hydrogen bonds [16, 39, 40]. It is based on the interaction of the electric vector of infrared radiation with a molecular dipole moment oscillating with the same frequency. In order for a vibrational mode to be IR active it needs to change its dipole moment. Thus, a permanent dipole moment is not needed, but a transition dipole moment. The transition dipole moment $\vec{\mu}_{nm}$ is a vector quantity given by:

$$\vec{\mu}_{nm} = \int \Psi_n^* \vec{\mu} \Psi_m d\tau \quad (2.1)$$

with respect to the energy eigenfunctions $\Psi_{n,m}$ of the states n, m involved in the transition and $d\tau$ being the volume element $dx dy dz$ [39, 41, 42]. $\vec{\mu}$ is the electric dipole moment vector obtained by summing over the product of all charges q_i multiplied by their position vectors \vec{r}_i [39, 42]:

$$\vec{\mu} = \sum_i q_i \vec{r}_i. \quad (2.2)$$

Whether a transition is allowed or forbidden depends on the properties of the wavefunctions, the orientation of the dipole moment, and the direction and polarization of the incident radiation [41]. For a heteronuclear diatomic molecule the electric dipole moment usually varies with the displacement of the internuclear distance from equilibrium $Q = r - r_e$. The resulting variation of the transition dipole moment can be expressed in a Taylor series as [39, 43]:

$$\vec{\mu}_{nm} = \vec{\mu}_e \int \Psi_n^* \Psi_m dQ + \left(\frac{d\vec{\mu}}{dQ} \right)_e \int \Psi_n^* Q \Psi_m dQ + \dots \quad (2.3)$$

The wavefunctions are eigenfunctions of the same hamiltonian and therefore orthogonal. Equation 2.3 becomes:

Figure 2.1.: Variation of the dipole moment $\vec{\mu}$ with the displacement of the internuclear distance Q . The blue curve corresponds to an isolated vibrational mode and the red curve to a hydrogen bonded mode.

$$\vec{\mu}_{nm} = \left(\frac{d\vec{\mu}}{dQ} \right)_e \int \Psi_n^* Q \Psi_m dQ + \dots \quad (2.4)$$

The IR intensity I is proportional to the square of the transition dipole moment $\vec{\mu}_{nm}$ [39, 42, 44]:

$$I \propto |\vec{\mu}_{nm}|^2 \quad (2.5)$$

and according to Equations 2.4 and 2.5 also to the squared derivative of the dipole moment $\vec{\mu}$ with respect to the displacement Q [39, 42]:

$$I \propto \left(\frac{d\vec{\mu}}{dQ} \right)_e^2. \quad (2.6)$$

A schematic curve of the relation $\vec{\mu}$ versus Q is shown in Fig. 2.1 for an isolated and a hydrogen bonded mode [39]. The slope $\left(\frac{d\vec{\mu}}{dQ} \right)$ at $Q=0$ (internuclear distance at equilibrium) is steeper for the hydrogen bonded vibrational mode. Therefore, the vibrational transition dipole moment (Equation 2.4) and the IR intensity (Equation 2.5) are larger for a hydrogen bonded than for an isolated vibrational mode [45, 46].

The dipole moment operator $\vec{\mu}$ has components along the cartesian axes. Accordingly, the transition dipole vector also has components in x , y , and z direction [39]:

$$|\vec{\mu}_{nm}|^2 = (\mu_{nm,x})^2 + (\mu_{nm,y})^2 + (\mu_{nm,z})^2 \quad (2.7)$$

Therefore, in an anisotropic environment such as a crystal being illuminated from

Figure 2.2.: Rotation of a relaxed monomer unit (here, methyl mandelate) into the desired orientation within the asymmetric unit of the crystal structure solved by X-ray analysis.

one direction, the x , y , and z components may have varying contributions to the intensity [47]. The observed IR intensity depends on the orientation of the crystal and on the polarization of the incident radiation. Crystal IR spectra can be modeled based on monomer calculations using the oriented gas model approach [25, 34, 35]. In this approach intermolecular interactions are neglected. This is not true for several modes in hydrogen bonded crystals.

Within this work a variation of the oriented gas model approach was developed. Spectra corresponding to the different crystal faces as well as for different polarizations are simulated for a better comparison between experiment and prediction. Monomers taken from the crystal structure are geometrically optimized to the nearest isolated minimum structure by quantum chemical calculations. The relaxed monomers are then rotated into the orientation of the molecules within the crystal (see Fig. 2.2). This yields a rotation matrix which is applied to the calculated dipole derivatives $\vec{\mu}'$ of a given vibration. Intensities of the different faces are approximated by summing up the squares of the x - and y -components of the dipole derivatives, if z is the direction of the incident light:

$$I \sim \mu_x'^2 + \mu_y'^2. \quad (2.8)$$

In the case of polarization measurements, the intensity corresponds to the square of the x -component ($I \sim \mu_x'^2$) and to the square of the y -component ($I \sim \mu_y'^2$) of the dipole derivatives. The dipole derivatives of the different molecules within the

Figure 2.3.: The direction of the vibrational transition dipole vectors (yellow, unit length) of the symmetric F-H stretching mode for small HF clusters ($n = 1-4$, B3LYP/6-31+G(d) level). The trimer and tetramer do not represent minimum structures.

asymmetric unit are first squared and then added. Thus, the oriented gas model spectra do not account for couplings within the crystal, but rather correspond to the center of the coupling patterns. A Matlab script [48] was written to rotate the relaxed monomer units from a view along the crystallographic c -axis into views along the crystallographic a - and b -axes of the monomer units within the crystal structure and to calculate nonpolarized and polarized intensities of the different crystals' faces (see Supplement A). In the following, the limits of this approach will be explored on the basis of HF.

HF crystallizes in the space group $Bmmb$ with one molecule in the asymmetric unit ($Z'=1$) and six molecules in the unit cell ($Z=6$). It forms disordered infinite F-H...F hydrogen bonded zigzag chains along the crystallographic b axis (ICSF REF Code: 14121) [49, 50]. Fragments of the zigzag chain are shown for small optimized HF clusters in Fig. 2.3. Note that the dimer [51] but not the trimer [52, 53] and tetramer [54] correspond to a minimum structure. The dipole derivatives of the imaginary frequencies are perpendicular to the molecular plane. Fig. 2.3 shows the influence of cluster size ($n=1-4$) on the direction of the vibrational transition dipole vector of the symmetric F-H stretching mode. In the case of the monomer, the vibrational transition dipole vector points along the F-H axis. The direction changes upon hydrogen bonding. It points roughly along the hydrogen bond axis in the dimer. In the presence of a hydrogen bonded chain the vibrational transition dipole vector shows more or less along the HF chain. This alignment improves with increasing cluster size largely due to symmetry reasons. It is therefore perfect in the case of an infinite chain which is realized in the crystal.

In Fig. 2.4 the limits of the oriented gas model approach are displayed for the hydrogen bonded HF dimer. The polarized spectra of two HF monomer units and of the HF dimer in the F-H stretching region are compared. The monomer units and the dimer are rotated in the molecular plane in the upper part of Fig. 2.4 compared

to the lower part. The black curves correspond to the nonpolarized spectra and are the same for the upper and lower part of Fig. 2.4. They already exhibit deficiencies of the oriented gas model approach. The calculation of the monomer cannot account for the red shift and intensification of the dimer modes which result from the hydrogen bond. The infinite hydrogen bonded chain in the HF crystal can be expected to lead to even larger red shifts and intensifications.

In Fig. 2.4 the polarized spectra are displayed in red for a horizontal polarization and in blue for a vertical polarization. Since the molecules of the lower part are rotated in comparison to the upper part, the polarization spectra differ. In the upper part the intensities are almost equal for both polarizations. In the lower part the intensity of the asymmetric stretching when applying a vertical polarization is almost as high as in the nonpolarized spectrum. The opposite is true for the symmetric stretching. Here, the intensity of the horizontally polarized spectrum is nearly as high as the nonpolarized. The opposite behavior results from nearly perpendicular vibrational transition dipole vectors which are aligned along the x and y axes. In the case of the monomer mode, the horizontal polarization leads to a 1.5 times higher intensity than the vertical polarization. This reflects the properties of the symmetric stretching with some contributions from the less perfectly aligned asymmetric mode.

An increased stabilization energy per hydrogen bond, strong red shifts of the F-H stretching frequency, and significantly enhanced IR intensities were found for HF₁₋₁₉ chains investigated by SCF calculations asymptotically approaching the solid properties [55, 56]. Monomer calculations cannot account for the intensification and wavenumber shifts in hydrogen bonded systems. Nevertheless, the relative intensity change upon different directions of polarization can be simulated by the oriented gas model approach. In the case of nonbonded modes, scaled monomer predictions are reasonable and suitable for wavenumber, intensity, and polarization simulations.

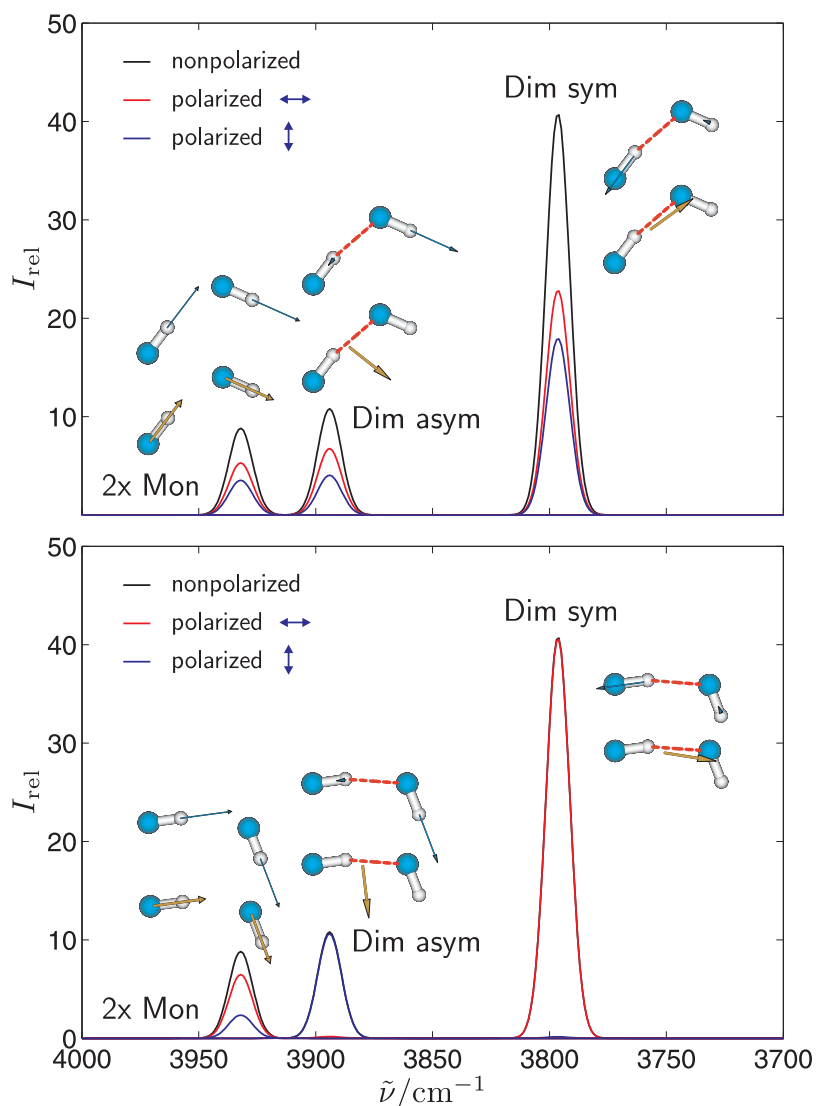

Figure 2.4.: Oriented gas model polarization spectra (B3LYP/6-31+G(d) level) of the HF dimer's (Dim) asymmetric (asym) and symmetric (sym) F-H stretching mode as well as the F-H stretching mode of two HF monomer units (2x Mon). The black curve corresponds to the nonpolarized, the red curve to the horizontally polarized, and the blue curve to the vertically polarized spectra. The direction of the vibrational transition dipole vectors (yellow, unit length) as well as the displacement vectors of each mode (blue) are indicated. The monomer and dimer units are rotated in the molecular plane in the upper in comparison to the lower part.

3. Methods

The results of this work were obtained using both experimental and theoretical approaches. The focus was on experimental investigations. Quantum chemical calculations supported their interpretation. In Sect. 3.1 the preparation of samples will be elucidated. The experimental methods will be illustrated in Sect. 3.2. The theoretical approaches will be described in Sect. 3.3.

3.1. Sample Preparation

3.1.1. Substances

Compounds used within the framework of the presented projects are listed in Supplement B. The chemical formulas, CAS-numbers, suppliers, and purity are also provided there. The synthesis of methyl-d₃ mandelate and the crystallization of racemic and deuterated compounds will be described in the following Section.

Synthesis of Methyl-D₃ Mandelate

CD₃-deuterated methyl mandelate (methyl-d₃ mandelate) was not commercially available. The synthesis of mandelates according to Refs. [57, 58] was modified to obtain methyl-d₃ mandelate [37]. 0.458 g *R*-mandelic acid (0.0030 mol) was dissolved in 3 mL methanol-d₃ (0.0742 mol, 25-fold molar excess). One droplet of concentrated sulfuric acid was added. The mixture was refluxed at 72°C for 3.5 hours. Afterwards, excess methanol-d₃ was removed using a rotary evaporator. The crude methyl-d₃ mandelate was dissolved in ether and washed twice with aqueous potassium carbonate followed by saturated aqueous sodium chloride solution. Finally, the organic layer was dried over anhydrous sodium sulfate, filtered, and distilled with the rotary evaporator. The yield of methyl-d₃ mandelate was 63 % (0.319 g). The chemical purity determined in cooperation with R. Machinek by ¹H

Figure 3.1.: Cross section of the sublimation cell with CaF_2 windows mounted on a Peltier element.

NMR ((300 MHz, CDCl_3): δ 3.5 (s, 1H) 5.2 (s, 1H) 7.3–7.4 (m, 5H)) was $\geq 90\%$. It can be assumed that the purity increased upon sublimation and resublimation.

3.1.2. Crystallization via Sublimation

A sublimation cell for the crystallization via sublimation and resublimation was built and tested within the framework of the present study. The cell is constructed to optimize the crystallization process by lowering the pressure and by applying a temperature gradient. The powdery substance sublimates at the bottom and resublimates in the form of microcrystals ($10\text{--}500\ \mu\text{m}$) at the top. Hereafter, the process of sublimation and resublimation will be referred to as sublimation only. By changing the pressure and temperature, the crystallization growth can be controlled and microcrystals suitable for transmission spectroscopy can be obtained. A scheme of the sublimation cell is depicted in Fig. 3.1.

The sublimation cell consists of two CaF_2 windows (Korth Kristalle GmbH) which transmit light in the range of $0.13\text{--}12\ \mu\text{m}$ ($\approx 77000\text{--}830\ \text{cm}^{-1}$). The windows have a diameter of $13 \pm 0.1\ \text{mm}$, a thickness of $2 \pm 0.1\ \text{mm}$, and a bevel of $1.5\ \text{mm} \times 45^\circ$. A 6 mrad wedge on the planar face and the optical polish reduce interference and light scattering. The anisotropic CaF_2 crystals are randomly oriented within the windows. The CaF_2 plates are held together by a PEEK (polyether ether ketone) holder which is temperature resistant (up to 300°C). The PEEK holder and the CaF_2 windows are sealed by using either perbunan[®] (up to 60°C) or viton[®] o-rings of $10 \times 1.0\ \text{mm}$ (up to 300°C). Two versions of the sublimation cell had been

constructed and tested. The first version was equipped with a PEEK olive which was connected to a plastic hose. For the second version a flexible steel hose with a flange is glued to the PEEK holder. With the second version low pressures are obtained faster and can be maintained longer. The sublimation cell can be connected to a turbomolecular pump (Pfeiffer Vacuum TSH 071 and MVP 015-2) and evacuated down to a pressure of less than 1 mbar (minimal pressure limited by leakage of the sublimation cell, see below). The pressure was measured with a baratron pressure gauge in the range of 0.001–10 mbar (MKS baratron type 626). The speed of the evacuation process can be controlled by using a needle valve (HOKE Milli-Mite 13335G6Y). The standard position for the evacuation of the sublimation cell was $8\text{ }\mu\text{m}$. The sublimation cell can be mounted on a Peltier element (Linkam PE94). Thus, it is possible to regulate the temperature at the bottom of the cell in a range of -25°C to $+120^{\circ}\text{C}$.

Generally, the sublimation process was performed in a pressure region of 0.1–10 mbar with a closed needle valve ($0\text{ }\mu\text{m}$). For crystallizations that took longer than one day, the needle valve remained open ($8\text{ }\mu\text{m}$) to compensate the leakage of the cell. The temperature was set at 20°C and increased in steps of 5°C in order to determine the approximate sublimation temperature for a given sample. The crystallization growth could be stopped by lowering the temperature at the bottom of the cell below the sublimation temperature. Occasionally, sublimation temperatures below room temperature were necessary. In these cases, either the air conditioner was used or the windows were opened during winter. By doing this, room temperatures as low as 10°C were obtained.

Crystallization via sublimation is optimized by applying a temperature gradient. Ideally, there is a perfect heat transfer from the Peltier element to the bottom of the cell but no heat transfer to the top. Temperature tests with the sublimation cell were performed in order to test the heat transfer from the Peltier element to the cell and the temperature gradient of the sublimation cell. Measured melting temperatures of several substances were compared with literature data. Also, the set temperature of the Peltier element was compared to the temperature measured with a thermocouple device.

The melting temperatures of different substances ((*R*)-alanine ethyl ester hydrochloride, (*R*)-methyl mandelate, (*RS*)-methyl mandelate, (*RS*)-menthol, ethyl ac-

3. Methods

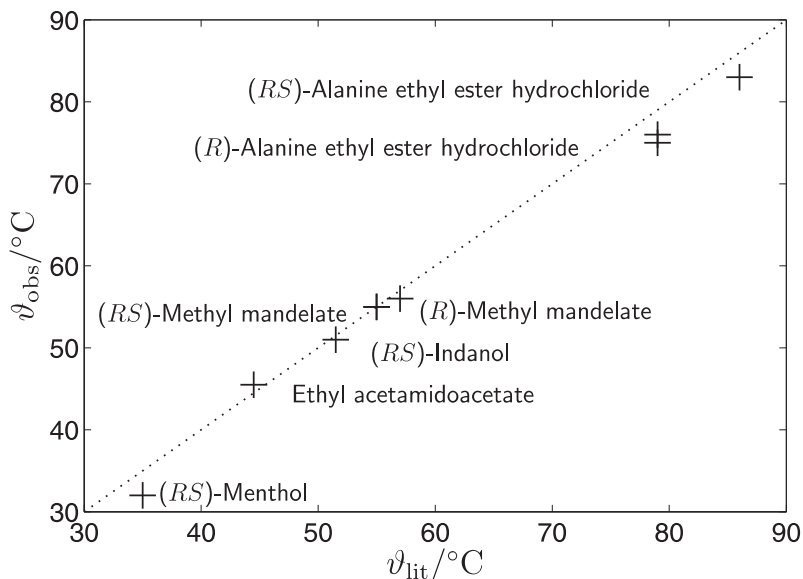

Figure 3.2.: Comparison of observed melting temperatures at the bottom of the sublimation cell (ϑ_{obs}) and melting temperatures provided by the supplier (ϑ_{lit}) in $^{\circ}\text{C}$ of different substances. The dotted line marks negligible deviation.

etamidoacetate, (*RS*)-indanol, and (*RS*)-alanine ethyl ester hydrochloride) provided by the supplier were compared with the temperature in the sublimation cell determined with the Peltier element. In Fig. 3.2 the melting temperatures provided by the supplier ϑ_{lit} are plotted versus the observed temperatures ϑ_{obs} (see also Tab. 3.1).

Fig. 3.2 shows a good agreement between literature and observed melting temperatures of the substances. A tendency of measuring slightly lower melting temperatures in the sublimation cell can be noticed. The deviation of less than 1°C can be explained by the loss of heat between the Peltier element and the bottom of the cell. An alternative explanation for the deviation of the melting temperature is the deviation between the set and actual temperature of the Peltier element. Nevertheless, the deviation in temperature is negligible for the sublimation experiments.

The heat transfer was also monitored by using a thermocouple device (Peak Tech, digital multimeter 2010). In order to account for deviations in the room temperature, the difference of the temperature set at the Peltier element and the room temperature was plotted against the difference between the measured temperature and room temperature in Fig. 3.3. The black line shows a perfect heat transfer ($\Delta\vartheta_{thermo}/^{\circ}\text{C} = \Delta\vartheta_{PE}/^{\circ}\text{C}$, not observed). The brown curve is the calibration curve

Table 3.1.: Literature ϑ_{lit} (information provided by supplier) and observed standard melting temperatures ϑ_{obs} of various substances used for the sublimation cell temperature test.

Substance	$\vartheta_{\text{lit}}/^{\circ}\text{C}$	$\vartheta_{\text{obs}}/^{\circ}\text{C}$
(<i>RS</i>)-Menthol	34–36	32
Ethyl acetamidoacetate	43–46	45.5
(<i>RS</i>)-Indanol	50–53	51
(<i>RS</i>)-Methyl mandelate	54–56	55/55
(<i>R</i>)-Methyl mandelate	56–58	56

(<i>RS</i>)-Alanine ethyl ester hydrochloride	85–87	83

of the thermocouple and shows the deviation of the thermocouple reading with an ice-water mixture ($\vartheta_{\text{PE}}=0^{\circ}\text{C}$) and boiling water ($\vartheta_{\text{PE}}=100^{\circ}\text{C}$, $\Delta\vartheta_{\text{thermo}}/^{\circ}\text{C}=0.96 \cdot \Delta\vartheta_{\text{PE}}/^{\circ}\text{C}+1.2$). The temperature measured at the heating plate of the Peltier element (blue) already shows a deviation to lower temperatures above approximately room temperature and to higher temperatures below approximately room temperature ($\Delta\vartheta_{\text{thermo}}/^{\circ}\text{C}=0.83 \cdot \Delta\vartheta_{\text{PE}}/^{\circ}\text{C}-0.57$). The deviation at the bottom of the cell (red-dish) was found to be roughly twice as high as the one at the heating plate at temperatures above approximately room temperature ($\Delta\vartheta_{\text{thermo}}/^{\circ}\text{C}=0.75 \cdot \Delta\vartheta_{\text{PE}}/^{\circ}\text{C}-0.85$). Below approximately room temperature the deviation is almost the same as at the heating plate.

The temperature measured at the inner part of the CaF_2 window without direct contact to the heating plate (hole for the beam, red) was approximately the same as at the outer part with direct contact (pink). The behavior for heating (circles) was approximately the same as for cooling (points), i.e. no hysteresis was observed. A much larger deviation was found at the top of the cell (green), being slightly larger when venting the sublimation cell (light green, $\Delta\vartheta_{\text{thermo}}/^{\circ}\text{C}=0.25 \cdot \Delta\vartheta_{\text{PE}}/^{\circ}\text{C}+0.52$), as compared to the evacuated cell (dark green, $\Delta\vartheta_{\text{thermo}}/^{\circ}\text{C}=0.30 \cdot \Delta\vartheta_{\text{PE}}/^{\circ}\text{C}+0.59$). The temperature steps were arbitrarily chosen. It should be noted that it was not possible to measure the temperature at the top of the cell from the inside. The temperature inside the cell can be estimated to have a slightly higher deviation from room temperature than the temperature outside.

Summing up, Fig. 3.3 shows that there is a good heat transfer from the Peltier

3. Methods

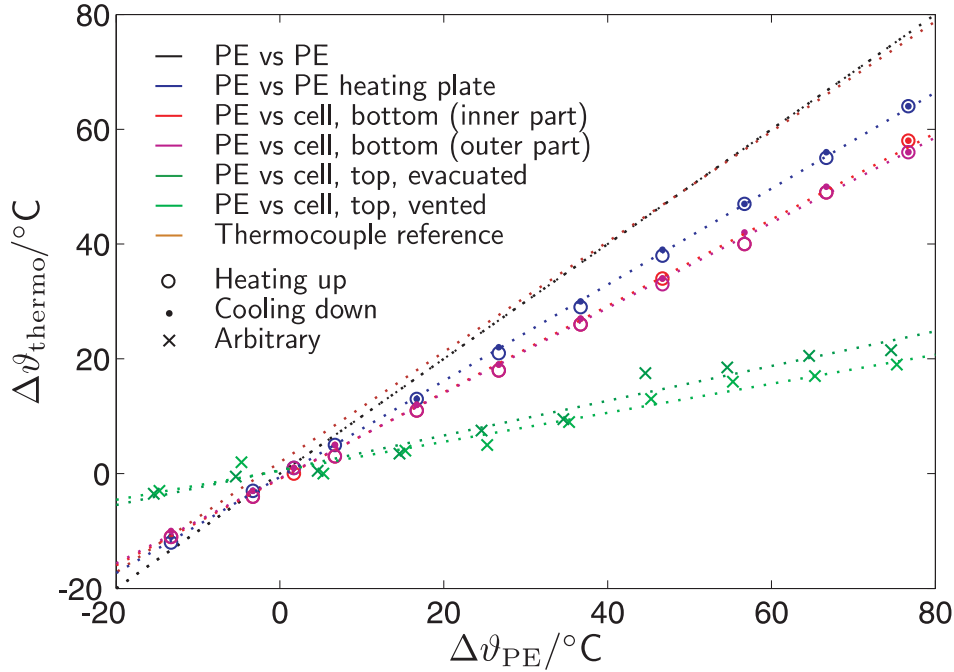

Figure 3.3.: Deviation of the temperature set at the Peltier element and the temperature measured with a thermocouple device at the heating plate of the Peltier element (PE vs PE heating plate, blue), at the bottom (PE vs cell, bottom, reddish) and the top of the sublimation cell (PE vs cell, top, greenish). Also, an ideal curve (PE vs PE, black, not observed) and the deviation of the thermocouple device from 0 $^{\circ}\text{C}$ of frozen and 100 $^{\circ}\text{C}$ of boiling water (thermocouple reference, brown) are shown.

element to the bottom of the cell and a good isolation of the top of the cell. Thus, an acceptable temperature gradient within the sublimation cell for crystallization can be obtained.

Low pressures assist the crystallization via sublimation in addition to a temperature gradient. It is possible to obtain pressures down to 0.01 mbar with the second version of the sublimation cell during evacuation. The leak tightness after closing the needle valve (and thus stopping the evacuation process) was tested. In Fig. 3.4 a typical leakage test with and without the sublimation cell is shown.

The setup was evacuated with a needle valve position of 8 μm until the pressure remained stable (± 0.001 mbar) for 10 seconds. Then the needle valve was closed. The pressure was measured with a baratron over a time period of 600 seconds (period of crystallization for most substances in this work) in order to observe the

sublimation cell's degree of leakage in comparison to the setup without sublimation cell. O-rings with two different cross sections (1.5 mm and 1.0 mm) were also tested. The upper green curve corresponds to the sublimation cell with a 1.5 mm o-ring connected to a T-piece. The centered curves correspond to measurements with the sublimation cell and a 1.0 mm o-ring connected to the T-piece (red) as well as to the T-piece covered with a blind flange instead of using the sublimation cell (blue). The lowest curve shows the pressure without using the T-piece nor the sublimation cell (black). The initial pressure of the setup without the T-piece or sublimation cell is the lowest (0.09 mbar and 0.06 mbar). When using the sublimation cell with the 1.0 mm o-ring the starting pressure was the same as using a blind flange on the T-piece (0.11 mbar and 0.10 mbar). The highest initial pressure was observed for the T-piece connected to the sublimation cell with a 1.5 mm o-ring (0.12 mbar and 0.11 mbar). However, initial pressures rather reflect differences in time and efficiency of pumping than tightness. The slope of all four curves is nearly equal (0.01 mbar per 100 sec) for a pressure range of 0.10–0.25 mbar, showing that the leakage rate is determined by the needle valve or the construction between needle valve and pump. It also shows that the leakage of the sublimation cell is minor in comparison to the whole construction.

A leakage test was also performed with the old version of the sublimation cell (olive + fabric tube for evacuation) (not shown). The pressure increased by a factor of 40 within the first 200 seconds (from ca. 5 mbar to ca. 200 mbar) reaching a saturation after a few minutes in the range of 1–5 mbar.

The leakage test shows a reasonable leak tightness of the sublimation cell for the crystallization via sublimation. Generally, an increase of pressure over 10 mbar was observed no earlier than 1 hour after closing the needle valve. Occasionally, a pressure less than 10 mbar was maintained for 24 hours.

Crystallization of Racemic and Deuterated Substances

Racemic compounds of methyl mandelate, norephedrine, and pseudoephedrine were crystallized by using an equal amount of both enantiomers. The enantiomers were pestled and put either in a glass tube or into the sublimation cell. Then, the glass tube or the sublimation cell was evacuated. Samples prepared in the glass tube were stored for one to ten weeks and regularly evacuated.

In order to obtain OD- or ND/OD-deuterated crystals, the pestled sample was

3. Methods

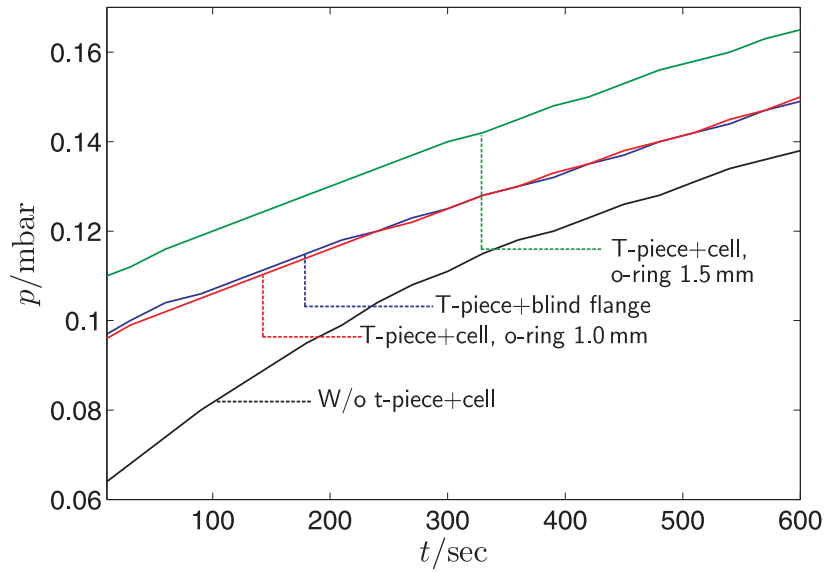

Figure 3.4.: Leakage test of the sublimation cell with a 1.5 mm and a 1.0 mm o-ring connected to a T-piece. The leakage of the T-piece with a blind flange and the leakage without the T-piece are also shown. The pressure p in mbar was recorded over a time interval t of 600 sec.

dissolved in a few drops of D_2O directly in the sublimation cell. Then, the cell was evacuated. Afterwards, the obtained amorphous or crystalline OD- or ND/OD-deuterated sample was sublimated. In these cases, the needle valve was not closed to prevent an exchange of deuterium with hydrogen from moist air and spectra were only measured directly in the sublimation cell.

3.2. Experimental Methods

A variety of spectrometric techniques was used within the framework of the present study. In order to investigate the molecular conformation and orientation of sublimated microcrystals polarization FTIR microspectroscopy was applied. Pestled solid samples without preferred orientations were recorded by FTIR-ATR spectroscopy for comparison. The relative vapor pressures of enantiopure and racemic compounds were investigated by mass spectrometry to assist the study of chirality recognition phenomena. The conformation and aggregation of small clusters were observed by using FTIR-jet and Raman-jet spectroscopy. In the following sections these setups will be described.

3.2.1. FTIR Microspectroscopy

Polarized FTIR microspectroscopy [17] was applied to investigate the molecular conformation and orientation of sublimated microcrystals (Chapters 5, 6, and 7), see also Refs. [27, 59]. The setup consists of a Vertex 70v FTIR spectrometer (Bruker Optics) and a Hyperion3000 microscope (Bruker Optics). For the sublimation of crystals a sublimation cell was constructed (Sect. 3.1). For rotation and polarization measurements a rotation device and a polarizer were available.

The Vertex 70v is an evacuable FTIR spectrometer with a cube-corner interferometer. For all microspectroscopic measurements a 12 V Globar mid infrared source and a KBr beamsplitter were used.

The optical pathway of the FTIR microscope is shown in Fig. 3.5. The microscope can be used in IR, visual (halogen light sources), and in a combined IR/Vis mode. For the measurements presented here, only the IR or the visual mode were used since the combination mode reduces the spectral quality. Three different objectives were available. A 4× visual objective (glass), a 15× IR/Vis objective, and a 20× ATR-IR/Vis objective. The 4× objective was used to get an overview, while the 15× objective was used for IR measurements and for the visual pictures shown in this dissertation. The photos were taken with a color CCD camera (Sony ExwaveHAD SSC-DC80P) attached to the microscope. For the IR detection two MCT (mercury cadmium telluride) detectors were applied, which will be described in detail below. Additional options include an IR or a visual polarizer as well as an analyzer that can be placed in the optical pathway. The microscope is purged with

3. Methods

dry air.

For regular measurements the single element MCT detector ($4000\text{--}1000\text{ cm}^{-1}$) with a recording area of $0.25 \times 0.25\text{ mm}^2$ and the $15\times$ IR/Vis objective were applied. The standard experiment *Hyperion_transmittance.xpm* (provided by Opus 6.5 [61]) with a spectral resolution of 4 cm^{-1} and an aperture of 2 mm was used. Additionally, a cutting aperture was applied to confine the area of interest. Normally, 32 or 50 scans were recorded. For a better signal-to-noise ratio 100 or 200 scans were occasionally taken.

In order to obtain chemical IR images a focal plane array (FPA) detector [62, 63] was available. The FPA detector with 64×64 elements has a recording area of $2.56 \times 2.56\text{ mm}^2$ which corresponds to a sample area of $0.170 \times 0.170\text{ mm}^2$ when applying the $15\times$ IR/Vis objective. It is a multiple MCT detector and thus covers the mid infrared region from 4000 to 1000 cm^{-1} . It can be used to obtain spatially resolved vibrational information of the sample. For measurements with the FPA detector a low pass filter and an attenuator were used. The standard experiment *Hyperion_3000_FPA.xpm* was applied. The aperture was set to 8 mm and 500 scans with a resolution of 8 cm^{-1} were recorded. The frame rate was set to 3773 Hz and an integration time of 0.15 ms was chosen. An offset of 230 and a gain of 1 were applied.

Crystal samples were directly measured in the closed sublimation cell or on the CaF_2 substrate after removing it from the sublimation cell. Occasionally, a rotation device was applied in order to measure the different faces of the crystals. Due to the small size of the sublimated crystals ($10\text{--}500\text{ }\mu\text{m}$) it was possible to record all spectra in transmission mode. A comparison of a transmission and a reflection spectrum of a sublimated (*R*)-methyl mandelate crystal is shown in Fig. 3.6. The signal-to-noise ratio is acceptable for both modes. However, the spectrum measured in transmission mode shows a superior spectral quality. In reflectance mode intense bands are attenuated.

Rotation Experiments

The microcrystals investigated in this work grow on one or two preferred faces. In order to record FTIR spectra from other faces, a rotation device was used (see Fig. 3.7). It consists of a 360° microrotation stage (Standa 7R128, 1° accuracy) and a rod of 5 cm in length and 0.5 cm in diameter. The CaF_2 window with a crystal

3. Methods

Figure 3.6.: Transmission (top) and reflectance (bottom) FTIR spectra of an (*R*)-methyl mandelate crystal on CaF₂ substrate. In reflection mode strong bands are attenuated.

can be glued with general purpose glue on top of the rod. The rotation device with the window can be screwed onto the *xy* stage of the microscope to prevent misalignment.

For rotation experiments, one microcrystal needs to be chosen and all others grown on the CaF₂ substrate need to be removed. Otherwise, there is the risk of several crystals appearing in the beam-pathway. For cleaning, a cotton bud of 2 mm diameter was used (NeoLab, 2-1022). No solvent was employed since it affects the crystal of interest. Occasionally, brushes (da Vinci Forte Basic 5/0, 135 or da Vinci Nova Synthetics 10/0, 245) were also used to remove bigger amounts of crystals.

In Fig. 3.8 visual pictures of a rotated crystal are shown. The rotated crystals exhibit a mirror image on the CaF₂ substrate. The right half shows the crystal, whereas the left part corresponds to its mirror image. In the following, the mirror image will not be shown.

Rotation spectra (especially along the long crystal axis, face C) exhibit large absorbances. Spectra a–g in Fig. 3.8 show the dependence of the spectral quality from the position of measurement indicated by the gray box. As expected there is no absorbance when the measured region includes the background (a and g) due to scattered light. The absorbance rises from spectrum a to c since less scattered light

Figure 3.7.: Scheme of a CaF_2 window with a crystal showing face A as implemented in the sublimation cell (a) and two rotated CaF_2 windows with a crystal showing face B (b) and face C (c). The crystal faces at the bottom correspond to a view along the IR beam.

hits the detector. The absorbance then falls when the mirror image is also measured (d and e), although less so than expected. In spectrum f the absorbance rises again even though only the mirror image is measured. In order to explain this unusual behavior further measurements are needed.

Polarizer

FTIR polarization studies were carried out to gain information about the spatial orientation of the molecules within the crystals. For polarization measurements a ZnSe holographic wire grid polarizer (Medway Optics Ltd) was used. It is 2 mm thick and has a diameter of 25 mm (unmounted). The clear aperture is 22.5 mm in diameter. The transmitted wavelength is $1\text{--}16\ \mu\text{m}$ ($10000\text{--}625\ \text{cm}^{-1}$). A wire grid polarizer transmits light with an electric vector perpendicular to the wires. The principal transmittances of a polarizer are the transmission efficiency (K_1) and the unwanted transmission (K_2). K_1 is the optical power transmitted by the polarizer with grid lines parallel and K_2 with grid lines perpendicular to the electric vector of a polarized source. In the case of a perfect polarizer K_2 equals 0. Properties which can be derived from K_1 and K_2 are the contrast ratio (r_{contr})

$$r_{\text{contr}} = \frac{K_1}{K_2}, \quad (3.1)$$

the extinction ratio (r_{ext}),

Figure 3.8.: FTIR spectra recorded at different positions of a rotated (1*S*,2*R*)-norephedrine crystal. The visual pictures show the crystal itself (right part) and its mirror image (left part). The gray box marks the spectroscopically investigated region. The absorbance A (maximum) of every spectrum is indicated.

Table 3.2.: The transmission efficiency (K_1), the unwanted transmission (K_2), the contrast ratio (r_{contr}), the extinction ratio (r_{ext}), and the degree of polarization (d_{pol}) of the ZnSe polarizer at $3\ \mu\text{m}$ ($3333\ \text{cm}^{-1}$) and at $10\ \mu\text{m}$ ($1000\ \text{cm}^{-1}$) are listed.

$\lambda/\mu\text{m}$	$\tilde{\nu}/\text{cm}^{-1}$	K_1	K_2	r_{contr}	r_{ext}	d_{pol}
3	3333	0.69	0.007	98:1	49:1	0.980
10	1000	0.72	0.002	360:1	180:1	0.994

$$r_{\text{ext}} = \frac{K_1}{2K_2} \quad (3.2)$$

and the degree of polarization (d_{pol}) [64]

$$d_{\text{pol}} = \frac{K_1 - K_2}{K_1 + K_2}. \quad (3.3)$$

Values for the used polarizer at $3\ \mu\text{m}$ ($3333\ \text{cm}^{-1}$) and at $10\ \mu\text{m}$ ($1000\ \text{cm}^{-1}$) can be found in Tab. 3.2. Small deviations between a nonpolarized spectrum and an average spectrum of two perpendicular polarized spectra were found to be erratic (not shown).

3.2.2. FTIR-ATR Spectroscopy

FTIR-ATR (attenuated total reflection) measurements of the substances used for microspectroscopic analysis were performed for comparison. ATR spectroscopy is based on an evanescent wave which penetrates the surface of the sample. The pestled samples used for the FTIR-ATR measurements represent a more or less perfect average over all orientations.

The FTIR-ATR measurements were performed in the sample compartment of the Vertex 70v FTIR spectrometer. The pestled sample was applied onto a diamond ATR unit (Harrick, MVP Pro-Star). For mid infrared measurements ($4000\text{--}400\ \text{cm}^{-1}$) a 12 V Globar source, a KBr beamsplitter, and a DTGS detector (deuterated triglycine sulfate) were used. The resolution was set at $4\ \text{cm}^{-1}$, the aperture at 6 mm, and the scanning velocity at 10 Hz in the standard experiment MVP-Pro-ATR-Diamond.xpm. In the cases of methyl mandelate, mandelic acid, and methyl lactate (Chapters 5 and 6) a total number of 200 scans ($2 \cdot 100$) were recorded

Figure 3.9.: FTIR spectra showing signal-to-noise ratios of three mylar (50μ , 23μ , and 6μ) and a massive silicon beamsplitter (Si).

whereas in the case of the phenylpropanolamines 50 scans were taken (Chapter 7).

Far infrared (FIR) measurements in combination with the diamond ATR unit were also recorded. They were performed using a 12 V or a 24 V Globar source with a massive silicon beamsplitter and a liquid helium cooled silicon bolometer (IRLab, Inc. HDL-5) in the range of 30 cm^{-1} to 470 cm^{-1} . The standard experiment used was FIR-DTGS(FIRSI).xpm. The resolution was 2 cm^{-1} with an aperture of 8 mm and a scanning velocity of 60 kHz. A total number of 400 scans ($4 \cdot 100$) were averaged.

In Fig. 3.9 the performance of the massive silicon beamsplitter is compared to different mylar beamsplitters ($6\mu\text{m}$, $12\mu\text{m}$, and $50\mu\text{m}$ multilayer). The FTIR spectra are shown in the spectral range of $550\text{--}140\text{ cm}^{-1}$ and were measured using an FIR-DTGS detector for 100 s (16 scans). The aperture was set to 6 mm and the scan velocity to 2.5 kHz. It can be seen that the signal-to-noise ratios of the 50μ and the 23μ mylar beamsplitters are rather low and have specific minima. The signal-to-noise ratio of the 6μ beamsplitter is comparable to the ratio of the silicon beamsplitter, but the ratio is slightly worse. Furthermore, this beamsplitter is very difficult to align. All in all, the massive silicon beamsplitter shows a reasonable signal-to-noise ratio which is more or less constant in the shown spectral range.

Figure 3.10.: Schematic layout of the mass spectrometer used to determine relative vapor pressures.

3.2.3. Mass Spectrometry

Mass spectrometry was employed in order to determine the relative vapor pressure of substances showing chirality recognition phenomena [38,65,66]. A layout of the setup is depicted in Fig. 3.10. It consists of a quadrupole mass spectrometer (QMS, Stanford Research Systems RGA 200). Its vacuum chamber can be evacuated by a rotary vane pump (Vacuubrand RS-4) and a turbomolecular pump (Leybold Turbovac 50) down to a pressure of 10^{-5} to 10^{-6} mbar. Solid pestled samples placed into three tubes can be temperature regulated in a bath cryostat (Haake CH/F3). The amount of vapor flowing into the mass spectrometer is regulated by a precision needle valve (HOKE Milli-Mite 13335G6Y).

The vapor is ionized in an electron impact ionizer. A Faraday cup detector measures the ion currents at an electron energy of 70 eV. It covers a range of 10^{-7} to 10^{-15} A for both positive and negative values with the same accuracy and resolution. Measurements can be performed in a range of 1 to 300 amu. The relative intensities of characteristic ion fragments were used to determine relative vapor pressures.

A specific amount of substance (usually 100 mg) was evacuated in one of the three glass tubes. Mass spectra of the intensity versus the m/z value were recorded every five minutes for about six hours. The software rga3.05 [67] which allows for scheduled measurements was used. The intensities of selected fragments were

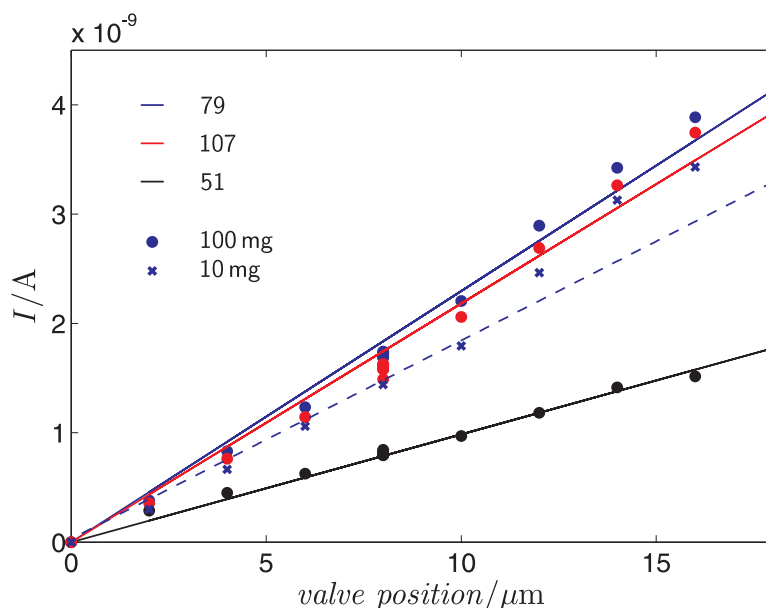

Figure 3.11.: Intensities of m/z values for different valve positions and different amounts of substance (here, racemic methyl mandelate).

automatically read and averaged with a script written in Matlab R2009b [48]. An example script can be found in Supplement C.

The optimal valve position for a stable dynamical equilibrium of leakage into the chamber and pumping-off was determined by performing a series of measurements with different valve positions. 100 mg and 10 mg of the test substance (racemic methyl mandelate) were thermostated at 20°C. Mass spectra were recorded at different valve positions every two minutes for 30 minutes. The average intensity of the peaks at an m/z value of 51, 79, and 107 are plotted against the setting of the needle valve in Fig. 3.11. The intensity increases linearly for larger openings of the valve. This shows that the stream of vapor is thermodynamically controlled. In the case of a kinetically controlled process, a leveling off of the intensities would be expected. To verify the results, measurements were also performed at a temperature of 5°C leading to the same results (not shown). A stable dynamical equilibrium of leakage was obtained after an induction period of a few minutes. Fig. 3.11 also shows that an amount of 10 mg leads to a bigger divergence of the linear fit. Furthermore, the intensity breaks down at a valve position of 18 μm .

Figure 3.12.: Schematic layout of the filet-jet taken from Ref. [71], modified.

3.2.4. Jet Spectroscopy

Jet spectroscopy is used for the spectroscopic investigation of isolated monomers and small clusters [68–70]. The adiabatic expansion from a higher to a lower pressure region causes the temperature to lower significantly. Especially, the translational and rotational temperatures are lowered and the Doppler broadening is reduced. The use of a noble gas (here helium and argon in helium) allows for a more efficient cooling. Vibrational spectra are simplified and can be more easily compared to quantum chemical calculations.

Two jet setups were used in the framework of the present work. One is based on FTIR and the other on Raman spectroscopy. Both setups will be briefly explained below.

FTIR-Jet Spectroscopy

FTIR-jet spectroscopic measurements were performed using the filet-jet (fine but lengthy, a description of the nozzle). A scheme of the setup is shown in Fig. 3.12. Detailed descriptions of the setup can be found in Refs. [71–74].

3. Methods

The substances of interest can be heated in two saturators which are purged with a carrier gas (helium). The gaseous mixture is then filled into a reservoir of 67 L volume using magnetic valves. The concentration was lowered by a third stream of the carrier gas to traces of up to 0.6%. Relative concentrations were roughly estimated based on relative intensities, vapor pressures, and mixing ratios. After reaching the stagnation pressure of 1 bar, the gas mixture is directed over six magnetic valves into a prechamber ensuring a homogeneous expansion. The mixture is then expanded through a high-throughput slit nozzle of 600 mm length and a width of 0.2 mm into the jet chamber (stainless steel, 776 mm length, 400 mm diameter). The jet chamber is connected to a buffer volume of 23 m³ which keeps the background pressure at less than a few mbar. After evacuating the jet chamber (2500 m³·h⁻¹) the magnetic valves are opened again and another expansion is induced.

FTIR scans were performed with an Equinox 55 FTIR spectrometer (Bruker Optics). In the meantime, this spectrometer has been replaced by the evacuable IFS66v/S which shows a better signal-to-noise ratio. The beam is aligned perpendicular to the direction of propagation to attain a long distance of absorption. For every pulse, a total of 25 scans are recorded. The first 20 scans are carried out before every gas pulse and averaged into one background spectrum. Two scans before and two after every gas pulse are used for control measurements. 150–200 pulse scans were averaged to improve the signal-to-noise ratio. Further parameters are listed in Supplement D.

Raman-Jet Spectroscopy

Raman-jet measurements were performed with the curry-jet (classical **un**restricted Raman spectroscopy). Four variants of the curry-jet were used within the present studies. Detailed parameters of the variants are listed in Supplement D. A schematic layout of the curry-jet is shown in Fig. 3.13.

A gaseous mixture is produced by running a carrier gas (helium or argon) through two temperature controlled saturators filled with the substances of interest. The pressure was set at 1.5 bar, but decreased during measurements to 1.0–1.1 bar. The expansion takes place through a 4.0 × 0.15 mm² slit nozzle into a jet chamber. The jet chamber is evacuated by a 250 m³·h⁻¹ roots pump backed up by a 100 m³·h⁻¹ rotary vane pump. In the newest version of the curry-jet a 500 m³·h⁻¹ roots pump has been added to increase the pumping capacity.

Figure 3.13.: Schematic layout of the curry-jet taken from Ref. [75], modified.

3. Methods

An 18 W 532 nm Nd:YVO₄ laser source is focused by a planoconvex lens on the jet expansion. A McPherson Inc. Model 2051 monochromator or a McPherson 205f spectrograph disperses the scattered radiation onto a Princeton Instruments Spec-10:400B/LN CCD camera. Wavelength calibrations were carried out with Ne atomic fluorescence lines. The absolute wavenumber scale is expected to be accurate within 1–2 cm^{−1}. An average of four to twelve independent acquisitions with an integration time of 200–600 s was smoothed to gain the final spectra. For a more detailed description see Refs. [11, 14, 75–80].

3.3. Theoretical Methods

Theoretical methods were applied to assist the vibrational interpretation. In the following, the performed quantum chemical calculations will be described. Data treatment to obtain FTIR images will also be illustrated. All spectra recorded with the single element MCT detector and with the ATR device are shown without any postprocessing. For the treatment of the Raman-jet spectra see Refs. [75,81].

3.3.1. Quantum Chemical Calculations

Quantum chemical calculations were performed to assist the assignment of experimental bands to different vibrational modes and to different clusters. The calculations provide information on the energy of a given conformation or cluster, their vibrational modes and frequencies, as well as the *x*-, *y*-, and *z*-components of the dipole derivatives. Quantum chemical calculations were performed for the sublimated crystals investigated by FTIR-microspectroscopy and for mixed alcohol-water clusters investigated by Raman- and FTIR-jet spectroscopy.

Sublimated Crystals

For the FTIR-microspectroscopic studies frequency calculations including dipole derivatives were performed on geometrically optimized (fully relaxed) structures of the most stable monomer conformations in the gas phase (structure provided by Refs. [38,82–87]) as well as on conformations taken from the crystal structures [38, 88–92]. Harmonic calculations were performed with the Gaussian03 program suite [93] employing B3LYP with the 6-311++G(3df,2p) basis set and the MP2 level with the 6-311+G(2d,p) basis (not employed in the case of the phenylpropanolamines). The calculated harmonic wavenumbers are scaled by a universal best fit factor of 0.966 which accounts for neglected anharmonicity in X-H stretching fundamentals and deficiencies of the B3LYP method.

In the case of methyl mandelate partly optimized structures (1–5 optimization steps) taken from the crystal structure [38] were also used. The conformations of these partly optimized structures are closer to the conformation of the frozen monomer than the fully relaxed monomers. For the partly optimized methyl mandelate monomers with 1–5 optimization steps no reasonable partial convergence was found. The O-H stretching wavenumbers listed in Tab. 3.3 show an erratic con-

3. Methods

Table 3.3.: Predicted harmonic wavenumbers of the O-H stretching mode $\omega(\text{O-H})$ in cm^{-1} and energy differences without and with zero point energies (ΔE and ΔE_0) in $\text{kJ}\cdot\text{mol}^{-1}$ of the frozen monomer, monomer optimized in 1–5 steps as well as the fully relaxed monomer taken from the crystal structure of enantiopure methyl mandelate and the most stable monomer [38].

	Frozen	Step 1	Step 2	Step 3	Step 4	Step 5	Fully relaxed	Most stable
$\omega(\text{O-H})$	5934	4931	3764	3803	3836	3858	3835	3723
ΔE	366.6	132.2	23.4	20.9	20.7	18.4	15.4	0.0
ΔE_0	370.9	131.6	21.4	19.6	19.8	17.0	14.6	0.0

vergence. As a result, only frequencies from fully relaxed structures are used in this work.

Alcohol-Water Cluster

Conformational Raman and IR frequency calculations were performed on small water-alcohol cluster with the Gaussian03 program suite [93]. The levels of harmonic calculations employed in this work (with their abbreviations given in parenthesis) include B3LYP/6-311+G(d) (B3-S), MP2/6-311+G(d) (MP2-S), MP2/6-311++G(2d,p) (MP2-M), and MP2/6-311++G(3df,2p) (MP2-L). S, M, and L indicate small, medium, and large basissets, respectively.

To compensate empirically for some deficiencies in the electronic structure treatment and other effects, the average of the corresponding harmonic O-H stretching wavenumbers $\omega(\text{th},n)$ calculated at the MP2-S and MP2-M levels was used. This ad hoc choice should be viewed as a pragmatic interpolation approach in the absence of more rigorous systematic calculations, including larger clusters.

The average harmonic dimer and trimer O-H stretching wavenumbers $\omega(\text{th},n)$ were shifted by the difference between the experimental water dimer donor wavenumber $\tilde{\nu}_{\text{ww}}(\text{exp})$ (3602 cm^{-1} for $(\text{H}_2\text{O})_2$ in the IR and Raman case, 2632 cm^{-1} for $(\text{D}_2\text{O})_2$) and the corresponding harmonic wavenumber prediction $\omega_{\text{ww}}(\text{th})$ (see Supplement E):

$$\tilde{\nu}(\text{th},n) = \omega(\text{th},n) + \tilde{\nu}_{\text{ww}}(\text{exp}) - \omega_{\text{ww}}(\text{th}) \quad (3.4)$$

Zero point energy corrections to binding energies were estimated in the harmonic approximation. This may not be a satisfactory approximation for the large ampli-

tude torsions and for intermolecular degrees of freedom [94].

IR intensities I were calculated as integrated band strenghts in units of $\text{km}\cdot\text{mol}^{-1}$. Raman intensities depend on the wavenumber of the used laser $\tilde{\nu}_0$. Differential scattering cross sections σ' in units of m^2sr^{-1} can be calculated using the calculated scattering activities A_{Raman} [75]:

$$\sigma' = \frac{2\pi^2 h}{45c\tilde{\nu}_k} \cdot \frac{(\tilde{\nu}_0 - \tilde{\nu}_k)^3 \tilde{\nu}_0}{1 - e^{-\frac{hc\tilde{\nu}_k}{kT}}} \cdot g_k A_{\text{Raman},k} \quad (3.5)$$

Since the investigated vibrational energies are much higher than the thermal excitation in the jet, $hc\tilde{\nu}_k \gg kT$ was assumed.

3.3.2. FTIR Images

To obtain the FPA-FTIR chemical images shown in this work two wavenumber regions were integrated using the baseline corrected integration method of OPUS 6.5 [61] and then subtracted using a prefactor to maximize the contrast between the two wavenumber regions. The integrated areas are chosen according to spectral differences of the substances.

In the case of methyl mandelate the regions of $3018\text{--}2982\text{ cm}^{-1}$ (H for high) and $2972\text{--}2934\text{ cm}^{-1}$ (L for low) were integrated. Twice the integral absorption of region H was subtracted from the integral of region L ($L - 2\cdot H$). Blue colors show a higher intensity of bands in the $3018\text{--}2982\text{ cm}^{-1}$ region, whereas red colors refer to a higher intensity in the $2972\text{--}2934\text{ cm}^{-1}$ region. Absorption free regions and regions with balanced intensities in the $3018\text{--}2982\text{ cm}^{-1}$ and $2972\text{--}2934\text{ cm}^{-1}$ windows are shown in green (BG).

In order to obtain chemical images of mandelic acid, the regions $3120\text{--}3100\text{ cm}^{-1}$ (H) and $3100\text{--}3080\text{ cm}^{-1}$ (L) were integrated. Three times the integral of region H was subtracted from the integral of L ($L - 3\cdot H$). Blue colors show a higher band intensity in the $3120\text{--}3100\text{ cm}^{-1}$ region, while red colors correspond to a higher intensity in the $3100\text{--}3080\text{ cm}^{-1}$ region.

The chemical images of pseudoephedrine were obtained by subtracting the integrated region of $3335\text{--}3310\text{ cm}^{-1}$ (Enant) from the integrated region of $3310\text{--}3290\text{ cm}^{-1}$ (Rac, Rac–Enant). Thus, higher band intensities in the region of $3335\text{--}3310\text{ cm}^{-1}$ are shown in blue and in the region of $3310\text{--}3290\text{ cm}^{-1}$ in red colors.

4. Alcohol-Water Clusters

Ethanol is the smallest organic molecule which shows conformational isomerism. There are three stable conformers, a trans conformer and two less stable gauche conformers, gauche+ and gauche– (see Fig. 4.1). This conformational preference is partially modified in the crystal which contains one trans and one gauche– ethanol conformation in the asymmetric unit [95]. The molecule adapts to its environment. Small ethanol clusters [10, 80] and ethanol-water [11, 14] clusters are elementary model cases to study such an adaptive aggregation.

Alcohol-water mixtures show some anomalies on the macroscopic scale [96], such as volume contraction [97, 98] and asymmetric heats of mixing [99, 100]. The anomalies are expected to emerge at a nanoscopic scale, at the level of hydrogen bonded clusters [101]. Alcohol-water mixtures are of great importance for industrial purposes and in daily life. Especially, ethanol-water mixtures are widely known for their neuroactive effects.

So far, remarkably little is known about the conformations and interactions within the smallest building blocks of aqueous solutions of the two simplest alcohols, methanol and ethanol. The structure of the methanol-water dimer was unravelled by microwave spectroscopy [102]. The methanol-water dimer and larger clusters were investigated by matrix isolation infrared spectroscopy [103]. Vacuum isolation studies, which lend themselves better to direct comparison between theory and

Figure 4.1.: Illustration of trans, gauche+, and gauche– ethanol conformations and the right (r) and left (l) lone pairs.

experiment, were started in the framework of the author's *Hausarbeit im Rahmen der Ersten Staatsprüfung für das Lehramt an Gymnasien* [81] and continued within the present project [11, 14, 75]. The sparsity of experimental data results from the absence of a suitable UV chromophore which would allow for sensitive double-resonance spectroscopy approaches. VUV double resonance techniques might be feasible but are still in their infancy [104] and do not always provide faithful infrared spectra [105].

In the following, the conformational preferences during adaptive aggregation of small methanol-water and ethanol-water clusters investigated by Raman- and FTIR-jet spectroscopy in the O-H stretching region will be analyzed. Concentration and relaxation studies as well as measurements of isotope labeled mixtures will be shown. Quantum chemical calculations of mixed methanol- and ethanol-water dimers to tetramers for structural investigations and for the assistance of the vibrational assignments will be presented.

The main results of this chapter are published in Refs. [11, 14]. Verbatim citations are used with permission of all co-authors. Results on relative donor/acceptor strengths, weak secondary hydrogen bonds, tunneling processes in acceptor lone pair switching, and thermodynamic anomalies are elucidated in Refs. [11, 14] and will not be repeated in this chapter.

4.1. Preliminary Considerations

Water and the alcohols methanol and ethanol possess a hydroxy group which can simultaneously act as a proton donor and acceptor for hydrogen bonding. In the case of water two hydroxy groups are present and therefore, hydrogen bonded networks can be established [106]. In the following, the hydrogen bond donor within a dimer will be named first and the acceptor second. The abbreviations **a** for alcohol, **m** for methanol, **e** for ethanol, and **w** for water will be used. Thus, **wm** names a dimer in which water takes the role of the proton donor and methanol the acceptor. The sequence of letters is irrelevant for higher cyclic clusters. In the case of ethanol the trans, gauche+, and gauche− conformations need to be considered. The abbreviations **e_t**, **e_{g+}**, and **e_{g−}** are used. There are two free electron pairs of each acceptor oxygen atom differentiated as right (r) and left (l) lone pairs (see Fig. 4.1). In case of cyclic structures, the molecules may point up (*u*) and down (*d*) with respect to

Figure 4.2.: Illustration of a methanol molecule pointing up (*u*) and two water molecules pointing down (*d*) the ring's plane.

the ring's plane (Fig. 4.2). The formation of hydrogen bonds, the presence of isomerism, and the arrangement of molecules influence the conformation of the mixed clusters and also the position of the O-H stretching band. The latter can be used to unravel the conformation of the clusters.

There are numerous quantum-chemical calculations for methanol, ethanol and their complexes with water available in the literature. Results for methanol-water dimers can be found in Refs. [94, 107–115], among others. Data for higher clusters are summarized in Refs. [110, 113, 116], whereas simulations on aqueous methanol mixtures are described in Refs. [117, 118]. Calculations for mixed ethanol-water dimers are presented in Refs. [107, 108, 112, 115, 119, 120]. Others also performed studies on higher ethanol-water clusters (e.g. see Refs. [116, 121–123]). In the present work, some of these calculations had to be repeated and complemented in order to obtain all the information relevant for this study. E.g. in Refs. [107, 115, 120, 121] conformational isomerism of ethanol is not considered. Refs. [108, 112] distinguish between *trans* and *gauche* ethanol but do not take into account the *gauche+* and *gauche–* variants which are spectroscopically distinguishable in mixed dimers. Additionally, Raman intensities were rarely calculated or a given level of approximation was not available for both alcohols.

To identify trends between methanol and ethanol in this work, reliable comparisons are indispensable. Calculations were carried out for all conceivable dimer structures (**aw** and **wa** including torsional variants). In the case of ethanol, the different conformers were considered. For mixed cyclic trimers (**aaw** and **aww**) no systematic calculations on all possible conformers were carried out due to expected and experimentally confirmed spectral overlap. Only clusters with the right electron pair being the hydrogen bond acceptor are considered since they are spectroscopically indistinguishable from their mirror images involving the left electron pair in the hydrogen bond. For further details on the selection of calculated structures see

Ref. [81]. Predicted harmonic wavenumbers are summarized in Supplement E.

Predicted intensities were modified taking into account the approximate alcohol mole fraction x_a as well as the number of possible conformers. The probability p for a given cluster type was estimated by a binominal distribution, leading to the following equations for dimers:

$$\begin{aligned} p_{ww} &= (1 - x_a)^2 \\ p_{wa} &= (1 - x_a) \cdot x_a \\ p_{aw} &= x_a \cdot (1 - x_a) \\ p_{aa} &= (x_a)^2 \end{aligned} \tag{4.1}$$

and trimers:

$$\begin{aligned} p_{www} &= (1 - x_a)^3 \\ p_{aww} &= 3 \cdot x_a \cdot (1 - x_a)^2 \\ p_{aaw} &= 3 \cdot (x_a)^2 \cdot (1 - x_a) \\ p_{aaa} &= (x_a)^3 \end{aligned} \tag{4.2}$$

To account for the lower abundance of trimers relative to dimers in the supersonic expansions, empirical intensity scaling factors are applied for the simulated spectra. For the methanol-water trimers, intensity scaling factors of $\frac{1}{2}$ and $\frac{1}{4}$ are applied for the simulated Raman and IR spectra, respectively. For the ethanol-water trimers, an intensity scaling factor of $\frac{1}{4}$ is applied for both the simulated spectra. Furthermore, the average intensities predicted by the MP2-S and MP2-M levels were used for the simulated spectra (see Figs. 4.5, 4.7, and 4.10 later on), based on the relative intensity information σ_{rel} and I_{rel} gathered in Supplement E.

4.2. Methanol-Water

Fig. 4.3 provides an overview of the O-H stretching region of the mixed methanol-water system comparing Raman- and FTIR-jet spectra with assignments of the corresponding clusters. Bands appearing in the spectra of the mixed system but not in the pure ones are assigned to mixed clusters. A list of assigned bands can be found

Figure 4.3.: Raman- and FTIR-jet spectra of the mixed methanol-water system in the O-H stretching region. Absorbance magnification factors are shown in the insets, which share the wavenumber scale of the main spectra. The left inset shows the effect of reduced methanol concentration, helping in the mixed dimer assignment. The right inset shows the evolution of mixed trimers with increasing methanol-to-water ratio.

in Tab. 4.1. Small IR/Raman differences of band positions are within the Raman calibration accuracy.

The mixed band near 3567 cm^{-1} appears in Raman- and FTIR-jet spectra, consistent with a dimer origin. It corresponds to the band at 3508 cm^{-1} observed in size selected ternary benzene-methanol-water trimers [125]. Two dimers **mw** and **wm** are found at all levels of calculation (see Fig. 4.4). For a better comparison between experimental and calculated spectra, the harmonic predictions of both dimers (see Supplement E) are shown in Fig. 4.5. On top an experimental Raman-jet spectrum and at the bottom the experimental FTIR-jet spectrum from Fig. 4.3 is repeated. In between, relative Raman scattering powers σ_{rel} and IR band strengths I_{rel} of mixed and pure clusters are plotted as stick spectra (for the scaling procedures see Sect. 3.3). The O-H stretching band of **mw** is predicted at higher wavenumber than **ww** where no band is observed, whereas the predicted red shift of **wm** matches the new band emerging in the mixed system. The associated intensity transfer from the relaxation of **mw** into **wm** is indicated by dotted arrows and lines in Fig. 4.5c. This conformational preference is in agreement with most quantum chemical calculations [94, 107, 109, 120, 126, 127] (but not at the B3-S and MP2-S levels) as well as

Figure 4.4.: Structures of the **mw** and **wm** dimer configurations at MP2-L level.

microwave spectroscopic investigations [102]. In cryogenic argon matrices, **wm** is also found to be the most stable dimer isomer [103, 126], whereas nitrogen matrices change this donor/acceptor preference [103, 128]. Diffusion Monte Carlo simulations for **wm** and **mw** have shown that the stability of the mixed dimers also depends on the zero point energy for the hindered internal rotation of the monomers [94]. The methanol hydroxy group is engaged in the hydrogen bond in **mw**. Thus, its torsion mode is more restricted than in **wm** and blue shifted. Its contribution to the zero point energy is thus strongly augmented, which contributes to the reduced stability of **mw** compared to **wm**.

In the central part of Fig. 4.3 the **wm** dimer region from a Raman measurement with relative concentration of $\mathbf{m:w} \approx 1:3$ (magnified by a factor of five) is also shown. The **wm** band persists, whereas the **mm** band decreases compared to the spectrum with a $\mathbf{m:w}$ ratio of 3:1. By taking a closer look at the **wm** band a hardly resolved splitting of approximately 2.5 cm^{-1} between a more intense band at 3568.0 cm^{-1} and a less intense one at 3565.5 cm^{-1} can be noticed. This splitting is not resolved in the corresponding IR spectrum due to more extensive rotational contours. Since the splitting cannot be traced back to conformational or donor-acceptor isomerism (see Refs. [14, 75]), a tunneling process is the probable cause. To further investigate this hypothesis, measurements with OD-deuterated methanol and deuterium oxide were carried out. Raman jet spectra of the O-D stretching region are shown in Fig. 4.6. The theoretical prediction shown in Fig. 4.7 is again unambiguous in terms of the donor/acceptor preference. The corresponding **wm** band was observed at 2611 cm^{-1} . No splitting can be resolved in the O-D stretching spectra. Therefore, a mass-independent cause for the splitting in the O-H stretching region can be excluded. The most likely reason for the splitting seems to be an exchange of the water donor between the methanol acceptor lone pairs (see Refs. [14, 75]).

Figure 4.5.: Comparison of calculated (MP2-S/MP2-M average) and experimental Raman and FTIR spectra of pure and mixed dimers and trimers of the methanol-water system: a) Raman-jet (Φ in $\text{counts}\cdot\text{s}^{-1}$), b) Raman prediction for pure clusters (σ'_{rel} in $10^{-36}\cdot\text{m}^2\cdot\text{sr}^{-1}$), c) Raman prediction for mixed clusters (σ'_{rel} in $10^{-36}\cdot\text{m}^2\cdot\text{sr}^{-1}$), d) IR prediction for mixed clusters (I_{rel} in $\text{km}\cdot\text{mol}^{-1}$), e) IR prediction for pure clusters (I_{rel} in $\text{km}\cdot\text{mol}^{-1}$), f) FTIR-jet ($A=\ln(\frac{I_0}{I})\cdot 10^3$). For the scaling procedure, see Sect. 3.3. In the trimer case, the most stable MP2-M structure with two equal molecules pointing into the same direction (Fig. 4.2) is used for the stick spectra.

Figure 4.6.: Raman-jet spectra of the mixed deuterated methanol-deuterium oxide system in the O-D stretching region.

Figure 4.7.: Comparison of calculated (MP2-S/MP2-M average) and experimental Raman spectra of pure and mixed dimers and trimers of the deuterated methanol-deuterium oxide system: a) Raman-jet (Φ in $\text{counts}\cdot\text{s}^{-1}$), b) Raman prediction for pure clusters (σ'_{rel} in $10^{-36}\cdot\text{m}^2\cdot\text{sr}^{-1}$), c) Raman prediction for mixed clusters (σ'_{rel} in $10^{-36}\cdot\text{m}^2\cdot\text{sr}^{-1}$). For the scaling procedure, see Sect. 3.3.

The more challenging trimer signatures are shifted further to low frequency. Due to their cyclic, quasisymmetric nature, largely different Raman and IR intensities for the individual O-H stretching bands can be expected. Concerted stretching [78] leads to the lowest frequency band with a large change in polarizability. The IR intensity profits from out-of-phase vibration of the three coupled oscillators. There is no obvious localization of the vibrational amplitude on either water or methanol. To discriminate among trimers of different compositions, Raman-jet results for different ratios of water and methanol are shown in the box in the upper-right corner of Fig. 4.3. Adding small amounts of water to methanol leads to the appearance of a band at 3425 cm^{-1} (**mmw**). With more water, a mixed trimer band at 3440 cm^{-1} is observed (**mw**). This **mw** feature can also be found in the FTIR-jet spectra at 3439 cm^{-1} , together with at least two new trimer bands which require quantum chemical predictions for a tentative assignment.

There is considerable isomerism expected for mixed methanol-water trimers despite the complete absence of competitive non-cyclic structures, as inferred experimentally from the analogous methanol case [129] and theoretically in many studies [107, 110, 111, 113]. This is somewhat different when a benzene chromophore is attached. In all cases, one unit (arbitrarily) points above the hydrogen bonded ring (*u*) and two below (*d*) in the most stable structure (Fig. 4.2). At B3LYP level, the two *d* units preferentially belong to different species, whereas MP2 calculations predict the two *d* units to be the same in the most stable variant (see Tab. 4.2). However, the differences are only on the order of 0.1 to $0.3\text{ kJ}\cdot\text{mol}^{-1}$ and therefore, emphasis will be given on the MP2 preference in the following. The full set of trimer results is summarized in Supplement E. There is a systematic increase of the trimer dissociation energy with increasing methanol content as expected based on dispersion energy contributions and also the trend in the dimers. Note, that the B3-S approach almost fails in reproducing this trend (Tab. 4.2).

The quality of the harmonic wavenumber predictions can be tested for the Raman active bands, which are straightforward to assign based on the experimental data. There, a large wavenumber shift from **www** to **mw** followed by smaller shifts in the same direction for **mmw** and **mmm** can be found. This is not fully reflected in the MP2 prediction shown in Fig. 4.5, where **mmw** even overshoots **mmm** slightly. However, the predicted shifts are within $20\text{--}30\text{ cm}^{-1}$ of experiment, which is reasonable at this elementary level of theory.

As shown in traces d) and e) of Fig. 4.5, the IR situation is considerably more

MP2-M	0.00	−4.16 (−3.06)	−4.39 (−3.20)	−8.41 (−6.09)	−8.58 (−6.31)	−12.85 (−9.44)
MP2-L	0.00	−5.24 (−4.26)	−5.48 (−4.30)	−10.68 (−8.54)	−10.81 (−8.73)	−16.21 (−13.09)

congested with up to 8 new trimer transitions expected, due to the lifting of the C_3 symmetry degeneracy. A comparison of traces e) and f) shows that the calculations overestimate this degeneracy lifting. For **mmm**, the predicted splitting of 21 cm^{-1} is to be compared to the experimental one of 5 cm^{-1} [129]. With this and the general error bar of $\approx 20\text{--}30\text{ cm}^{-1}$ in mind, some mixed assignments of the three trimer bands which fall in the region between the dimer absorption and the Raman active trimer bands may be proposed (see Tab. 4.1). The band at 3533 cm^{-1} is expected to have **www** contributions [130], but may derive most of its intensity from **mmw**. The band at 3514 cm^{-1} is likely to have contributions from both mixed trimers. However, one can clearly see that the Raman active bands are less ambiguous.

In the case of OD-deuterated methanol co-expanded with deuterium oxide only one new band is present in the trimer region of the Raman-jet measurements (see Fig. 4.6). No other band appears when the ratio of deuterated methanol and deuterium oxide is changed. A comparison of experimental and calculated spectra is shown in Fig. 4.7. It can be seen that the mixed trimers (**mww** and **mmw**) are predicted near the turning point of the **www** \rightarrow **mmm** sequence, lower in wavenumber than **mmm** and closely neighboured. Therefore, the mixed band at 2536 cm^{-1} can tentatively be assigned to overlapping mixed trimers. The overshooting red shift of mixed clusters, which was already predicted at some levels for non-deuterated mixtures (see Supplement E) but not observed in the experiment, is fully developed after deuteration in both experiment and theory. This points at substantial excess effects in the mixtures, which are discussed in Refs. [11, 14].

A Raman-jet concentration study performed in order to investigate higher clusters

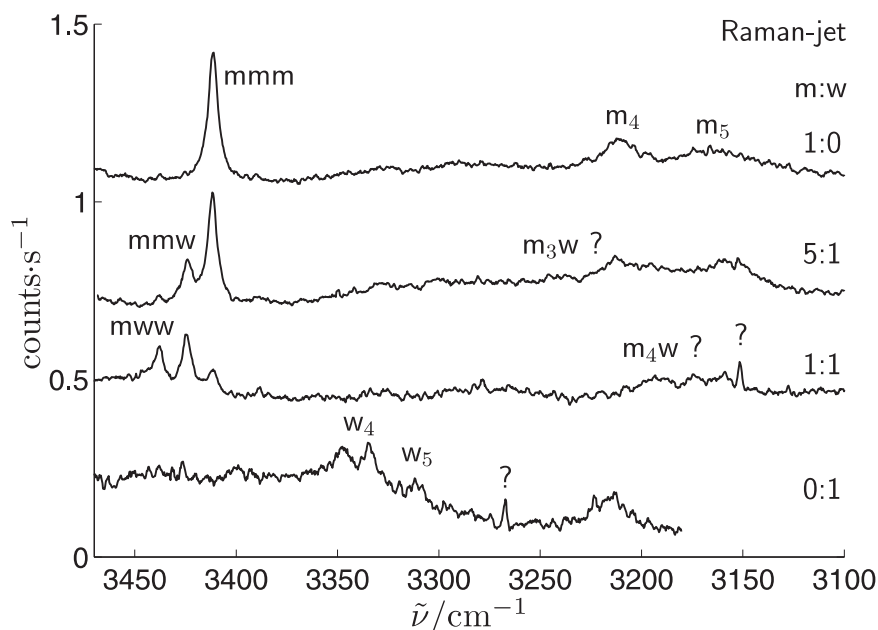

Figure 4.8.: Raman-jet spectra of the mixed methanol-water system in the O-H stretching region of higher clusters. The pure water spectrum at the bottom was taken from Fig. 6.1 in Ref. [77].

is shown in Fig. 4.8. By adding water to the pure methanol-water system, two bands at slightly higher wavenumbers than the pure methanol tetramer and pentamer arise. A mixed methanol-water tetramer $\mathbf{m}_3\mathbf{w}$ at 3239 cm^{-1} and a mixed methanol-water pentamer $\mathbf{m}_4\mathbf{w}$ 3191 cm^{-1} can tentatively be assigned. A better signal-to-noise ratio and comparison with quantum chemical calculations would be needed to support the assignments.

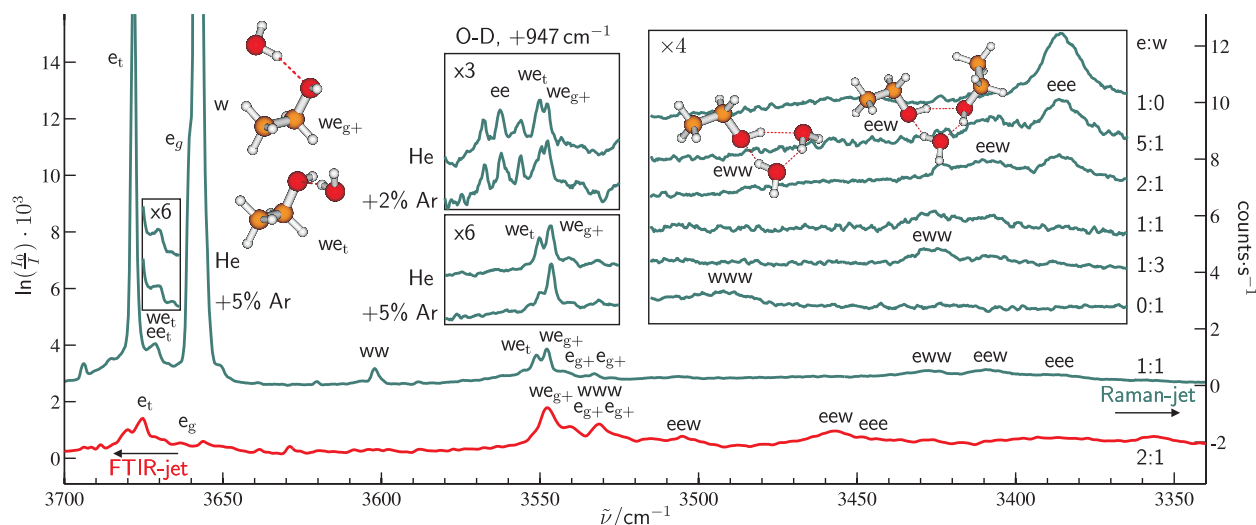

Figure 4.9.: Raman- and FTIR-jet spectra of the mixed ethanol-water system in the O-H (and O-D) stretching region. Absorbance magnification factors are shown in the insets, which share the wavenumber scale of the main spectra. The bottom centered inset shows relaxation of we_t to we_{g+} by adding Ar. The top centered inset shows the analog relaxation in the O-D region (shifted in wavenumber to match the we_{g+} O-H spectrum). The right inset shows the evolution of mixed trimers with increasing ethanol-to-water ratio.

4.3. Ethanol-Water

Fig. 4.9 displays a survey of the Raman- as well as the FTIR-jet spectrum of the mixed ethanol-water system. The Raman-jet spectrum was recorded at an estimated ethanol:water concentration ratio of 1:1, whereas the ethanol:water ratio in the FTIR-jet spectrum is approximately 2:1. Assignments of the observed bands are summarized in Tab. 4.3.

In analogy to the methanol-water system, mixed dimer bands are present in the Raman and FTIR-jet spectra. However, while the Raman spectrum shows two peaks at 3551 and 3548 cm^{-1} , the former is only a weak shoulder in the FTIR spectrum. It is caused by a metastable conformation, which is relaxed into the more stable conformation due to the larger average nozzle distance and therefore colder expansion in the FTIR experiment. The mixed dimer band at lower wavenumber is due to a gauche ethanol acceptor subunit, whereas the band at higher wavenumbers is assigned to a trans acceptor. The left inset in Fig. 4.9 shows the acceptor region of

trans ethanol for Raman measurements without (top) and with (bottom) 5% argon. In the lower central inset of Fig. 4.9 the hydrogen bonded O-H stretching bands are shown. The intensity of the **we_t** band at 3551 cm^{-1} decreases along with the acceptor band of trans ethanol when the heavier collider argon is added, showing that **we_{g+}** is more stable. Assuming a conservative lower limit of the effective conformational temperature in the argon doped expansion of 10 K and at most 10% remaining **we_t** fraction, a lower limit for the energy difference between **we_t** and **we_{g+}** of $0.2\text{ kJ}\cdot\text{mol}^{-1}$ from the Boltzmann population can be derived. These assignments are also supported by quantum chemical calculations (see Fig. 4.10 and Supplement E). At all levels of calculation five mixed ethanol-water dimer configurations can be optimized. Relative stabilities and local minimum structures are illustrated in Fig. 4.11. In the three most stable structures, water acts as the hydrogen bond donor. In these cases, not only the conformation of ethanol (trans or gauche) is relevant, but also the choice of the acceptor lone pair (see Sect. 4.1). As illustrated in Fig. 4.11, **we_{g+}** (with a hydrogen bond to the right lone pair of ethanol) is predicted to be the most stable and most compact mixed dimer at MP2-L level. In contrast to **we_{g-}** it is stabilized by a secondary hydrogen bond-like interaction between a C-H group and the water oxygen [131]. It bends the primary hydrogen bond slightly further away from the linear arrangement. The enhanced stability of **e_g** in this complex parallels the stabilization observed for ethanol dimers [10,75,78], as does the enhanced red shift. The donor/acceptor roles of ethanol and water in a matrix are analogous to those of methanol and water, with **we** being the more stable one in argon and **ew** in nitrogen [103]. In the jet, **ew** dimers are expected to relax into the more stable structures, as implied by the intensity shifts postulated in Fig. 4.10 by the dotted lines. The **we**-splitting shrinks by a factor less than 2 upon OD-deuteration of both ethanol and water (see Fig. 4.9). Theory predicts this factor to be 1.3 (MP2-L). Furthermore, the relaxation behavior is analogous to that of the nondeuterated dimer, although less pronounced because a smaller amount of argon is added. Therefore, it is clear that the **we**-splitting is not due to tunneling, as in **wm**, but rather to conformational isomerism.

To assign the trimer bands in the Raman-jet spectra, concentration variation was applied (see the rightmost box in Fig. 4.9 with relative concentration estimates). In analogy to the mixed methanol-water trimer bands, the intensity of the band at higher wavenumber (3427 cm^{-1}) increases with an increasing content of water,

Figure 4.10.: Comparison of calculated (MP2-S/MP2-M average) and experimental Raman and FTIR spectra of pure and mixed dimers and trimers of the ethanol-water system: a) Raman-jet (Φ in $\text{counts} \cdot \text{s}^{-1}$), b) Raman prediction for pure clusters (σ'_{rel} in $10^{-36} \cdot \text{m}^2 \cdot \text{sr}^{-1}$), c) Raman prediction for mixed clusters (σ'_{rel} in $10^{-36} \cdot \text{m}^2 \cdot \text{sr}^{-1}$), d) IR prediction for mixed clusters (I_{rel} in $\text{km} \cdot \text{mol}^{-1}$), e) IR prediction for pure clusters (I_{rel} in $\text{km} \cdot \text{mol}^{-1}$), f) FTIR-jet ($A = \ln(\frac{I_0}{I}) \cdot 10^3$). For the scaling procedure, see Sect. 3.3.

Figure 4.11.: Structures and relative stabilities of **we/ew** dimer isomers at MP2-L level. Secondary hydrogen bond-like C-H \cdots O contacts and hydrogen bond lengths as well as the O-H \cdots O angles are indicated.

while the more red shifted band at 3409 cm^{-1} increases with the relative ethanol content. As supported by the calculations in Fig. 4.10 (and Supplement E), the band at 3427 cm^{-1} can be assigned to **eww**, while the band at 3409 cm^{-1} corresponds to **eew**. Isomerism does not scramble the coarse-grained sequence from **www** over **eww** and **eew** to **eee** in the spectrum. The stability of the trimers (Tab. 4.4) increases with an increasing alcohol content (except for the B3-S level), see also Ref. [111]. Again, the most stable configurations appear to be those with equivalent molecules pointing in the same direction relative to the ring plane, but the preference is weak. Trimers containing trans ethanol tend to be more stable than those containing the gauche conformation, however no systematic exploration was attempted. At the MP2-M and MP2-L levels only trimers containing trans ethanol with two equal molecules pointing into the same direction were calculated and plotted (Fig. 4.10). Unlike in the methanol-water case, the prediction of the trimer sequence matches the experimental one in its qualitative behavior. There is no overshooting of the red shift as a function of alcohol content, before the pure alcohol value is reached. However, the size of the shifts is underestimated towards high ethanol content.

As Fig. 4.10 illustrates, the IR absorption of the Raman active trimer bands involving synchronous O-H stretching motion is too low to make them detectable. Instead, there are a few stronger bands predicted at higher wavenumbers e.g., the

band at 3457 cm^{-1} may correspond to **ee**w, as may the band at 3505 cm^{-1} . Overall, the IR spectra are more ambiguous to assign due to the higher congestion. More reliable quantum chemical predictions would be helpful.

4.4. Conclusions

Dimers and trimers composed of water and either methanol or ethanol were studied by Raman and FTIR spectroscopy in supersonic jets, complemented by harmonic quantum chemical calculations to explore their limitations in reproducing the O-H (O-D) stretching manifold. In mixed alcohol-water dimers water was found to assume the role of the hydrogen bond donor. A simple case of adaptive aggregation is the water-ethanol dimer. Here, water forces ethanol into its less stable gauche conformation upon dimerization. This dimer conformation profits from the interaction with a C-H hydrogen bond of the methyl group. For mixed alcohol-water clusters a cyclic structure can be assumed. A tentative assignment was made for a mixed methanol-water tetramer and a pentamer.

The study of higher alcohols with water would be interesting in order to investigate how an increased aliphatic chain [132] affects the hydrogen bond and also the structures by introducing competing dispersion interactions. The study of highly polar fluorinated alcohols [133] in combination with water [134] is also of interest.

The investigated ethanol-water dimer represents one of the simplest model cases of what happens when a molecule being capable of hydrogen bond interactions is embedded into a crystal. It will typically rearrange its functional groups in order to

optimize intermolecular interactions. The conformational preferences of more complex hydrogen bond formers within a crystal and their interactions will be discussed in the following Chapters.

5. Methyl Mandelate

Methyl mandelate is a chiral α -hydroxycarboxylic acid ester with an ester, a hydroxy, and a phenyl group (see Fig. 5.1). Due to its numerous functional groups it is a good model system to explore the competition between a variety of interactions [38] e.g., inter- and strained intramolecular O-H \cdots O=C hydrogen bonds, which are important for the structure and function of biomolecules. Furthermore, methyl mandelate is suitable to study the competition between dispersion forces and hydrogen bond interactions. The aromatic ring is a weak acceptor for free OH groups and is also responsive to π - π - and CH- π interactions [135, 136]. Since its functional groups are close to the chiral center (marked with an asterisk (*) in Fig. 5.1) aggregation might be influenced by effects of chirality recognition [3]. Furthermore, it shows structural similarities to mandelic acid and some neurotransmitters which will be discussed later on in Chapters 6 and 7.

Monomers and small clusters of methyl mandelate were extensively studied by FTIR-jet spectroscopy and double-resonance IR/UV spectroscopy [38, 137, 138]. IR and vibrational circular dichroism studies were performed on methyl mandelate in solution [139–141]. KBr pellet and ATR-IR spectra are reported for the solid state [38]. X-ray structure analysis and polarization FTIR microspectroscopic measurements were initiated within the present framework and are reported

Figure 5.1.: (*S*)- and (*R*)-methyl mandelate monomers. The center of chirality is marked with an asterisk (*).

in Refs. [37, 38]. The relative vapor pressure of enantiopure and racemic methyl mandelate was also determined [38, 142, 143].

In this chapter the aggregation of methyl mandelate and chirality recognition phenomena will be discussed. First, the results of the X-ray structure analysis [38] will be described and compared to FTIR-ATR spectroscopic [143] and relative vapor pressure measurements [38, 142, 143]. Based on this, the monomer conformation within the crystal structures and the most stable monomer in the gas phase will be compared. Preliminary spectral considerations will be made before discussing FTIR microspectroscopic results of sublimated methyl mandelate crystals. Emphasis will be put on preferred growth directions, the assignment of the CH chromophores, and the deduction of the molecular orientation from the spectra of the different crystal faces. The vibrational assignment of the C-H stretching modes will be performed by comparing the FTIR microspectra to quantum chemical calculations, FTIR-ATR spectra of related compounds, and isotope labeling. Vibrational transition dipole vectors will be deduced from crystal rotation and polarization experiments. The direction of these vectors will be used to constrain the absolute orientation of the molecules within the crystal and for the assignment of further vibrational bands. In doing this, it will be shown that the polarization FTIR microspectroscopic method is suitable for determining the molecular orientation and for the assignment of vibrational modes.

The (*S*)- and (*R*)-enantiomers of methyl mandelate show equivalent FTIR spectra (not shown). All spectra of enantiopure methyl mandelate depicted in this work were measured using the (*R*)-form. Nevertheless, the (*S*)-enantiomer is consistently used in all figures since it matches the configuration of the enantiopure crystal solved by the X-ray structure analysis.

Parts of this chapter are published in Refs. [37, 38]. Verbatim citations of Ref. [37] are used with the consent of the co-author.

5.1. Crystal Structures

Since no crystal structure of methyl mandelate had been published before, the structure analysis was carried out within this study and is published in Ref. [38]. Two crystallization techniques were employed. Slow solvent evaporation of methyl mandelate solutions in water, methanol, ethanol, and toluene was performed and subli-

mation in evacuated glass tubes (ca. 10 mbar) at room temperature was carried out. The X-ray structure analysis was carried out by B. Dittrich. Details on refinement data can be found in Ref. [38].

(*S*)-methyl mandelate crystals were obtained by cooling of an oversaturated aqueous solution. Sublimation also led to large single crystals. In both cases, the enantiopure crystals showed a needle-like habit. Enantiopure methyl mandelate crystallizes in the monoclinic space group $P2_1$ (see Fig. 5.16 later on). Attempts to obtain racemic crystals by sublimation of racemic methyl mandelate were unsuccessful. However, needle-like crystals with an (*RRRS*) pattern were obtained (see Fig. 5.21 later on). The quality of these crystals was poor, but after several attempts a small untwinned specimen was obtained. The formation of non-racemic, non-enantiomeric crystals is rarely observed [144, 145]. Like enantiopure methyl mandelate, the (*RRRS*) compound also crystallizes in the monoclinic space group $P2_1$. The racemic compound was finally obtained from a solution of the racemate in toluene. It also shows a rather rare (*RRRS* – *SSSR*) pattern [146] similar to the mixed pattern of the (*RRRS*) crystal (see Fig. 5.20 later on). Racemic methyl mandelate crystallizes in the triclinic space group $P\bar{1}$.

The three stereoisomeric crystal structures of methyl mandelate have common features. Each compound has eight molecules in the unit cell ($Z=8$) and four molecules in the asymmetric unit ($Z'=4$). In one dimension there are infinite zigzag chains of bifurcated $\text{O-H} \cdots \text{O}=\text{C}$ and $\text{O-H} \cdots \text{O-H}$ hydrogen bonds with different distances and angles (see Fig. 5.2 for enantiopure methyl mandelate and Tab. 5.1). Orthogonal to the hydrogen bonds, the aromatic rings interlock with each other by π - π -interactions. These two layers are held together by van der Waals interactions of the methyl ester groups and aromatic rings in a third dimension. Besides the configurations and patterns, a major difference is the orientation of the aromatic ring. In the enantiopure compound the aromatic rings alternately point up and down with regard to the hydrogen bond chain. In the mixed (*RRRS*) and the racemic crystals, every fourth monomer is enantiomeric to the others and does not follow the alternating up/down pattern observed in the enantiopure crystal. Therefore, the stapling of π - π interlocked hydrogen bonded chains is less efficient than in the case of the enantiopure compound. In the case of the racemic crystal, (*RRRS*) and (*SSSR*) layers alternate.

The monomers within the unit cell of all three crystals have the same qualitative conformation (see Fig. 5.5 later on) but differ in their interactions. Stronger and

Figure 5.2.: Hydrogen bonded network of (*S*)-methyl mandelate showing four different hydrogen bonded OH groups [38]. Hydrogen bond distances are given in Å. Circled numbers enumerate the monomer units. Note that only hydrogen bonds with a maximum H-X distance of 2.5 Å and a minimum angle of 130° are shown.

weaker hydrogen bonds alternate (see Fig. 5.2 for enantiopure methyl mandelate, Tab. 5.1). The average H···O distance of the bifurcated O-H···O=C and O-H···O-H hydrogen bonds falls in the range of 2.0–2.2 Å. Either a strong and a weak or two intermediate contacts are formed. The average between both hydrogen bond angles varies from 139–144°. The only exception is the monomer unit 4 of enantiopure methyl mandelate which has an average angle of 131°.

The formation of three different crystal structures was verified by FTIR-ATR spectroscopy and by mass spectrometric measurements of the relative vapor pressures. Mid infrared ATR spectra of enantiopure, 3:1 mixed, and racemic methyl mandelate are shown in Fig. 5.3. The spectra exhibit differences regarding the shape and position of several bands of the enantiopure compound compared to the 3:1 and the racemic crystal. Most bands of the enantiopure substance appear blue shifted relative to the other compounds. No significant differences are observed for the mixed (*RRRS*) and the racemic crystal in the mid infrared region.

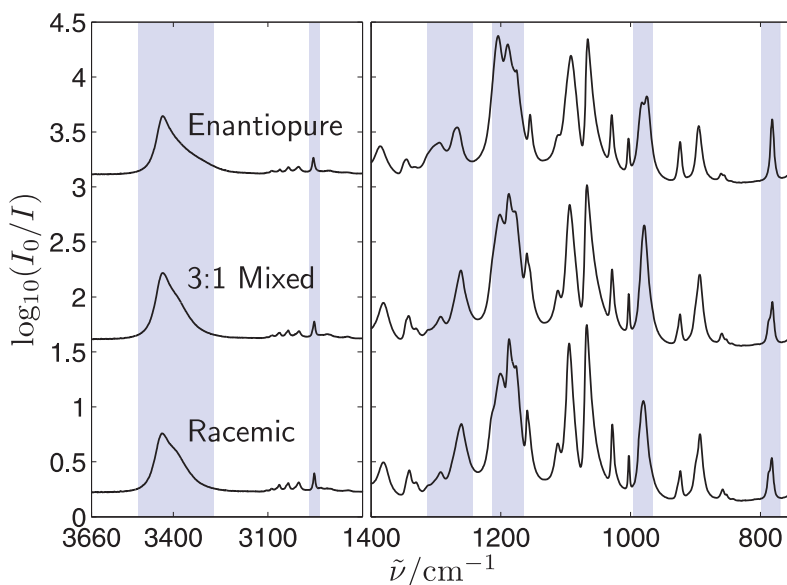

Figure 5.3.: FTIR-ATR spectra of enantiopure (*S*), mixed (*RRRS*), and racemic (*RRRS* – *SSSR*) methyl mandelate recorded in the mid infrared region (3660–2800 cm^{−1}, 1400–750 cm^{−1}). The blue bars mark regions of spectral differences.

The far infrared FTIR-ATR spectra of enantiopure, 3:1 mixed, and racemic methyl mandelate (Fig. 5.4) show substantial differences experienced by lattice vibrations. The relative differences of the enantiopure compound on one hand and 3:1 and racemic methyl mandelate on the other hand are more pronounced in this spectral region. Especially, the appearance of a new peak at 340 cm^{−1}, the intensity gain and sharpening at 220 cm^{−1}, and the shifts at 170 and 60 cm^{−1} should be noted. The spectra of the mixed (*RRRS*) and the racemic crystal also show differences in the far infrared region. One difference is the band at 165 cm^{−1} which appears intermediate in the spectra of the 3:1 crystal showing that the spectrum of the mixed (*RRRS*) crystal cannot be represented by a superposition of the enantiopure and the racemic crystal. This supports the formation of a third crystal structure next to the enantiopure and the racemic crystal.

Relative vapor pressures of the three different methyl mandelate compounds were determined by quadrupole mass spectrometry. The relative vapor pressures of enantiopure and racemic methyl mandelate already had been measured by L. Schrader and J. Zischang [38, 142, 143]. Within the scope of this work, the results were verified and the relative vapor pressure of the mixed (*RRRS*) compound was measured

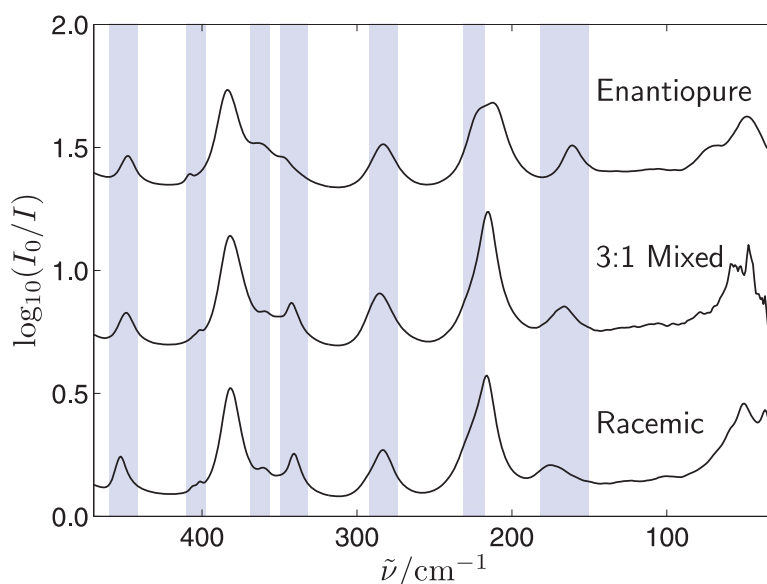

Figure 5.4.: FTIR-ATR spectra of enantiopure (*S*), mixed (*RRRS*), and racemic (*RRRS* – *SSSR*) methyl mandelate recorded in the far infrared region ($470\text{--}30\text{ cm}^{-1}$). The blue bars mark regions of spectral differences.

newly. Based on the mass peaks 79 and 107, the relative vapor pressure of the enantiopure and the racemic compound is determined as $(19\pm 5)\%$ and the relative vapor pressure of the 3:1 mixed compound and the racemic methyl mandelate is determined as $(35\pm 10)\%$ at $293.0\pm 0.5\text{ K}$. Thus, although the FTIR-ATR spectra only show subtle differences, the vapor pressures are considerably different as a result of intermolecular diastereoisomerism.

5.2. Monomer Conformations

To characterize the conformation of methyl mandelate monomers a three-letter nomenclature was employed [138]. It describes the syn (*S,s*), cis (*C*), skew (*sk*), gauche (*G*), and anti (*A*) conformations of the H-O-C-C, the O-C-C=O, and the O=C-O-CH₃ dihedral angles.

The monomer units of enantiopure, 3:1 mixed, and racemic methyl mandelate do not differ qualitatively within the unit cell but also not for the different crystals. The energies and predicted wavenumbers are thus the same for relaxed (geometrically optimized) enantiopure, 3:1 mixed, and racemic methyl mandelate monomer units.

Figure 5.5.: Frozen and relaxed monomer units ((*S*)-enantiomer) taken from the crystal structure of enantiopure methyl mandelate [38] as well as the most stable monomer [138] (B3LYP/6-311++G(3df,2p) level).

Therefore, only the enantiopure crystal's monomer unit is shown in Fig. 5.5 and will be considered in the remainder. It exhibits an AsC conformation. No intramolecular hydrogen bond is formed in this conformation.

The most stable monomer conformation was determined by IR/UV double resonance and resonant two-photon ionization spectroscopy in combination with quantum chemical calculations on the MP2/6-31G(d,p) and DFT levels of approximation [138]. Two stable monomers were found, the more stable monomer having an SsC and the other a GskC structure. The results were confirmed by FTIR-jet spectroscopy [38, 137]. Both conformations form an intramolecular O-H \cdots O hydrogen bond. In the case of the SsC structure the O=C is the hydrogen bond acceptor, whereas in the GskC monomer the O-CH₃ group takes on this role. The structure and frequencies of the SsC conformation were recalculated on the B3LYP/6-311++G(3df,2p) and MP2/6-311+G(2d,p) levels of theory within the current framework. The most stable monomer calculated on the B3LYP method is depicted in Fig. 5.5.

The energy differences without and with zero point energies between the relaxed monomer unit from the crystal structure and the most stable monomer conformation as well as the distance and angle of the intramolecular O-H \cdots O hydrogen bond of the most stable monomer are summarized in Tab. 5.5. The energy difference with and without zero point energies of 13–15 kJ \cdot mol⁻¹ (B3LYP and MP2 levels) results from the establishment of a hydrogen bond within the most stable monomer. Nevertheless, the energetically unfavorable monomer unit is present in the crystal structure since it is capable of stronger intermolecular hydrogen bonds than the most stable monomer unit. Thus, the energy difference of the monomer units reflects the

Table 5.2.: Distances d in Å ($d_{\text{H-O}}$ and $d_{\text{O-O}}$) and angle α in ° of the O-H...O hydrogen bond in the most stable monomer as well as energy differences without and with zero point energies (ΔE and ΔE_0) of the relaxed monomer unit from the crystal structure [38] and the most stable monomer [138] of methyl mandelate in $\text{kJ}\cdot\text{mol}^{-1}$ on the B3LYP/6-311++G(3df,2p) and MP2/6-311+G(2d,p) levels of theory. No imaginary frequencies are observed.

benefit of intermolecular over intramolecular hydrogen bonds.

5.3. Preliminary Spectral Considerations

Methyl mandelate possesses a hydroxy group, a phenyl ring, and an ester functional group (see Fig. 5.5 above). Therefore, a variety of fundamental bands can be expected in the mid infrared region. There will be an O-H stretching fundamental, several C-H stretching bands (aromatic, methyl, and α -acidic), a C=O stretching band, C-C stretching modes, and several combination bands. Predicted wavenumbers are listed in Supplement F.

The position and intensity of the O-H stretching band strongly depend on the nature and strengths of the hydrogen bonds [147, 148]. The stronger the hydrogen bond the more red shifted and intensified the band is e.g., the position of the theoretically localized O-H stretching band of the water monomer ($\frac{\text{sym}+\text{asym}}{2}$) red shifts from 3707 cm^{-1} to 3602 cm^{-1} in the water dimer and to 3567 cm^{-1} in the mixed water-methanol dimer (see Chapter 4) [14, 81]. The O-H stretching band of the methyl mandelate monomer was found to appear at 3549 cm^{-1} and 3552 cm^{-1} by FTIR-jet and IR/UV depletion spectroscopy, respectively [38, 138]. Several dimer bands were observed $10\text{--}35\text{ cm}^{-1}$ red shifted to the monomer. Only one dimer band is blue shifted by 7 cm^{-1} . The trimer and a higher cluster's O-H stretching band are red shifted by 88 cm^{-1} and 248 cm^{-1} as shown by FTIR-jet spectroscopy [38]. The small shifts of the dimer O-H stretching bands result from the isolated character of the hydrogen bonds and the competition from intramolecular hydrogen bonding in

the monomer. Within the crystal the monomers form hydrogen bonded chains (see Sect. 5.1). Therefore, larger red shifts can be expected.

Methyl mandelate has three different types of CH groups. There are the aromatic CH groups, the ester methyl group, and one α -acidic CH. The aromatic C-H stretch may show a multiplet of up to five bands in the 3100 cm^{-1} to 3000 cm^{-1} region [148]. The aliphatic ROC-H₃ stretching bands appear in the $2995\text{--}2865\text{ cm}^{-1}$ spectral region with the asymmetric stretchings at higher wavenumber than the symmetric [148]. C-H stretching bands of methyl mandelate monomers were found at 3101 cm^{-1} , 3076 cm^{-1} , 3043 cm^{-1} , 3009 cm^{-1} , 2964 cm^{-1} , and 2804 cm^{-1} by FTIR-jet spectroscopy [38]. Only slightly different positions (3105 cm^{-1} , 3080 cm^{-1} , 3045 cm^{-1} , 3009 cm^{-1} , 2963 cm^{-1} , and 2900 cm^{-1}) were observed using IR/UV depletion spectroscopy [38, 138]. The bands at higher wavenumbers are assigned to aromatic C-H stretching modes, while the bands at 3009 cm^{-1} , 2964 cm^{-1} , and 2900 cm^{-1} are assigned to aliphatic C-H stretchings [138].

The C=O stretching mode appears as a strong band in the region of $1800\text{--}1650\text{ cm}^{-1}$ [148]. The C=O stretching band of the methyl mandelate monomer was detected at 1752 cm^{-1} by FTIR-jet spectroscopy [38]. Dimer bands were found to be shifted by -17 cm^{-1} to $+11\text{ cm}^{-1}$. C-C stretching bands appear around 1600 cm^{-1} . The modes show a lifted degeneracy and may appear as a quadruplet [147, 148]. In benzene these modes are doubly degenerate. The substitution of the benzene ring destroys the high symmetry of the ring.

Complex in-phase and antiphase coupling patterns for many molecular vibrations (factor group splittings) can be expected [16]. Further spectral splittings may result from quantitative differences in the molecular structures discussed in Sect. 5.1.

5.4. FTIR Microspectroscopy

5.4.1. Enantiopure Methyl Mandelate

In the following section, results on sublimated microcrystals of enantiopure methyl mandelate studied by polarized FTIR microspectroscopy which are published in Ref. [37] will be presented. Enantiopure methyl mandelate is a white powder with a melting point of $56\text{--}58^\circ\text{C}$ under ambient conditions (according to the supplier). There is no evidence that it is hygroscopic.

The sublimation of enantiopure methyl mandelate led to microcrystals with two

Figure 5.6.: Type A and B FTIR spectra of enantiopure methyl mandelate crystals as well as the difference spectrum of type A subtracted from type B (B–A). Wavenumbers for selected bands in the difference spectrum are given in cm^{-1} . They may differ slightly from those of the band maxima in the raw spectra. Regions H and L used for integration are marked in blue and red, respectively.

different habits. Liquid droplets which often formed above $+35\text{ }^{\circ}\text{C}$ crystallized into dendritic carpets. Tabular crystals were directly obtained by sublimation in a temperature range of $+28\text{ }^{\circ}\text{C}$ and $+40\text{ }^{\circ}\text{C}$. After nucleation the methyl mandelate crystals grew to a size of $10\text{ }\mu\text{m}$ and larger within seconds.

The sublimated methyl mandelate crystals (dendritic carpets as well as tabular crystals) show two different types of spectra which are denoted as type A and type B in Fig. 5.6. The spectra differ in relative intensities (e.g., in the C–C stretching or C–H bending region), in band shape (e.g., the O–H stretching band), and in wavenumber (e.g., the C=O stretching band). Different spectral types may result from polymorphism, solvent content, or different crystal faces. The appearance of a crystal hydrate appears to be rather unlikely since none was observed by X-ray structure analysis (see Sect. 5.1). Furthermore, the crystallization was performed via sublimation which minimizes the presence of solvents. A difference spectrum of type A subtracted from type B (B–A) emphasizes the spectral differences (Fig. 5.6). Wavenumbers of maxima and minima in the difference spectrum are given in cm^{-1} .

Figure 5.7.: FTIR image of an enantiopure methyl mandelate polycrystal showing that type A and B spectra can coexist in a sample.

FTIR images were recorded in order to determine if both types of spectra can coexist and whether a single crystal only shows one spectral type. The images shown in Figs. 5.7 and 5.8 were obtained by integrating the regions $3018\text{--}2982\text{ cm}^{-1}$ (H) and $2972\text{--}2934\text{ cm}^{-1}$ (L) with the OPUS 6.5 [61] baseline corrected integration method (see Chapter 3). Twice the integral absorption of region H was subtracted from the integral of region L ($L - 2 \cdot H$) to maximize the contrast between the two C-H stretching sections. Blue colors show a higher intensity of bands in the region of $3018\text{--}2982\text{ cm}^{-1}$, whereas red colors refer to a higher intensity in the region of $2972\text{--}2934\text{ cm}^{-1}$. Absorption free regions and regions with balanced intensities in the $3018\text{--}2982\text{ cm}^{-1}$ and $2972\text{--}2934\text{ cm}^{-1}$ windows are shown in green (BG).

The FTIR image of a dendritic crystal shows that the two types of spectra can coexist in a sample (Fig. 5.7). The images of two single crystals (Fig. 5.8) exhibit that the crystals either show type A (top) or type B spectra (bottom). The visual pictures next to the images show that the type A crystals' shape is rectangular, whereas type B spectra result when the shorter edge of the crystal is not orthogonal to the long edge. This correlation was also observed for other single methyl mandelate crystals not shown here. A 1:1 ratio for the occurrence of crystals showing type A and B spectra was noticed as well.

Rotation experiments around the long crystal axis revealed that type A and type B spectra can be interchanged (Fig. 5.9). This shows that the spectral differences cannot be attributed to polymorphism or solvation, but to different faces the crystals are growing on and therefore to the molecular orientation. Since the distribution of both spectral types was found to be balanced, the growth direction of the crystals on the CaF_2 substrate appears to be largely statistical with respect to these short axes [149]. In the following, crystal faces showing type A spectra are named face

Figure 5.8.: FTIR images of enantiopure methyl mandelate crystals showing only one type of spectra for single crystals.

A and crystals showing type B spectra face B.

Also, enantiomerically mixed (unknown ratio), OD-deuterated enantiopure, and CD₃-deuterated enantiopure methyl mandelate crystals grow on two faces. The spectra are analog to the two spectral types observed in the enantiopure case as shown for enantiomerically mixed methyl mandelate in Fig. 5.10. A comparison of the difference spectra (Fig. 5.11) exhibits the similarities which result from similar interactions within the crystal structures (see Sect. 5.1) and their directions of growth. The polarization microspectra of the enantiomerically mixed methyl mandelate crystals will be shortly discussed in Sect. 5.4.2.

There are strong differences in the region of the C-H stretching bands of face A and B spectra. Especially, the intensities of the bands at 3003 cm⁻¹ and 2954 cm⁻¹ differ. FTIR-ATR spectra of methyl mandelate were compared to those of the structurally similar molecules mandelic acid (MA), methyl lactate (ML), and methyl-d₃ mandelate (Fig. 5.12) for the assignment of the C-H stretching bands to the aromatic and aliphatic groups.

The C-H stretching bands in the 3100–3020 cm⁻¹ region appear in the spectra of methyl mandelate, mandelic acid, and methyl-d₃ mandelate but not in the spectrum of methyl lactate. Thus, the bands in this region can be assigned to aromatic C-H stretching modes (see Tab. 5.3). While the spectra of mandelic acid and methyl-

Figure 5.9.: FTIR spectra obtained after rotation of methyl mandelate microcrystals showing type A and type B spectra. Rotating the crystal interconverts the spectral types A and B and exhibits a spectrum of type C.

Figure 5.10.: Type A and B FTIR spectra of enantiomerically mixed methyl mandelate crystals of unknown ratio as well as the difference spectrum of type A times 0.75 subtracted from type B ($B - 0.75 \cdot A$). Wavenumbers for selected bands in the difference spectrum are given in cm^{-1} . They may differ slightly from those of the band maxima in the raw spectra.

Figure 5.11.: FTIR difference spectra of type A subtracted from type B of non-deuterated enantiopure, nondeuterated enantiomerically mixed (unknown ratio, nonenantiopure), OD-deuterated enantiopure, and D₃-deuterated enantiopure methyl mandelate crystals.

Figure 5.12.: FTIR-ATR spectra of methyl mandelate (MM), mandelic acid (MA), methyl lactate (ML), methyl-d₃ mandelate (MM-D₃), and a difference spectrum of nondeuterated and methyl-d₃ mandelate (MM–MM-D₃).

d_3 mandelate do not show bands around 3003 cm^{-1} and 2954 cm^{-1} , the spectra of methyl mandelate and methyl lactate do. Accordingly, the two bands must be due to C-H stretchings of the methyl groups. This matches the assignments of the C-H stretching signals observed in FTIR-jet and IR/UV depletion spectra at 3009 cm^{-1} and 2964 cm^{-1} [38, 138] (see Sect. 5.3). The weak band at 2903 cm^{-1} can be assigned to the stretching vibration of the α -acidic CH in agreement with an aliphatic C-H stretching band appearing at 2904 cm^{-1} in the FTIR-jet and at 2900 cm^{-1} IR/UV depletion spectra [38, 138]. The difference spectrum of methyl- d_3 mandelate subtracted from methyl mandelate (MM–MM- D_3) exhibits a weak band of a third methyl C-H stretching mode at 3035 cm^{-1} . It is hidden underneath the aromatic C-H stretching bands in the nondeuterated methyl mandelate spectrum. This methyl C-H stretching mode may also contribute to the band at 3043 cm^{-1} in the FTIR-jet spectrum [38]. It was not assigned in the IR/UV depletion spectrum, because of its low intensity and its overlap with aromatic signals [138].

The bands at 1973 cm^{-1} , 1956 cm^{-1} , 1600 cm^{-1} , 1587 cm^{-1} , 1454 cm^{-1} , and 1491 cm^{-1} (see Fig. 5.6) do not appear in the methyl lactate spectrum but they do appear in the spectra of the aromatic compounds. These bands are due to aromatic fundamental modes with C-H bending and C-C stretching character. In particular the two doublets near 1600 cm^{-1} and below 1500 cm^{-1} are robust signatures of the phenyl group as discussed in Sect. 5.3 [147]. The bands at $2850/2848\text{ cm}^{-1}$ and $1436/1433\text{ cm}^{-1}$ do not appear in methyl- d_3 mandelate and can be assigned to bending vibrations of the methyl group.

Fig. 5.13 shows a comparison of the experimental FTIR-ATR and quantum-chemically predicted methyl mandelate spectra. It can be seen that the scaled harmonic predictions for isolated molecules (universal best fit factor 0.966) largely agree with the experimental assignments, although some intensities are distorted and the splitting between symmetric and asymmetric C- H_3 modes is exaggerated. Based on these predictions, it is possible to assign the methyl vibration bands at 3035 cm^{-1} and 3003 cm^{-1} to the asymmetric methyl stretching modes, while the band at 2954 cm^{-1} corresponds to the symmetric stretching of the methyl group. In contrast to the methyl vibrations, the aromatic C-H stretching bands are predicted too close together for a detailed assignment based on theoretical band positions. However, comparison to the mandelic acid case (see Chapter 6) and information on the vibrational transition dipole vectors allow for the tentative assignment given in Tab. 5.3.

Figure 5.13.: Comparison between calculated spectra on the B3LYP/6-311++G(3df,2p) level and experimental FTIR-ATR spectra of methyl mandelate (MM), mandelic acid (MA), methyl lactate (ML), and methyl- d_3 mandelate (MM- D_3) in the C-H stretching region. Calculated spectra are scaled by a factor of 0.966 to roughly match the experimental spectrum despite a neglect of anharmonic effects. Aromatic positions are marked with a circle (\circ , blue), methyl bands are marked with a triangle (\triangle , red), pointing downward (∇ , pink) in the case of the second methyl group of ML, and the position of the α -acidic group is marked with a cross (\times , green).

Figure 5.14.: Polarized FTIR spectra through face A and B of enantiopure methyl mandelate. The double arrows show the direction of the electric vector of the radiation which passes the polarizer and can excite corresponding vibrational transition dipole vector components.

The spectral differences of the faces A and B provide information about the direction of the vibrational transition dipole vector. The intensity of the band at 3003 cm^{-1} ($\nu(\text{C-H}_{3,\text{asym}2})$) decreases significantly when turning the crystal from face A to B. This suggests that its vibrational transition dipole is more or less perpendicular to face B. In order to confirm its orientation within face A, polarization experiments were carried out. In Fig. 5.14 the direction of the electric vector (double arrow) and the corresponding spectra measured through face A and B are shown. Clearly, the vibrational transition dipole has a negligible component along the long crystal axis consistent with the vanishing band for face B. Fig. 5.15 shows the polarization spectra through face A including the direction of the vibrational transition dipole vector for several other bands. It can be noticed that the vibrational transition dipole vectors of several closely spaced pairs of bands point in different directions. In many cases, this is caused by in-phase and antiphase vibrations of the same molecular mode within the crystal, i.e. factor group splitting.

In the weakly interacting C-H_3 stretching case, this splitting is not spectrally resolved, thus allowing for a direct statement about the average molecular orientation in the crystal. E.g., when looking at face A the vibrational transition dipole vec-

Figure 5.15.: Polarized FTIR spectra of a methyl mandelate crystal showing face A. Several neighboring bands show vibrational transition dipole vectors in two directions as indicated by the arrows.

tor of the band at 3003 cm^{-1} ($\nu(\text{C-H}_{3,\text{asym2}})$) points in the short direction of the crystal, while the one of the band at 2954 cm^{-1} ($\nu(\text{C-H}_{3,\text{sym}})$) points more in the long direction. However, its largest component is perpendicular to face A. This is consistent with the orientation of the molecules for the three crystal faces shown in Fig. 5.16. Thus, face A largely corresponds to a view along the crystallographic b axis, whereas face B corresponds to a view along the a axis. Beyond this spatial orientation, which can also be obtained from pure X-ray studies, the polarized spectra show that the band at 3003 cm^{-1} corresponds to the asymmetric component perpendicular to the plane of the ester group. This is in agreement with the quantum chemical predictions for the isolated molecule (see Supplement F).

Intermolecularly coupled oscillators such as the O-H stretching modes can also be used to check or determine the absolute molecular orientation in the microcrystals. The preferential orientation of the hydrogen bonded chains along the long crystal axis is confirmed by the appearance of the lower frequency O-H stretching mode for IR polarization along this direction, because the symmetric mode in a hydrogen bonded zigzag chain is always the one with the lower frequency due to the cooperative nature of such hydrogen bonds. However, the underlying hydrogen bonds themselves differ quite substantially (see Fig. 5.2 and Tab. 5.1 in Sect. 5.1), super-

5. Methyl Mandelate

Figure 5.17.: Comparison of experimental (top, black) and oriented gas model (bottom, blue) polarization spectra (B3LYP/6-311++G(3df,2p) level) for face A and B in the O-H and C-H stretching region of enantiopure methyl mandelate. Wavenumbers of the oriented gas model spectra are scaled by a factor of 0.966 and the theoretical intensity scale is matched qualitatively to the C-H stretching region.

imposing the coupling pattern in a complex way. Pronounced couplings can also be found for the C=O stretching band due to its large transition dipole moment [150], rendering a detailed assignment difficult.

In Fig. 5.17 a comparison of experimental and oriented gas model spectra for nonpolarized and polarized spectra of face A and B is made. The polarization and face dependence of the asymmetric and symmetric methyl stretching bands are reproduced satisfactorily. The broadening, intensification, and low-frequency shift of the O-H stretching bands in the hydrogen bonded crystal are beyond the reach of the oriented gas model as hydrogen bonds are neglected (Chapter 2). Nevertheless, predicted intensity ratios of the different faces and polarizations are in reasonable agreement with the experiment. The molecular orientation of the different faces is confirmed. Crystal phase calculations of the vibrational spectra were started in cooperation with R. Tonner [36]. The preliminary results are encouraging.

Further bands can be assigned by comparing the experimental and oriented gas model polarization spectra. The bands at 3103 cm^{-1} , 1600 cm^{-1} , 1587 cm^{-1} , 1491 cm^{-1} , and 1454 cm^{-1} (see Fig. 5.15) are caused by aromatic groups. The experimental and calculated vibrational transition dipole vectors of the symmetric

aromatic C-H stretching mode at 3103 cm^{-1} as well as the aromatic C-C stretching modes at 1600 cm^{-1} and 1491 cm^{-1} [147] point in a similar direction as the ones of the asymmetric methyl C-H stretching band at 3003 cm^{-1} , while the directions of the vibrational transition dipole vectors of the aromatic stretching modes at 1587 cm^{-1} and 1454 cm^{-1} are more in agreement with the symmetric methyl C-H stretching band at 2954 cm^{-1} . The band assignments can be found in Tab. 5.3. The corresponding vibrations are depicted in Supplement F. Thus, there is no need to invoke a factor group splitting for their assignment.

The methyl bending bands at 1435 cm^{-1} and 1411 cm^{-1} are too congested for an individual assignment, but the persistence of structure in the molten phase (Fig. 5.18) suggests that factor group splitting is not the only explanation for their appearance. The bands at $2850/2848\text{ cm}^{-1}$, 1973 cm^{-1} , and 1956 cm^{-1} are caused by overtone or combination vibrations. The methyl band at $2850/2848\text{ cm}^{-1}$ can be assigned to a bending overtone with the fundamental mode at $1409\text{--}1436\text{ cm}^{-1}$.

In summary, large couplings between different molecules in the unit cell can be found for $\nu(\text{O-H})$ and for $\nu(\text{C=O})$. For methyl and C-C stretching vibrations, the coupling is negligible. In both cases, the polarization experiments provide information on the molecular orientation in the crystal, whereas intermediate couplings are not easily interpreted in terms of molecular orientation for such a complex crystal structure with eight molecules in the unit cell.

5.4.2. Enantiomerically Mixed Methyl Mandelate

Racemic methyl mandelate melts at a slightly lower temperature than enantiopure methyl mandelate. According to the supplier the melting temperature is $54\text{--}56^\circ\text{C}$ under ambient conditions. Racemic methyl mandelate is a white powder. There is no evidence that it is hygroscopic.

The racemic compound as it was provided by the supplier and not a mixture of both enantiomers was chosen for the sublimation experiments. Several sublimation attempts at ambient temperatures were needed to obtain single crystals suitable for the X-ray structure analysis as described in Sect. 5.1. For the microspectroscopic analysis a temperature range of $30\text{--}40^\circ\text{C}$ was applied at the bottom of the sublimation cell. Polycrystals consisting of needle-like to tabular single crystals were obtained with this method.

As in the enantiopure case, two types of spectra were obtained which are shown

Figure 5.18.: FTIR spectra of enantiopure methyl mandelate crystals (face A and B), FTIR-ATR spectrum of the powder multiplied by a factor of ten and FTIR spectrum of molten enantiopure methyl mandelate.

in Fig. 5.19. The spectral types are similar to type A and B spectra of enantiopure methyl mandelate. The spectral differences of type A subtracted from type B spectra for enantiopure and enantiomerically mixed methyl mandelate of unknown ratio are compared in Fig. 5.11 above. The spectral behavior upon polarization is analogous as well. Band positions are summarized in Tab. 5.4. Also, the habits of the crystal faces are similar (face A: rectangular, face B: shorter edge not orthogonal to the long edge) although not as well defined as in the enantiopure case. Similar crystal structures can be assumed on the basis of the spectral and facial similarities. As discussed in Sect. 5.1, the crystal structures of enantiopure, mixed (*RRRS*), and racemic (*RRRS* – *SSSR*) methyl mandelate do indeed show the same patterns. Along the three crystal axes comparable interactions take place within the three crystal structures.

The sublimation of a racemic mixture at ambient temperatures leads to mixed (*RRRS*) and not to a racemic crystal (see Sect. 5.1). Therefore, the sublimation of the racemate in the sublimation cell is likely to have also led to the mixed (*RRRS*) crystal and not the racemate. As discussed, the mid infrared ATR spectra of racemic and 3:1 mixed methyl mandelate (Fig. 5.3) are not distinguishable. Therefore, by comparing mid infrared spectra it is not possible to decide whether a racemic or a 3:1 crystal is

Figure 5.19.: Polarized FTIR spectra through face A and B of enantiomerically mixed methyl mandelate of unknown ratio. The double arrows show the direction of the electric vector of the radiation which passes the polarizer and can excite corresponding vibrational transition dipole vector components.

present. Additionally, the comparison of polarized spectra and vibrational transition dipole vectors do not lead to a decisive conclusion since the molecular conformation and their average arrangement are the same. Deviations between experimental and oriented gas model polarization spectra are larger than the differences between the oriented gas model spectra of the different crystals. Therefore, no oriented gas model spectra were prepared for racemic and 3:1 methyl mandelate.

Figs. 5.20 and 5.21 show the molecular orientation along the crystal axes assuming a racemic and a mixed (*RRRS*) crystal, respectively. If racemic crystals are present, face A corresponds to a view along the crystallographic *c* axis and face B corresponds to a view along the *a* axis. Assuming the presence of mixed (*RRRS*) crystals, face A corresponds to a view along the *c* axis and face B corresponds to a view along the *b* axis. An assignment to either the racemic or the 3:1 crystal needs further investigations.

Table 5.4.: Assignments of experimental band maxima in the FTIR microscopic spectra of enantiomerically mixed methyl mandelate of face A, face B, and FTIR-ATR spectra. 5.5. Conclusions

The FTIR microspectroscopic method of sublimated crystals investigated in transmission mode was tested using methyl mandelate [37]. Prior to this, the crystal structures were determined and FTIR-ATR spectra and relative vapor pressures were measured. It was found that methyl mandelate crystals grow on two faces on the CaF_2 substrate of the sublimation cell exhibiting two types of spectra. Spectral differences of nonpolarized and polarized measurements were used to infer the molecular orientation of the crystals. The orientation of the hydrogen bonded chains and of the methyl group along the long axis were confirmed. Detailed assignment of closely spaced normal modes was possible by comparison of experimental methyl mandelate spectra with structurally similar substances, partial deuteration, as well as a comparison of experimental and oriented gas model polarization spectra. The increased complexity of the crystal compared to gas phase spectra was turned into an advantage by applying crystal rotation, IR polarization, and monomer calculations. The FTIR microspectroscopic method will also be applied for mandelic acid in Chapter 6 and for some phenylpropanolamines in Chapter 7. It was also applied to the methylxanthines caffeine, theophylline, and theobromine [151,152], but these results are not presented here. Assignments made in this Chapter will be used for the spectral interpretation of mandelic acid and the phenylpropanolamines.

6. Mandelic Acid

Mandelic acid is an aromatic α -hydroxycarboxylic acid with one center of chirality (marked with an asterisk (*) in Fig. 6.1). It is the corresponding acid to the ester methyl mandelate which was discussed in Chapter 5. Like methyl mandelate it contains a phenyl group, an α -acidic CH, and a carbonyl group. In contrast to methyl mandelate it possesses two OH groups which are chemically very different. The alcoholic hydroxy group is also present in methyl mandelate but not the acidic carboxyl group. Therefore, there is a larger variety of hydrogen bond interactions.

Due to its chirality, mandelic acid is used in the field of enantioselective chemistry for the separation of racemates, with important applications in the pharmaceutical industry [145, 153–156]. A variety of phase diagrams are determined [157, 158]. The enantiomeric purity in solutions can be measured by simultaneous dual circular dichroism and UV spectroscopy [159]. Solutions of mandelic acid were also investigated by IR spectroscopy [140, 160–163]. FTIR-ATR spectra of solid mandelic acid were measured as well [20, 163–165]. The crystal structures of enantiopure and racemic mandelic acid were solved by means of X-ray structure analysis [88, 166–168].

In the following, the crystal structures of enantiopure and racemic mandelic acid will be described. Then, the monomer units within the crystal structures which ex-

Figure 6.1.: (S)-enantiomers of methyl mandelate and mandelic acid. Centers of chirality are marked with an asterisk (*).

hibit the same conformation as the most stable monomer will be discussed. Based on the crystal structure of enantiopure mandelic acid and the monomer conformation preliminary spectral considerations will be made. Experimental and oriented gas model spectra of enantiopure mandelic acid will be compared. Vibrational transition dipole vectors will be deduced from crystal rotation and polarization experiments. The molecular orientation and a spectral assignment of several fundamental modes will be inferred by a comparison of polarization spectra, deduced vibrational transition dipole vectors, oriented gas model spectra, the crystal structure of enantiopure mandelic acid, and the results gained for methyl mandelate in Chapter 5.

The (*S*)- and (*R*)-enantiomers of mandelic acid exhibit the same FTIR-spectra [164]. All mandelic acid spectra depicted in the present work were measured using the (*R*)-enantiomer. Nevertheless, the (*S*)-form is consistently used in all figures since it matches the configuration of the enantiopure crystal characterized by X-ray crystallography [88]. No spectra of the racemic compound were recorded.

The content of this chapter is published in Ref. [37]. Verbatim citations are used with permission of the co-author.

6.1. Crystal Structures

In the case of mandelic acid the crystal structures of both the enantiopure and the racemic compound were solved by X-ray structure analysis [88, 166–168]. (*S*)-mandelic acid crystallizes in the monoclinic space group $P2_1$ (CSD REF Code: FEGHAA) [88]. It contains four molecules in the unit cell ($Z=4$) and two molecules in the asymmetric unit ($Z'=2$). Patil et al. report a hexagonal, platy habit for enantiopure mandelic acid when crystallized from chloroform or from a 9:1 ethanol-methylene chloride mixture [88]. However, the sublimation at 110–112°C under atmospheric pressure led to very thin needles. The molecules form corrugated chains with $\cdots[\cdots\text{OH}\cdots\text{O}=\text{C}-\text{OH}\cdots]$ repeat units, where three intermolecular hydrogen bonds link the alcoholic OH and the C=O group of an individual molecule (see Fig. 6.2 and Fig. 6.7 later on). There are no hydrogen bonds connecting two corrugated chains. The alcoholic and the acidic OH groups are nearly orthogonal to each other. The angle between two neighbored hydrogen bonds $\text{H}\cdots\text{O}$ are 86° or 87°, whereas the O-O-O angles are 102° for both chains.

Two polymorphs of racemic mandelic acid are known, one thermodynamically

Figure 6.2.: Crystal structure of (*S*)-mandelic acid [88] along the crystallographic *c*-axis. Two different types of O-H \cdots O hydrogen bonds nearly orthogonal to each other are shown. H-O hydrogen bond distances are given in Å.

stable (I) and one metastable form (II) [166, 167, 169]. The stable form crystallizes in the orthorhombic space group *Pbca* (CSD REF Codes: DLMAND01, DLMAND03) [167, 168]. It contains 8 molecules in the unit cell ($Z=8$) and one molecule in the asymmetric unit ($Z'=1$). The molecules form a two-dimensional hydrogen bonded network along the crystallographic *a* and *c* axes (not depicted). Molecules of the same enantiomer are connected by O=C-OH \cdots OH hydrogen bonds along the *c* axis. In addition, every molecule forms OH \cdots O=C-OH hydrogen bonded dimeric units with the opposite enantiomers along the *a* axis. The dimeric units are alternately oriented. The formation of solid racemate I from a 1:1 mixture of powdered (*R*)- and (*S*)-enantiomers in Nujol mull at ambient temperature is reported to occur within 2 hours [165].

The metastable form was obtained from an undersaturated aqueous solution by slow evaporation at room temperature in the dark (CSD REF Code: DLMAND02) [166]. It crystallizes in the monoclinic space group *P2₁/c* with eight molecules in the unit cell ($Z=8$) and two molecules in the asymmetric unit ($Z'=2$). The metastable racemic mandelic acid forms O=C-OH \cdots OH hydrogen bonded strings of enantiomeric molecules running along the crystallographic *a* axis (not depicted). Two strings are connected by dimeric units of opposite enantiomers held together by two OH \cdots O=C-OH hydrogen bonds along the *b/c* bisector. There are two parallel

Figure 6.3.: Frozen and relaxed monomer units ((*S*)-enantiomer) taken from the crystal structure of enantiopure mandelic acid [88] as well as the most stable monomer (B3LYP/6-311++G(3df,2p) level). The conformations of the relaxed monomer from the crystal structure and the most stable monomer are the same.

chains which contain different monomer units. The units differ by the orientation of the phenyl group. The two chains are held together by π -stacking along the crystallographic a/c bisector. The crystal structure of racemate II exhibits similarities to the crystal structure of enantiopure mandelic acid. Both structures consist of two symmetry independent double chains made up of only one kind of molecule. In contrast, the crystal structure of racemate I differs significantly from enantiopure and racemate II mandelic acid by forming two-dimensional networks.

6.2. Monomer Conformations

Mandelic acid monomers can be described by a two-letter nomenclature in analogy to the nomenclature used for methyl mandelate (see Chapter 5) [138]. It describes the syn (Ss), cis (C), skew (sk), gauche (G), and anti (A) conformations of the H-O-C-C and O-C-C=O dihedral angles.

The monomer conformations within the crystal structures of enantiopure and racemic (stable and metastable) do not differ qualitatively. Therefore, the energies and wavenumbers of the relaxed monomer units are also the same by means of quantum chemical optimization. In the following, only the monomer of (*S*)-mandelic acid will be considered. An Ss conformation is exhibited which contains an intramolecular O-H \cdots O=C hydrogen bond (see Fig. 6.3). Note, that a rotation of the phenyl group by about 45° takes place during structure optimization.

There are no studies reported on the most stable monomer conformation of mandelic acid. It can be assumed that isolated mandelic acid exhibits an Ss conformation in analogy to the most stable monomer of methyl mandelate which was found to have an SsC conformation (see Chapter 5). The Ss form is the same conformation found in the crystal structures of mandelic acid. Structure and frequency calculations of this mandelic acid monomer were performed on the B3LYP/6-311++G(3df,2p) and MP2/6-311+G(2d,p) levels within the current framework.

The H-O distance of the intramolecular O-H...O=C hydrogen bond is 2.1 Å, the O-O distance 2.7 Å, and the angle 118° on the B3LYP/6-311++G(3df,2p) level. A slightly different angle of 119° is predicted on the MP2/6-311+G(2d,p) level. The distances and the angle of the intramolecular hydrogen bond are nearly the same as calculated for the most stable conformer of methyl mandelate (see Chapter 5).

6.3. Preliminary Spectral Considerations

Several vibrational modes of mandelic acid can be expected to appear at similar spectral positions with similar vibrational transition dipole vectors as in the case of methyl mandelate. Tab. 6.1 summarizes the wavenumbers of fundamental modes found in the ATR spectra of methyl mandelate (see Chapter 5 as well). The absence of the methyl group in mandelic acid enables a less ambiguous assignment of the aromatic C-H modes in the mandelic acid spectra. The carboxylic acid group itself introduces a very strong intermolecular binding motif. Predicted wavenumbers and intensities are listed in the Supplement F. Vibrational modes and transition dipole vectors can also be found there.

Two O-H stretching bands, one of the alcoholic and one of the acidic OH group, can be expected for mandelic acid. The spectral position of an O-H stretching mode strongly depends on its hydrogen bond environment as discussed in Chapter 5. Also, the nature of the OH group itself is important. Within a hydrogen bond, the acidic O-H stretching mode is generally more red shifted and broadened than the O-H stretching of the alcoholic O-H group [148]. Since the two OH groups are nearly orthogonal to each other the corresponding modes will show opposite polarization behavior, if the electric vector of the IR radiation does not bisect the vibrational transition dipole vectors.

The C-H stretching region as well as the region below 1600 cm⁻¹ are less con-

Table 6.1.: Wavenumbers $\tilde{\nu}$ in cm^{-1} of experimentally observed reference bands in the ATR spectra of methyl mandelate (see Chapter 5).

Assignment	Methyl Mandelate
$\nu(\text{O-H})_{\text{alcoholic}}$	3434

$\nu(\text{C-H})_{\text{aromatic, 4}}$	3049
$\nu(\text{C-H})_{\text{aromatic, 5}}$	3035
$\nu(\text{C-H}_{\alpha})$	2904
$\nu(\text{C=O})$	1811
$\nu(\text{C=O})$	1736
$\nu(\text{C=O})$	1698
$\nu(\text{C=O})$	1669
$\nu(\text{C-C})_{\text{aromatic, 1}}$	1600
$\nu(\text{C-C})_{\text{aromatic, 2}}$	1586
$\nu(\text{C-C})_{\text{aromatic, 3}}$	1491
$\nu(\text{C-C})_{\text{aromatic, 4}}$	1455

gested compared to methyl mandelate due to the absence of the methyl group. This enables a less ambiguous assignment of the aromatic C-H and C-C stretching modes and supports the assignment made for methyl mandelate in Chapter 5.

The monomer units of the mandelic acid crystal are qualitatively the same and undergo the same interactions unlike in the case of methyl mandelate (see Sect. 6.1 and Chapter 5). Nevertheless, complex in-phase and antiphase coupling patterns (factor group splittings) can also be expected for many molecular vibrations [16] due to the complexity of the unit cell.

6.4. FTIR Microspectroscopy

In the following section, results on sublimated microcrystals of enantiopure mandelic acid studied by polarized FTIR microspectroscopy which are published in Ref. [37] will be presented.

(*R*)-mandelic acid is a white powder. There is no evidence that it is hygroscopic. Its melting point under ambient pressure is 130–134°C (according to the supplier). (*R*)-mandelic acid crystallizes at temperatures between +38°C and +45°C in the

Figure 6.4.: FTIR image of enantiopure mandelic acid crystals grown on two faces A ($\approx 95\%$ abundance) and B ($\approx 5\%$ abundance).

sublimation cell. The sublimated crystals have a platy (oblate) habit. They can grow on two faces, A and B as shown in Fig. 6.4. Face A is about 20 times more abundant. However, this likely reflects a preferred position of the final crystals due to their platy (oblate) shape and gravitation, rather than a preference emerging at the nucleation stage.

Rotation experiments were carried out in order to verify that type A and B spectra actually correspond to different faces of a given mandelic acid crystal. Fig. 6.5 shows that rotation of a crystal exhibiting a type A spectrum leads to a type B spectrum. Due to oversaturation, it was not possible to record suitable face C spectra (through the long crystal axis). The aromatic C-H stretching band at the highest wavenumber (3107 cm^{-1} , H) only appears for face B, whereas the next C-H stretching band at 3089 cm^{-1} (L) is only present in type A spectra.

Polarized FTIR spectra of face A of mandelic acid exhibit large differences regarding the relative intensities of the alcoholic (3454 cm^{-1}) and acidic ($3230\text{--}2370\text{ cm}^{-1}$) O-H stretching bands as well as the aromatic C-H stretching bands (Fig. 6.6). Further differences can be found for the C=O stretching band as well as in the C-C stretching and C-H bending region. The nearly complementary intensity pattern for the alcoholic and acidic O-H stretching bands with rotation of the polarizer can be explained by almost perpendicular O-H vibrational transition dipole moment projections, which are aligned with the microcrystal axes (see Sects. 6.1 and 6.2). The aromatic C-H stretching bands all follow the behavior of the alcoholic O-H stretching band. Thus, the aromatic CH group projections are also perpendicular to the acidic OH group transition moment.

Face B exhibits similar polarization behavior, although the intensity pattern changes somewhat. Again, the alcoholic O-H stretching and the C-H stretching

Figure 6.5.: FTIR spectra of enantiopure mandelic acid obtained after rotation of crystals growing on face A (top) to face B (bottom, strong peaks attenuated by stray light) as well as a reference spectrum of face B (center). Regions H and L used for integration are marked in blue and red, respectively.

Figure 6.6.: Polarized FTIR spectra of enantiopure mandelic acid through face A and B. The double arrows show the direction of the electric vector of the radiation which passes the polarizer and can excite corresponding vibrational transition dipole vector components. Wavenumbers for selected bands in the difference spectrum are given in cm^{-1} .

bands are anti-correlated with the acidic O-H stretching band. The two findings can be reconciled by positioning the common plane of the alcoholic OH and the phenyl groups more or less parallel to face C, with most vibrational transition moments pointing between the faces A and B. Assuming only weak deviations between bond and transition moment vectors, structural information about the molecules in the crystal can thus already be extracted from the polarization behavior in the crystal.

Fig. 6.7 shows the postulated orientation of the mandelic acid unit cell along the three microcrystal faces assuming the same modification in the sublimation and X-ray experiments [88]. The orientation along the crystallographic axes *a* and *c* reflects the structural results obtained by the polarization experiments. The alcoholic and acidic OH groups are almost perpendicular to each other, and the plane of the phenyl group is perpendicular to the acidic OH group. The OH groups do not align with the *ab* or *bc* cell planes, consistent with the polarization measurements for the microcrystal's A and B faces. Like in the methyl mandelate case, the strong hydrogen bonded chain direction is the preferred growth direction in the sublimation process.

A comparison of experimental and oriented gas model polarization spectra of face A and B in Fig. 6.8 confirms that the alcoholic O-H stretching band gains in intensity, while the acidic O-H stretching band decreases and vice versa. Thus, the experimental O-H stretching bands can be easily assigned due to their opposite polarization behavior (Tab. 6.2) despite the dramatic shortcomings of the oriented gas model for the acidic O-H stretching shift. The latter correlates with a shorter hydrogen bond length (see Fig. 6.2). There is also good agreement between experimental and oriented gas model spectra of the aromatic C-H stretching bands. For both faces the intensities increase with a polarization along the short crystal axis. The detailed directions of the calculated transition moments of the two highest frequency transitions are not as complementary as in the experiment (Fig. 6.6). This may be due to the relatively large distortion of the phenyl ring orientation in the crystal compared to the relaxed monomer conformation (see Fig. 6.3) and invites a crystal calculation. The assignment of the aromatic C-H stretching bands is thus based mostly on the sequence of the predicted modes.

The mandelic acid bands at 1604 cm^{-1} , $1588/1589\text{ cm}^{-1}$, $1496/1495\text{ cm}^{-1}$, and 1456 cm^{-1} (see Fig. 6.6) are very close to those of methyl mandelate (1600 cm^{-1} , 1587 cm^{-1} , 1491 cm^{-1} , and 1454 cm^{-1}) and can be assigned to the same vibrational modes. An overview of the band assignments is given in Tab. 6.2. The corre-

Figure 6.7.: Molecular orientation of (*S*)-mandelic acid along the three crystal faces. The crystal structure was taken from Ref. [88]. The continuous frames mark the observed faces, whereas the unobserved face is dash-framed.

Figure 6.8.: Comparison of experimental (top, black) and oriented gas model (bottom, blue) polarization spectra (B3LYP/6-311++G(3df,2p) level) of face A (left) and face B (right) of enantiopure mandelic acid.

Table 6.2.: Assignments of experimental band maxima in the FTIR microscopic spectra of mandelic acid of face A, face B, FTIR-ATR spectra (without ATR correction) as well as calculations of the relaxed monomer unit taken from the crystal structure ($\text{Mon}_{\text{crystal}}$) on the B3LYP/6-311++G(3df,2p) level. All wavenumbers are given in cm^{-1} . The stretching and bending vibrations are indicated as ν and δ and the symmetric and asymmetric vibrations with sym and asym.

sponding modes are visualized in the Supplement F. The band at 1456 cm^{-1} ($\nu(\text{C-C}_{\text{aromatic},4})$) has a higher intensity in face A than in face B spectra, suggesting the orientation of face A to be perpendicular to the c axis. The aromatic C-C stretching bands at 1604 cm^{-1} and $1496/1495\text{ cm}^{-1}$ ($\nu(\text{C-C}_{\text{aromatic},1})$ and $\nu(\text{C-C}_{\text{aromatic},3})$) are weak or absent in face A spectra. The vibrational transition dipole vectors of both point more or less along the C-C bond between the phenyl group and the substituent. Therefore, they are not excited when looking along the c axis. This confirms the assignment of the crystallographic c axis perpendicular to face A or else provides a detailed normal mode assignment of these aromatic bands. All four C-C stretching bands appear in face B spectra. Polarization spectra (Fig. 6.6) show that the vibrational transition dipole vectors of $\nu(\text{C-C}_{\text{aromatic},1})$ and $\nu(\text{C-C}_{\text{aromatic},3})$ are oriented along the short axis of face B. This again suggests that face B includes the crystallographic c axis as shown in Fig. 6.7 and it shows that the predicted sequence and shape of the C-C stretching modes (Supplement F) is consistent with the one found in the microcrystals.

6.5. Conclusions

Polarization FTIR microspectra of sublimated mandelic acid crystals were recorded and vibrational transition dipole vectors inferred. Experimental and predicted results were compared and the molecular orientation within the crystal structure determined. An assignment of several vibrational modes was performed which supports the vibrational assignment made for methyl mandelate in Chapter 5. Overall, the performance of the polarization FTIR microspectroscopic method of sublimated crystals was shown on another substance.

So far, only the enantiopure compound of mandelic acid was investigated. It might be worthwhile to also investigate the racemic compound. As reported, the stable racemate shows spectral differences compared to the enantiopure compound in the mid infrared region [20, 164, 165]. A comparison of enantiopure and racemic mandelic acid polarization spectra might support the assignment of vibrational bands appearing in the region of $1400\text{--}1000\text{ cm}^{-1}$. Further light may also be shed on the polymorphism observed in the racemate [166–168, 170].

7. Phenylpropanolamines

The 1-phenylpropan-1-ol-2-amines (1*R*,2*S*)-norephedrine (NE), (1*S*,2*S*)-pseudonorephedrine (PNE), (1*R*,2*S*)-ephedrine (E), and (1*S*,2*S*)-pseudoephedrine (PE) can be found in the Ephedra species of plants [171]. They are biologically active and act on the sympathetic nervous system by altering the natural neurotransmission process. E.g., (1*R*,2*S*)-norephedrine is used as an appetite suppressant, (1*R*,2*S*)-ephedrine for broncho dilatation, and (1*S*,2*S*)-pseudoephedrine in flu medication [171].

Norephedrine, pseudonorephedrine, ephedrine, and pseudoephedrine are structurally similar chiral substances (see Fig. 7.1). Norephedrine and pseudonorephedrine are diastereoisomers ($\text{C}_6\text{H}_5\text{--CHOH--CHNH}(\text{CH}_3)\text{--CH}_3$), as are ephedrine and pseudoephedrine ($\text{C}_6\text{H}_5\text{--CHOH--CHNH}_2\text{--CH}_3$). All possess a phenyl, a hydroxy, and an amino group next to two acidic C-H groups (α and β) and at least one methyl group. The phenylpropanolamines of interest have two chiral carbon atoms (marked with an asterisk (*) in Fig. 7.1, (1): CHORR', (2): CHNRR') and are open for chirality recognition. They are available for hydrogen bonding at the oxygen and the nitrogen functionalities as well as for aromatic interactions. An overview of their FTIR-ATR spectra (Fig. 7.2) exhibits spectral similarities. Furthermore, they also show structural similarity to methyl mandelate and mandelic acid which have been extensively studied within the framework of the present work (see Chapters 5 and 6). Their melting points, sublimation and condensation temperatures are listed in Tab. 7.1.

In this chapter, the aggregation of sublimated microcrystals of (1*S*,2*R*)-norephedrine, (1*R*,2*R*)-pseudonorephedrine, (1*R*,2*S*)-ephedrine, and (1*S*,2*S*)-pseudoephedrine as well as mixtures of both enantiomers of norephedrine as well as pseudoephedrine will be analyzed. Molecular recognition phenomena will be investigated in the case of norephedrine and pseudoephedrine. In the case of ephedrine an anhydrate and a hydrate will be observed. Polarization FTIR spectra of the above mentioned microcrystals will be presented. The molecular conformation of

Table 7.1.: Standard melting temperature (information provided by supplier and Ref. [173]) (ϑ_m°) as well as observed sublimation (ϑ_{Subl}) and liquid condensation temperatures (ϑ_{Cond}) of the investigated phenylpropanolamines set at the bottom of the sublimation cell.

the molecules within the crystals [89–92, 172] will be derived by a comparison of experimental and oriented gas model spectra, by comparison with the results gained from methyl mandelate and mandelic acid (Chapters 5 and 6), and by comparison of the crystal habit and the interactions. It will be shown, that an assignment of the molecular conformation is possible. Tentative molecular orientations will be derived for enantiopure and racemic pseudoephedrine. Also, an assignment of several vibrational bands will be carried out. The crystal structures, the conformations within the published crystal structures [89–92, 172] and those of the most stable monomers [82–87] as well as preliminary considerations concerning expected vibrational bands will be discussed beforehand. A variety of N-H modes will be analyzed in Sect. 7.8.

Note, that the configuration of pseudonorephedrine investigated within the present work (1*R*,2*R*) differs from the configuration in the published crystal structure (1*S*,2*S*) [90]. Both enantiomers show equivalent spectra (verified in the methyl mandelate case [37], see Chapter 5). If not stated otherwise, the form found in the crystal structure (1*S*,2*S*) is depicted in all figures.

7.1. Crystal Structures

The crystal structures of a variety of phenylpropanolamines and their salts have already been determined [89–92, 172]. The molecular conformations in the crystal structures provided by the Cambridge Structural Database (CSD) (see Ref. [174])

Figure 7.1.: Phenylpropanolamines investigated by polarization FTIR microspectroscopic sublimation experiments. The figure exhibits structural similarities of the phenylpropanolamines among each other and with regard to methyl mandelate and mandelic acid. Centers of chirality are marked by an asterisk (*). The shown configurations are those investigated in the solid state.

Figure 7.2.: FTIR-ATR spectra of enantiopure norephedrine (NE, enant), racemic norephedrine (NE, rac), enantiopure pseudonorephedrine (PNE, enant), enantiopure ephedrine hemihydrate (E-H, enant), enantiopure pseudoephedrine (PE, enant), and racemic pseudoephedrine (PE, rac). Band positions are given in cm^{-1} .

are used for quantum chemical calculations and the simulation of spectra (see Chapter 3). The crystal structures and the interactions which affect the habit of the sublimated microcrystals will be analyzed in the corresponding Sections. No polymorphism has been reported for any of the investigated phenylpropanolamines. There is an anhydrous and a hydrous form in the case of ephedrine.

Similar patterns of interactions are present in the crystal structures of all investigated phenylpropanolamines. Tab. 7.2 summarizes the types of hydrogen bonds, their distances and angles. In one direction there are infinite chains of O-H...N hydrogen bonds with a distance of 1.9–2.0 Å. These infinite strands are held together by weaker N-H...O and C-H...O hydrogen bonds with a distance of 2.2–2.5 Å. The resulting layers are held together by van der Waals interactions.

7.2. Monomer Conformations

The conformation of monomers within a crystal depends on the possibility of forming intra- as well as intermolecular interactions. The conformation can vary within the unit cell of a given crystal (conformational isomorphism, e.g., *trans*-1,4-cyclohexanediol [175]), for different polymorphs (conformational polymorphism, e.g., vitamin A acid [176–178]) or for solvates (e.g., ephedrine anhydrate and ephedrine hemihydrate [91], see below). A crystal's monomer conformation may vary from the most stable conformation under vacuum-isolated conditions. In the following, the conformations and energy differences of fully relaxed crystal and most stable monomer structures will be compared.

Butz et al. introduced an A/G notation for the different conformations of norephedrine, ephedrine, pseudoephedrine, and hydrated clusters of ephedrine and pseudoephedrine [82–84]. The notation describes the anti (A) and gauche (G) arrangements of the CCCN and OCCN groups. In the published crystal structure of norephedrine the monomer units adopt a GG conformation [89]. In contrast, pseudonorephedrine, ephedrine (anhydrate as well as hemihydrate) and pseudoephedrine were found to have an AG conformation also in the crystal structures [90–92]. The amino groups of ephedrine anhydrate on one hand and ephedrine hemihydrate and pseudoephedrine on the other hand are enantiomeric to each other. To account for this, the structure of ephedrine anhydrate is named AG(a) and the ones of ephedrine hemihydrate and pseudoephedrine are named AG(b) [82–84]. The monomer conformations found in the crystal structures of the investigated phenylpropanolamines are depicted in Fig. 7.3. It should be noted, that hydrogen atoms are weak X-ray diffractors and the position is often geometrically calculated and then refined [13, 179]. It is possible that not the AG(a) but the AG(b) conformations and vice versa are present in the crystal structures. Nevertheless, the positioning of the hydrogens is in agreement with the establishment of hydrogen bonds within the crystals. In the following, the correctness of the hydrogen position will be assumed.

The most stable monomer conformations of norephedrine, ephedrine, and pseudoephedrine as well as of 1:1 and 1:2 ephedrine water clusters were determined by combining resonant two-photon ionization, laser induced fluorescence, and resonant ion-dip infrared jet-spectroscopy in combination with *ab initio* calculations (HF/6-31G(d), B3LYP/6-31+G(d), MP2/6-311+G(d,p)) by Butz et al. [82–84]. The conformations of ephedrine (calculated on the MP2/6-311++G(d,p) level) and pseudoephedrine (calculated on the CC/aug-cc-pVDZ level) were confirmed by Karaminkov et al. who also carried out low- and high-resolution resonantly enhanced two-photon ionization spectroscopic studies with mass selection of jet cooled molecules [85, 86]. A mixed ephedrine-water dimer as well as two conformations of ephedrine were observed with the same technique [180]. Further conformations of norephedrine, ephedrine, and pseudoephedrine were found by Alonso et al. using gas phase molecular beam Fourier transform microwave spectroscopy in combination with MP2/6-311++G(d,p) level calculations [87]. The most stable monomer and some other conformations of ephedrine were also found in FTIR-jet spectroscopic studies [181].

Figure 7.3.: Frozen and relaxed monomer units taken from the crystal structures [89–92] as well as the most stable monomers [82–87] (B3LYP/6-311++G(3df,2p) level) of the investigated phenyl-propanolamines. Centers of chirality are marked with an asterisk (*).

The most stable structures of norephedrine, ephedrine (monomer as well as hydrated ephedrine), and pseudoephedrine were all found to have an AG or an AG(a) conformation [82–87]. In this conformations intramolecular O-H \cdots N hydrogen bonds are established. The AG and AG(a) conformations were recalculated within the current framework using the B3LYP/6-311++G(3df,2p) level of theory (see Chapter 3). No studies have been reported for pseudonorephedrine so far. Therefore, the AG conformation was also assumed for pseudonorephedrine. The structures of the most stable monomer conformations are shown in Fig. 7.3 as well.

The energy differences without and with zero point energies between the relaxed monomer unit from the crystal structure and the most stable monomer conformation are summarized in Tab. 7.3. The conformations taken from the crystal structures are 4–12 kJ \cdot mol $^{-1}$ higher in energy and form intramolecular N-H \cdots O contacts, whereas in the most stable monomers O-H \cdots N hydrogen bonds are established. Only in the monomer unit of the ephedrine hemihydrate crystal an O-H \cdots N bond is present as well. The types, distances, and angles of the Y-H \cdots X contacts are also summarized in Tab. 7.3.

The energy differences between the most stable monomer conformation and the relaxed monomer unit from the crystal structure are the highest for norephedrine (12 kJ \cdot mol $^{-1}$ and 10 kJ \cdot mol $^{-1}$). This can be explained with the energetically unfavorable GG conformation in the crystal structure and the long distance of the intramolecular Y-H \cdots X contact in the relaxed monomer (2.8 Å compared to 2.2 Å). Also, in the case of ephedrine anhydrate the energy differences are rather high (10 kJ \cdot mol $^{-1}$ and 9 kJ \cdot mol $^{-1}$). Both monomers establish an AG conformation, but the amino group is rotated. The AG(a)' conformation of the relaxed monomer of the crystal structure is energetically less favorable. The energy differences of the relaxed monomer from the crystal structure and the most stable monomer are lower for pseudonorephedrine (5 kJ \cdot mol $^{-1}$ and 4 kJ \cdot mol $^{-1}$), ephedrine hemihydrate (5 kJ \cdot mol $^{-1}$), and pseudoephedrine (6 kJ \cdot mol $^{-1}$ and 5 kJ \cdot mol $^{-1}$). This can be explained with a similar conformation (AG) and similar H \cdots X distances (2.3 Å compared to 2.1 Å for pseudonorephedrine, 2.2 Å compared to 2.2 Å for ephedrine hemihydrate, and 2.2 Å compared to 2.1 Å for pseudoephedrine). The monomer units of the ephedrine hemihydrate and the pseudoephedrine crystals adopt an AG(b) conformation which seems to be energetically favorable compared to the AG(a)' conformation found within the anhydrous ephedrine crystal. But, the energetical preference of AG(b) over AG(a)' might be subtle. The establishment of

Table 7.3.: Types, distances d in Å ($d_{\text{H-X}}$ and $d_{\text{Y-X}}$), and angles α in ° of Y-H...X contacts as well as energy differences without and with zero point energies (ΔE and ΔE_0) of the relaxed monomer units from the crystal structure [89–92, 172] and the most stable monomers [82–87] of the investigated phenylpropanolamines in kJ·mol^{−1}. No imaginary frequencies are observed.

		$d_{\text{H-X}}$	$d_{\text{Y-X}}$	α	ΔE	ΔE_0

stable	O-H...N	2.1	2.7	120	0.0	0.0

an O-H...N hydrogen bond within the ephedrine hemihydrate monomer and the shorter N-H...O contacts of pseudoephedrine are more likely the reason for the lower energy differences.

7.3. Preliminary Spectral Considerations

The phenylpropanolamines are structurally similar to mandelic acid and methyl mandelate (Fig. 7.1). They have an alcoholic hydroxy group, an aromatic group, a methyl group, and an α -acidic CH group in common. Therefore, several vibrational modes can be expected to appear at similar wavenumbers and to have similar vibrational transition dipole vectors. Tab. 7.4 summarizes band positions of methyl mandelate and mandelic acid (see Chapters 5 and 6) which are expected to be observed. In addition, the phenylpropanolamines possess an amino or a methylamine

Table 7.4.: Wavenumbers $\tilde{\nu}$ in cm^{-1} of experimentally observed reference bands in the ATR spectra of enantiopure methyl mandelate and mandelic acid (see Chapters 5 and 6).

Assignment	Methyl Mandelate	Mandelic Acid
$\nu(\text{O-H})_{\text{alcoholic}}$	3434	3443
$\nu(\text{C-H})_{\text{aromatic,sym}}$	3103	3108

$\nu(\text{C-C})_{\text{aromatic},4}$	1455	1455

group and a second CH group (β -acidic). In the following, modes involving these functional groups will be discussed in detail (for all others see Chapter 5). Predicted wavenumbers and intensities are listed in the Supplement F. Also, vibrational modes and transition dipole vectors are depicted there.

The position and the intensity of the O-H stretching band strongly depend on aggregation and the resulting interactions. The hydroxy groups of the phenylpropanolamines are hydrogen bonded to amino groups ($\text{O-H} \cdots \text{N}$) as mentioned in Sect. 7.1. They form long strands of monomer units and are therefore expected to be further red shifted and intensified.

N-H Stretching Mode

Norephedrine and pseudonorephedrine are primary amines, ephedrine and pseudoephedrine secondary amines. Therefore, there is a splitting resulting in an asymmetric and a symmetric N-H stretching mode for norephedrine and pseudonorephedrine but only one N-H stretching mode for ephedrine and pseudoephedrine. The asymmetric N-H stretching band can be expected at $3375 \pm 25 \text{ cm}^{-1}$ and the symmetric one at $3300 \pm 30 \text{ cm}^{-1}$ [147, 148]. The N-H

stretching band of the secondary amines usually appears around 3300 cm^{-1} as well. The position and intensity may be affected by hydrogen bonding but less so than for the O-H stretching band because the NH group is a poorer hydrogen bond donor [147]. The integrated N-H band strength of primary amines is about twice the one of secondary amines [148].

Tab. 7.5 summarizes predicted wavenumbers of the N-H and N-D stretching vibrations for the investigated phenylpropanolamines (monomers relaxed from the crystal structure and most stable monomers, see Sect. 7.2), its fragments isopropylamine, methylisopropylamine, ethylamine, and methylethylamine and the aggregated fragments of ethylamine and methylethylamine with dimethylether or methanol (see Fig. 7.4). The fragments are chosen to model the amino group and its behavior upon conformation, methylation, intramolecular coordination, and aggregation. Two conformations (I and II) of the isopropylamine as well as the methylisopropylamine fragment are present in the investigated phenylpropanolamines. Isopropylamine I is a fragment of the norephedrine crystal and of the most stable structure of pseudonorephedrine, isopropylamine II of the most stable conformer of norephedrine and of the pseudonorephedrine crystal. Methylisopropylamine I is realized in the ephedrine anhydrate crystal and in the most stable monomer of pseudoephedrine, methylisopropylamine II in the ephedrine hemihydrate crystal, the most stable monomer of ephedrine, and in the pseudoephedrine crystal. The monomers and clusters of ethylamine and methylethylamine are based on the structures of isopropylamine and methylisopropylamine. In the case of methylethylamine one trans and two gauche conformations ((a) and (b)) are considered.

The N-H stretching modes of the methylated amines are predicted to appear midway between the asymmetric and symmetric N-H stretching modes of the corresponding primary amines. Only for the monomer unit from the ephedrine hemihydrate crystal and the most stable pseudoephedrine monomer this is not true. Here, the N-H stretching of the methylated substance are approximately 30 and 40 cm^{-1} more red shifted than the average of the symmetric and asymmetric N-H stretching modes. An explanation for these deviations will be given below. The N-H stretching modes of form I and II of isopropylamine and methylisopropylamine are predicted at different wavenumbers. Form I is red shifted by approximately $10\text{--}20\text{ cm}^{-1}$. Also, the position of the methyl group in methylethylamine has an influence on the wavenumber. The trans conformation shows the smallest wavenumber, followed by gauche(a) which is shifted by 9 cm^{-1} to higher wavenumber. The N-H stretching

7. Phenylpropanolamines

Table 7.5.: Predicted harmonic wavenumbers ω in cm^{-1} and IR intensities I in $\text{km}\cdot\text{mol}^{-1}$ of the N-H and N-D stretching modes of relaxed monomers from the crystal structure (X_{crystal}), of the most stable monomers (X_{stable} , see Sect. 7.2) and of fragments of the investigated phenylpropanolamines (NE, PNE, E, and PE) on the B3LYP/6-311++G(3df,2p) level. The fragments are isopropylamine (IPA, I and II) and methylisopropylamine (MIPA, I and II) as well as (nondeuterated and ND/OD-deuterated) ethylamine (EA) and trans-, gauche(a)-, and gauche(b)-methylethylamine (MEA) with and without the aggregation partners dimethylether (DME) and methanol (MeOH) (see Fig. 7.4).

Figure 7.4.: Isopropylamine (I and II), methylisopropylamine (I and II), ethylamine, trans-, gauche(a), and gauche(b)-methylethylamine monomers, and complexes of ethylamine, trans-, gauche(a)-, and gauche(b)-methylethylamine with dimethylether or methanol. The two clusters of ethylamine with dimethylether are denoted d and u for down and up.

mode of gauche(b)-methylaniline is predicted at 25 cm^{-1} higher wavenumber than the trans-form. The predicted wavenumbers of ethylaniline and methylethylaniline shift upon aggregation with dimethylether or methanol. The resulting red shift is in the order of $8\text{--}20\text{ cm}^{-1}$. It is almost the same for aggregation leading to an $\text{N-H}\cdots\text{O}$ or an $\text{O-H}\cdots\text{N}$ hydrogen bond. The red shift increases to about 30 cm^{-1} in the case of the cooperative $\text{O-H}\cdots\text{N-H}\cdots\text{O}$ hydrogen bond of the methanol-ethanol-dimethylether cluster.

The deviation of the predicted N-H stretching wavenumbers of the nine phenylpropanolamine monomers (average position of the asymmetric and symmetric N-H stretch for nonmethylated amines) compared to the predicted wavenumber of ethylaniline (3533 cm^{-1}) is between -14 cm^{-1} and $+36\text{ cm}^{-1}$ with a mean value of $+4\text{ cm}^{-1}$ and a root mean square ($\text{rms}=\sqrt{\frac{1}{n}\cdot\sum_{i=1}^n x_i^2}$) of 18 cm^{-1} . These wavenumber deviations are a result of multiple interactions taking place within the calculated monomers, such as inductive effects. In order to identify the influencing parameters and shifts, N-H stretching wavenumbers of eight methylisopropanolamines which are fragments of ephedrine and pseudoephedrine (see Fig. 7.5) were calculated in addition to the phenylpropanolamines and the fragments discussed above. The full set of 25 compounds deviates from the ethylaniline N-H stretching mode average by -17 to $+36\text{ cm}^{-1}$ with a mean value of $+7\text{ cm}^{-1}$ and a root mean square deviation of 17 cm^{-1} . Tab. 7.6 summarizes the predicted wavenumbers, the deviations to the N-H stretching wavenumber of ethylaniline, postulated parameters influencing these wavenumbers as well as the resulting shifts, predicted wavenumbers starting from ethylaniline (3533 cm^{-1}) which was chosen as the interaction free reference system and adding the influence of these parameters, and the difference between the predicted and calculated wavenumbers. Ideally, the predicted wavenumbers should have the same value as the calculated wavenumbers.

Figure 7.5.: Methylisopropanolamines I–VIII. I is a fragment of the monomer from the ephedrine anhydrate crystal, III from the ephedrine hemihydrate crystal, IV of the most stable ephedrine monomer, V of the monomer from the pseudoephedrine crystal, and VII of the most stable pseudoephedrine monomer. The methylisopropanolamines II, IV, VI, and VIII have an inverted amino group relative to I, III, V, and VI.

Table 7.6.: Predicted harmonic B3LYP/6-311++G(3df,2p) wavenumbers ω_{calc} of the N-H stretch, the distance to the N-H stretching wavenumber of ethylamine $\Delta\omega_{\text{EA}-c}$, postulated parameters influencing the predicted wavenumbers (nonterminal amine, methylated amine, no trans H-N/C-H, and Y-H...X hydrogen bonds and contacts) of ethylamine (EA), methylamine (MEA), isopropylamine (IPA), methylisopropylamine (MIPA), methylisopropanolamines (MIPOA), and the investigated phenylpropanolamines, the wavenumbers after removing the influence of the parameters ω_{pred} in cm^{-1} , and its deviation to the calculated wavenumbers $\Delta\omega_{p-c}$. An average wavenumber of the asymmetric and symmetric N-H stretching modes is used for the nonmethylated amines.

A nonterminal amine is on average red shifted by 15 cm^{-1} and a methylated amine by 10 cm^{-1} . E.g., the nonterminal amine isopropylamine I is predicted by calculation at 3519 cm^{-1} and by the model at 3518 cm^{-1} . Gauche(a)-methylethylamine calculated at 3522 cm^{-1} is the methylated analog to ethylamine and would be predicted at 3523 cm^{-1} . The absence of a trans arrangement between the N-H and the β -acidic C-H group causes a blue shift of about 15 cm^{-1} . E.g., gauche(b)-methylethylamine calculated at 3538 cm^{-1} is blue shifted by 16 cm^{-1} compared to gauche(a)-methylethylamine calculated at 3522 cm^{-1} . Y-H...X contacts within the monomer lead to a blue shift with one exception causing a red shift. The blue shift is about 15 cm^{-1} for the O-H...N with an antiparallel arrangement of the N-H and O-H rotors. The blue shift is also 15 cm^{-1} for the N-H...O contact and ca. 5 cm^{-1} for the C-H...O contact. E.g., the O-H...N contact in methylisopropanolamine IV calculated at 3540 cm^{-1} causes a blue shift of 17 cm^{-1} compared to methylisopropylamine II calculated at 3523 cm^{-1} . The monomer unit from the crystal structure of pseudonorephedrine with an N-H...O contact is predicted 16 cm^{-1} towards higher wavenumber (calculated at 3547 cm^{-1}) compared to isopropylamine II calculated at 3531 cm^{-1} . The C-H...O contact of methylisopropanolamine II causes a blue shift of 5 cm^{-1} to 3528 cm^{-1} compared to methylisopropylamine II calculated at 3523 cm^{-1} . Only in the case of O-H...N hydrogen bonds with an approximately perpendicular arrangement of the NH and OH rotors, as defined by a small HNCC torsional angle, the N-H stretching wavenumbers are red shifted. Such an O-H...(H)N hydrogen bond is e.g., present in methylisopropanolamine III at 3501 cm^{-1} but not in the case of methylisopropylamine II at 3523 cm^{-1} causing a red shift of 22 cm^{-1} .

The differences of the predicted and calculated wavenumbers are between -12 cm^{-1} and $+10\text{ cm}^{-1}$ with a mean value of -1 cm^{-1} and a root mean square of 6 cm^{-1} for the full set of 25 compounds. This shows that the wavenumber differences of the N-H stretching mode can be formally described with the above mentioned parameters. However, it should be emphasized that these parameters only model a theoretical quantity and the description is not necessarily unique, but will be subject to revisions. Nevertheless, it provides a first instrument to predict N-H stretching wavenumbers based on the conformation and its interactions in comparison to other amines [132]. The residual deficiencies corresponding to a root mean square of 6 cm^{-1} are smaller than the expected model misinterpretations. Furthermore, it is reasonable to assume that the shift caused by the Y-H...X contacts varies

within a certain range depending on the strength of the given contact.

N-H stretching intensities (summarized in Tab. 7.5) are low, but can be enhanced upon hydrogen bonding [147]. The intensity of the asymmetric stretching is generally higher than the intensity of the symmetric stretching. For the calculated isopropylamines this is not true. The intensity of the symmetric stretching remains higher on the MP2/6-311+G(d) level. Also, in the case of ethylamine and its clusters the asymmetric N-H stretching intensity is not higher than the intensity of the symmetric stretching. The predicted intensities of the investigated amines increase about 20–100 fold upon forming N-H \cdots O hydrogen bonds with dimethylether. The predicted intensities of the N-H stretching bands also increase when the amino group acts as the hydrogen bond acceptor (O-H \cdots N) in complexes with methanol but less so. The highest intensification (50–130 fold) is predicted for the methanol-ethylamine-dimethylether cluster in which a cooperative O-H \cdots N-H \cdots O hydrogen bond network is established. In jet expansions the N-H stretching bands were found to be rather weak. E.g., no N-H stretching band appears for aminoethanol monomers [182] and only the asymmetric stretching band was observed with significant band strength for the glycine ethyl ester monomer [183]. Upon aggregation a pronounced intensity increase was found e.g., for pyrrolidine clusters in jet expansions (up to three orders of magnitude) [74, 184] and dimethylamine in the gas phase [185]. Also, in the spectra of crystals an enhancement of the intensities is expected especially in the case of a cooperative hydrogen bond network.

Fig. 7.6 shows the influence of a hydrogen bond on the direction of the vibrational transition dipole vector of the N-H stretching modes for ethylamine and methylethylamine. The vectors of isopropylamine and methylisopropylamine (I and II) are shown for comparison. For the vibrational modes and vibrational transition dipole moments of the phenylpropanolamines see Supplement F. The single N-H stretching mode of the methylated amines tends to have a vibrational transition dipole vector perpendicular to the N-H bond in direction of the lone pair. For the non-methylated amines, the direction of both N-H stretching modes is dictated by local symmetry. The vibrational transitional dipole vector of the asymmetric stretch is perpendicular and the symmetric one parallel to a hypothetical average N-H bond. If the nonmethylated or methylated NH group engages as an N-H \cdots O hydrogen bond donor (aggregation with dimethylether) the vector aligns with the hydrogen bond. If the methylated amine group engages as an O-H \cdots N hydrogen bond acceptor (aggregation with methanol) the vibrational transition dipole vector aligns along

the hydrogen bond as well. In the case of the nonmethylated amines the local symmetry present for the monomer is conserved upon forming an $\text{O-H} \cdots \text{N}$ hydrogen bond (aggregation with methanol).

Overall, two N-H stretching bands can be expected for norephedrine and pseudonorephedrine, one for ephedrine hemihydrate, and one less intense N-H band for ephedrine anhydrate and pseudoephedrine. The single N-H stretching bands can be expected to appear in between the symmetric and asymmetric N-H stretching bands of the corresponding nonmethylated phenylpropanolamines. The N-H stretching modes will intensify after forming an $\text{N-H} \cdots \text{O}$ hydrogen bond within the crystal. The vibrational transition dipole vectors will align approximately along the hydrogen bonds.

Deuteration of the OH and NH group (ND/OD deuteration) will lead to strong red shifts. This helps identifying bands appearing in the same spectral region (e.g., C-H stretching bands). Predicted wavenumbers of the N-D stretching bands are summarized in Tab. 7.5. Wavenumbers are listed for relaxed monomers of the crystal structure, the most stable monomers, and chosen fragments (ethylamine and methylethylamine) without and with aggregation partner (dimethylether and methanol). The red shift upon deuteration is predicted to be between 930 cm^{-1} and 980 cm^{-1} . The red shift is around 940 cm^{-1} for the asymmetric N-H/N-D stretching band, it is around 970 cm^{-1} for the symmetric stretching, and $940\text{--}950\text{ cm}^{-1}$ for the methylated amines. Therefore, the splitting between the asymmetric and symmetric stretching is predicted to be larger for the N-D than for the N-H stretching mode. This rather untypical behavior is probably related to mode mixing of the N-D with a C-H stretching mode. The predicted intensities remain more or less the same upon deuteration which also results from the above mentioned mode mixing. Only for the $\text{N-D} \cdots \text{O}$ deuterium bonded complexes the intensity is lower than in the nondeuterated $\text{N-H} \cdots \text{O}$ bonded cases. A small loss of intensity can also be noticed for the $\text{O-D} \cdots \text{N}$ bonded clusters. Since the deuterated phenylpropanolamine crystals establish $\text{N-D} \cdots \text{O}$ or $\text{O-D} \cdots \text{N}$ deuterium bonds a decrease of intensity can be expected compared to the nondeuterated substances. In the partly deuterated ethylamine-dimethylether complexes the N-H and N-D stretching modes have a localized character. The modes of the hydrogen and deuterium bonded group appear in between the asymmetric and symmetric stretching modes with closer vicinity to the symmetric mode and are much more intense than the isolated N-H and N-D stretching mode.

7. Phenylpropanolamines

Figure 7.6.: Influence of the position of the methyl group and the influence of a hydrogen bond on the direction of the vibrational transition dipole vectors of the N-H stretching modes in ethylamine and methylethylamine. The direction of the vibrational transition dipole vectors (yellow, unit length) as well as the displacement vectors of each mode (blue) are indicated.

N-H Bending Mode

The N-H bending mode of primary amines is known to appear in the region of 1650–1590 cm^{-1} [147, 148]. The bending mode of the secondary amines is reported to appear in the region of 1650–1550 cm^{-1} by Ref. [148] and around 1500 cm^{-1} by Ref. [147]. Therefore, the bands fall into the region of the C-C_{aromatic} stretching bands. They show a blue shift, intensification, and broadening upon aggregation [147, 148]. The N-H bending mode of primary amines is more intense than the one of secondary amines [148].

Tab. 7.7 summarizes the predicted wavenumbers of the N-H (and N-D) bending modes for the investigated phenylpropanolamines (monomers relaxed from the crystal structure and most stable monomers, see Sect. 7.2), its fragments isopropylamine, methylisopropylamine, ethylamine, and methylethylamine and the aggregated fragments of ethylamine and methylethylamine with dimethylether or methanol (Fig. 7.4). The N-H bending modes of the primary amines are to a great extent local modes, while the N-H bending modes of the secondary amines are mixed N-H/C-H₃ (or C-H₃/N-H) bending modes (see Supplement F and Fig. 7.7). The contribution of the N-H bend in the mixed N-H/C-H₃ bending modes varies for the different substances. Only the two highest frequency mixed modes are listed in Tab. 7.7. Upon ND/OD deuteration only one dominant N-D bending mode is present.

7. Phenylpropanolamines

Table 7.7.: Predicted harmonic wavenumbers ω in cm^{-1} and IR intensities I in $\text{km}\cdot\text{mol}^{-1}$ of the N-H and N-D bending modes of relaxed monomers from the crystal structure (X_{crystal}), of the most stable monomers (X_{stable} , see Sect. 7.2) and of fragments of the investigated phenylpropanolamines (NE, PNE, E, and PE) on the B3LYP/6-311++G(3df,2p) level. The fragments are isopropylamine (IPA, I and II) and methylisopropylamine (MIPA, I and II) as well as (nondeuterated and deuterated) ethylamine (EA) and trans-, gauche(a)-, and gauche(b)-methylethylamine (MEA) with and without the aggregation partners dimethylether (DME) and methanol (MeOH) (see Fig. 7.4).

Figure 7.7.: Influence of the position of the methyl group and the influence of a hydrogen bond on the direction of the vibrational transition dipole vectors of the N-H bending modes in ethylamine and methyllethylamine. The direction of the vibrational transition dipole vectors (yellow, unit length) as well as the displacement vectors of each mode (blue) are indicated.

The N-H bending modes of the primary amines are predicted at roughly 130 cm^{-1} and 170 cm^{-1} higher wavenumbers than the mixed N-H/C-H₃ bending modes of the secondary amines. In the deuterated case the N-H bend of the primary amines is predicted at about 30 cm^{-1} lower wavenumber than the secondary amine bend. The shift upon deuteration is thus significantly larger for the primary amines (420 cm^{-1}) than for the secondary amines (240 cm^{-1} for an averaged mixed N-H/C-H₃ bending mode). The aggregation with dimethylether (N-H \cdots O hydrogen bond) leads to an average blue shift of 10 cm^{-1} , whereas the aggregation with methanol (O-H \cdots N hydrogen bond) causes a red shift of about 10 cm^{-1} on average. Only in the case of the nondeuterated methylethylamine-methanol complexes no red shift is predicted for the mixed N-H/C-H₃ mode at higher wavenumber. In the methanol-ethylamine-dimethylether complex ethylamine simultaneously acts as a hydrogen bond donor and acceptor. In this case, the N-H bending mode is blue shifted by 10 cm^{-1} . This points at a stronger influence of the N-H \cdots O than of the O-H \cdots N hydrogen bond on the spectral position of the N-H bending mode. However, in the case of ethylamine the aggregation with dimethylether (EA+DME(u)) causes a blue shift of 11 cm^{-1} , while the aggregation with methanol causes a red shift of 4 cm^{-1} . This shows that whether a red or blue shift is present for amines being hydrogen bond donor and acceptor depends on the specific case. For the partly deuterated ethylamine-dimethylether complexes two N-H(D) bending modes with a higher bending contribution of the N-H than the N-D bend (not depicted) are predicted. They fall between the positions of the nondeuterated and the deuterated amines with a tendency towards higher wavenumbers and show a mixing with C-H bends. Both modes of the hydrogen bonded complex (EA-NDH \cdots DME(u)) are predicted to appear at higher wavenumber than the modes of the deuterium bonded complex (EA-NHD \cdots DME(u)).

The N-H bending modes of the nondeuterated primary amines are predicted to be more intense than the mixed modes of the secondary amines. An exception is the predicted intensity of the monomer conformation realized in the pseudoephedrine crystal. Deuteration tends to have an intensity decreasing influence on the N-H bending mode of the primary amines. However, in most cases of the secondary amines the mixed mode is intensified. The intensities of the N-D modes of the primary and secondary amines are more or less comparable. Upon aggregation with dimethylether or methanol the intensities decrease in most cases. For a classification of the effects further evaluations are needed. In the case of the deuterated

amines aggregation leads to a decrease of the intensity for all substances. In the partly deuterated case the higher frequency mode is the more intense one for both complexes.

In Fig. 7.7 the directions of the vibrational transition dipole vectors of the N-H bending mode are shown for isolated and aggregated fragments of the phenylpropanolamines (for the vectors of the investigated phenylpropanolamines see Supplement F). The vector bisects the two N-H bonds in the case of the primary amines. Deviations result from asymmetric substituents. The direction of the vibrational transition dipole moment of the primary amines remains more or less conserved upon aggregation. The directions of the mixed modes are quite different (also for the deuterated substances, not shown). They depend on the relative contributions of the NH and the CH groups, on the conformation, and on aggregation. For a systematic classification further evaluations would be needed.

Further Modes

O-H and N-H stretching band positions, intensities, and shapes depend much on the interactions present. However, C-H stretching bands are less influenced, especially the aromatic ones [138, 147, 186]. It can be expected that the aromatic C-H stretching bands will appear at the same position ($\pm 10 \text{ cm}^{-1}$) as in the methyl mandelate and mandelic acid case (Tab. 7.4). Similar wavenumbers ($\pm 9 \text{ cm}^{-1}$) are indeed predicted by quantum chemical calculations (see Supplement F). Red shifts of $15\text{--}50 \text{ cm}^{-1}$ are calculated for the methyl C-H stretching modes of the phenylpropanolamines compared to methyl mandelate. The methyl C-H stretching vibrations are predicted to couple with the α - and β -acidic C-H stretching and with the N-methyl C-H stretching modes in the case of ephedrine and pseudoephedrine.

Also, similar polarization behavior and thus directions of vibrational transition dipole vectors were found for several modes in the methyl mandelate and the mandelic acid case. The transition dipole vectors of the $\text{C-H}_{\text{aromatic,sym}}$ and the $\text{C-C}_{\text{aromatic}}$ stretching modes of the investigated phenylpropanolamines are visualized in Fig. 7.8 (see also Supplement F). The directions of the $\text{C-H}_{\text{aromatic,sym}}$ (green) and the $\text{C-C}_{\text{aromatic,2}}$ (brown) transition dipole vectors roughly point along the $\text{C-C}_{\text{aromatic}}$ stem but deviate into the direction of the α -acidic CH group. In the case of norephedrine it is perpendicular to the $\text{C-C}_{\text{aromatic}}$ stem. The vibrational transition dipole vector of the $\text{C-C}_{\text{aromatic,1}}$ stretching mode (purple) is aligned along the

Figure 7.8.: Directions of the vibrational transition dipole vectors of several stretching modes of the investigated phenylpropanolamines. In the cases of norephedrine (NE) and pseudonorephedrine (PNE) the direction of the $\text{C-H}_{\text{arom,sym}}$ and the $\text{C-C}_{\text{arom},1}$ stretching mode deviate as indicated, respectively.

backbone between the phenyl ring and the amine moiety ($\text{C}_{\text{aromatic}}\text{-C-C-N(-C)}$). In most cases, it is parallel to the $\text{C-C}_{\text{aromatic}}$ stem. The direction is perpendicular to the $\text{C-C}_{\text{aromatic}}$ stem in the case of pseudonorephedrine due to mixing with the N-H stretching mode. The directions of the $\text{C-C}_{\text{aromatic},3}$ (blue) and $\text{C-C}_{\text{aromatic},4}$ (red) transition dipole moments are parallel and perpendicular to the $\text{C-C}_{\text{aromatic}}$ stem. The directions are more or less in agreement with the observations in the methyl mandelate and mandelic acid cases.

FTIR-ATR Spectra

FTIR-ATR spectra of the investigated phenylpropanolamines are shown in Fig. 7.2. The enantiopure compounds were measured for all substances, in the case of pseudonorephedrine and pseudoephedrine also the racemic compounds were investigated. As predicted, two N-H stretching bands appear in the spectra of nor- and pseudonorephedrine and only one in the spectra of ephedrine hemihydrate and pseudoephedrine. They are located around 3330 cm^{-1} . Note, that the N-H stretching band of racemic pseudoephedrine is more intense than the one of the enantiopure compound. This might be an evidence for the presence of an $\text{N-H}\cdots\text{O}$ bond within the racemic crystal.

A broad O-H stretching band is present in the region of $3200\text{--}2500\text{ cm}^{-1}$. It overlaps with the C-H stretching modes. Four $\text{C-C}_{\text{aromatic}}$ stretching bands appear

around $1600\text{--}1450\text{ cm}^{-1}$ at similar positions as for methyl mandelate and mandelic acid. The bands overlap with an N-H bending band and several C-H bending modes.

In the case of ephedrine a broad band around 3500 cm^{-1} and a smaller one at 1650 cm^{-1} appear additionally. These bands can be assigned to the O-H stretching and bending modes. Ephedrine is known to be hygroscopic and can crystallize in the form of a hemihydrate [172]. The ephedrine bottle used for measurements has not been freshly opened before measurements. The ephedrine probably hydrated and the recorded FTIR-ATR spectra belong to ephedrine hemihydrate. No FTIR-ATR spectra were recorded for anhydrous ephedrine.

7.4. Norephedrine

7.4.1. Enantiopure Norephedrine

Enantiopure norephedrine (Fig. 7.9) is a white powder which melts at 51–53°C (according to the supplier, Tab. 7.1). There is no evidence that it is hygroscopic. No crystal structure is reported for enantiopure norephedrine.

Crystallization

It was not possible to sublime crystals of enantiopure norephedrine at room temperature (22–23°C) in a time period of a few hours. The air conditioner was used to lower the room temperature and thus also the upper window of the cell to 18–20°C. The evacuation of the sublimation cell to less than 1 mbar already led to single crystals as well as a few polycrystals without the need of heating up the bottom of the cell. At temperatures above 28°C (bottom window) liquid drops of norephedrine condensed on the top window (Tab. 7.1).

The habit of the obtained norephedrine crystals was varying. Single crystals showed diverse profiles from triangular to hexagonal as well as tabular and platy habits. FTIR measurements exhibited three types of spectra (see Fig. 7.10) which might be due to different crystal faces or due to different polymorphs. Squarish tabular crystals (with variable profiles) revealed spectra denoted Face A (see Fig. 7.10). Platy crystals showed spectra named Face B, whereas Face C spectra

Figure 7.9.: Frozen and relaxed monomer units ((1*S*,2*R*)-enantiomer) taken from the crystal structure of racemic norephedrine [89] as well as the most stable monomer [83, 87] (B3LYP/6-311++G(3df,2p) level). Centers of chirality are marked with an asterisk (*).

Figure 7.10.: Enantiopure norephedrine polarization FTIR spectra of face A, B, and C. The arrows show the direction of the electric field vector. Spectra of face B are multiplied by a factor of 3. The visual pictures of the measured crystals are shown above the corresponding spectra. Band positions are given in cm^{-1} .

were obtained after measuring elongated tabular crystals (see Fig. 7.10). The occurrence of the three spectral types was nearly equally distributed. It was not possible to perform rotation measurements in order to verify if the spectral differences are caused by different faces of the same polymorph. The density of sublimated crystals on the substrate was rather high, so the isolation of the designated crystals was not possible. Furthermore, the different morphologies would have made an assignment to specific faces difficult.

ND/OD-deuterated enantiopure norephedrine was obtained from a solution of (1*S*,2*R*)-norephedrine in D_2O . The solution was evacuated in the sublimation cell at a laboratory temperature of 15°C (with opened windows in winter time). Liquid drops were obtained at the bottom and the top of the cell. By lowering the room temperature to 10°C two types of polycrystals formed at the top of the cell. There

Figure 7.11.: ND/OD-deuterated enantiopure norephedrine FTIR spectra of the melt (top), of a polycrystal of type I (center), and polarized FTIR spectra of a polycrystal of type II (bottom) after sublimation. The arrows show the direction of the electric field vector. The measured section of the type II polycrystal is shown above the corresponding spectra. The type I crystal did not show much contrast and is therefore not shown. Band positions are given in cm^{-1} .

were polycrystals which contained oval single crystals of $5\text{--}10\ \mu\text{m}$ (type I) as well as platy polycrystals with a defined growth direction (type II). In Fig. 7.11 FTIR spectra of a liquid drop and a polycrystal of type I as well as polarized FTIR spectra of a type II polycrystal are shown. The visual image depicted in Fig. 7.11 shows a section of the polycrystal measured. The type I spectrum shows similar C-H stretching patterns as the spectrum of the nondeuterated face C crystal. Therefore, analogous faces can be assumed. There is no nondeuterated spectrum which corresponds to the ND/OD-deuterated type II spectrum. Either the faces of the crystal correspond to different crystallographic axes or a polymorphic form is present.

FTIR Spectra

The vibrational assignments of enantiopure norephedrine are summarized in Tabs. 7.8 and 7.9. The assignments of the N-H and O-H stretching and the N-H bending modes are performed by comparison of experimental and predicted

wavenumbers (see also Sect. 7.3) as well as by comparing spectra of the nondeuterated and ND/OD deuterated substance in which the corresponding bands are shifted towards lower wavenumber. The positions and intensities of the N-H stretching modes will be discussed in Sect. 7.8. The N-H bending band is slightly blue shifted with regard to the scaled relaxed monomer prediction (see the comparison of experimental and oriented gas model spectra of racemic norephedrine in Fig. 7.18 later on) due to hydrogen bonding (Sect. 7.3).

The band at $3182/3184\text{ cm}^{-1}$ in the spectra of the nondeuterated compound (Fig. 7.10) vanishes upon deuteration (Fig. 7.11). Thus, it is also caused by the NH or OH group. It can be more specifically assigned to the N-H bending overtone with the fundamental being at $1608/1606\text{ cm}^{-1}$. The band appears about 35 cm^{-1} more red shifted than a harmonic overtone would be ($3216/3217\text{ cm}^{-1}$). The red shift results from a negative diagonal anharmonicity constant ($x_{1,1}$) [79] and a Fermi-resonance between the N-H bending overtone and the symmetric N-H stretching mode [187, 188].

In the spectrum of ND/OD deuterated enantiopure norephedrine three bands appear in the N-D stretching region of type I (Fig. 7.11) and only two bands in the spectra of the melt and the type II crystal. The bands at 2490 cm^{-1} and 2376 cm^{-1} in the spectrum of type I can be assigned to the asymmetric and symmetric N-D stretching modes in agreement with the assignments made for the other primary phenylpropanolamines in this Chapter. They show a larger splitting than the corresponding nondeuterated N-H stretching bands, consistent with the predictions (see Sect. 7.3). The band at 2416 cm^{-1} corresponds to the localized and bonded N-D stretching mode of partly deuterated norephedrine resulting from an isotopic exchange. The band at 3273 cm^{-1} is the analogous localized N-H stretching mode. Both bands appear in closer vicinity to the symmetric than to the asymmetric stretching mode. In the spectra of type II and the liquid an N-D stretching band at $2499/2501\text{ cm}^{-1}$ appears broadened and slightly blue shifted compared to the asymmetric N-D mode in the type I spectrum due to a weakening of the deuteration bonds. The symmetric stretch disappears in the broad O-H stretching band.

A comparison of molten phase spectra measured in the sublimation cell of ND/OD-deuterated and nondeuterated enantiopure norephedrine as well as ATR spectra of the solid state of enantiopure norephedrine is shown in Fig. 7.12. The N-H and N-D stretching bands are broadened in the liquid phase due to the lack of a periodic hydrogen bond network. Also, the positions of the N-H stretching bands

Table 7.8.: Assignments of experimental band maxima in the FTIR microscopic spectra of enantiopure norephedrine of face A, face B, face C (Fig. 7.10), FTIR-ATR spectra (without ATR correction, Fig. 7.2), FTIR spectra of the melt (not shown) as well as calculations of the relaxed monomer unit taken from the crystal structure (Mon_{crystal}) on the B3LYP/6-311++G(3df,2p) level. All wavenumbers are given in cm⁻¹. The stretching and bending vibrations are indicated as ν and δ and the symmetric and asymmetric vibrations with sym and asym. Tentative assignments and bands without assignment are labeled with a question mark (?).

Figure 7.12.: Liquid transmission spectra of the ND/OD-deuterated and the nondeuterated melt as well as an FTIR-ATR spectrum of the nondeuterated solid sample of enantiopure norephedrine. The ATR spectrum is multiplied by a factor of 4. Band positions are given in cm^{-1} .

are less red shifted in the spectrum of the melt. In analogy, the N-H bending mode is less blue shifted. The presence of the N-H bending band in the region around 1600 cm^{-1} can nicely be recognized by a comparison with the ND/OD-deuterated norephedrine spectrum in which this mode does not appear. The positions of the C-H stretching bands are nearly the same in the ND/OD- and the nondeuterated norephedrine spectra.

The aromatic C-H and C-C_{aromatic} stretching bands are assigned according to observations made in the cases of methyl mandelate, mandelic acid, and the other phenylpropanolamines in this Chapter. The tentative assignment of the aliphatic C-H stretching modes is performed on the basis of the assignments made for the other phenylpropanolamines in this Chapter.

So far, no crystal structure of enantiopure norephedrine has been published. Thus, only the spectral differences of the three faces can be used to infer the molecular orientation within the crystal. The orientation along the different faces will be discussed separately. The conclusions about the molecular orientation refer to the average over the unit cell. Single molecules within the unit cell may deviate from the proposed orientation. Note, that it is only a simplistic scheme which does not reflect

the dimensionality correctly and which does not include all functional groups.

The O-H stretching band appears for both polarizations of face A, but the intensities are approximately two times higher for a horizontal polarization. Nearly horizontally aligned O-H...X hydrogen bonds can be assumed. The case of the NH₂ group is more complicated. The intensities of the asymmetric N-H stretching and the N-H bending band are nearly equal for both polarizations. For the asymmetric N-H stretching and the N-H bending mode a diagonal transition dipole vector can be assumed, while the one of the symmetric modes seems to be horizontally aligned. In Sect. 7.3 the influence of a hydrogen bond on the vibrational transition dipole vector of the NH₂ group was analyzed. It was shown, that in the case of an N-H...X hydrogen bond both the asymmetric and symmetric N-H transition dipole vectors align more or less along the N-H hydrogen bond. Since the polarization behavior of the asymmetric and symmetric N-H stretching bands differ, this is only partially the case. The directions of the transition dipole vectors of the three N-H modes suggest a sideways slightly downpointing orientation of the amine group (see Fig. 7.13). The C-C_{aromatic,3} stretching band at 1493 cm⁻¹ is much stronger at a vertical polarization, while the C-C_{aromatic,4} stretching band at 1456 cm⁻¹ shows the opposite behavior. Therefore, a vertical transition dipole vector and a vertical orientation of the C-C stem can be assumed. The symmetric C-H stretching band of the phenyl group is visible for both directions of polarization. The band seems to be more pronounced in the vertically polarized spectrum. But this is probably affected by the overlaying O-H stretching band. It can be assumed that the vibrational transition dipole vector is diagonal to the probed directions. This and the relatively strong intensity of the symmetric C-H stretching band fits to a view on the plane of the aromatic group with the C-C stem being vertically aligned (in agreement with the considerations made above).

In the spectra of face B the polarization behavior of the four N-H stretching and bending bands and the O-H stretching band differs. The N-H bands are strong for the vertical polarization, while the O-H stretching band appears in the horizontally polarized spectra. This is in agreement with a horizontal O-H and a vertical N-H hydrogen bond. The C-C_{aromatic,3} stretching band does not appear in the spectra of face B. The same is true for the symmetric phenyl C-H stretching mode. A view along the C-C stem can therefore be assumed. However, the C-C_{aromatic,4} stretching band at 1454 cm⁻¹ is present for both polarizations, but shows a stronger intensity at a vertical polarization. This points at a rather vertical orientation of the phenyl

Figure 7.13.: Schematic layout of a norephedrine molecule oriented according to the measured crystal faces. Note, that this simplistic view does not reflect the dimensionality correctly and that it does not include all functional groups.

group. The proposed orientation corresponding to face B is depicted in Fig. 7.13. It shows substantial analogies to the orientation of a face A racemic crystal (see Sect. 7.4.2) rotated by 90° around the z -axis. This is in agreement with very similar polarization spectra and similar morphologies. It can be assumed that the crystal structures are alike.

Assuming that the tentative assignments of the C-H stretching modes in Tab. 7.8 are correct, one can also derive the orientations of the aliphatic C-H groups of face B (here the C-H stretching region does not suffer from oversaturation). The asymmetric1 methyl stretching at 2999 cm^{-1} is more intense for a vertical polarization, while the asymmetric2 methyl stretching at 2962 cm^{-1} is intense in the horizontally polarized spectrum. The symmetric stretching is stronger in the vertical polarization. Therefore, the methyl group is oriented such that one CH points upwards and the other two are diagonally aligned. The C- CH_3 stem points more or less into the z direction. The α -acidic C-H stretching mode is present in the horizontally polarized spectrum and the β -acidic C-H stretching in the vertically polarized one. Thus, the α -acidic CH is horizontally and the β -acidic CH vertically oriented. The proposed orientation is shown in Fig. 7.14. Note that the OH group may be rotated since the spectral information of the O-H stretching band refers to the direction of the hydrogen bond. For the NH_2 group this is only partially the case. The vibrational transition dipole vector of the N-H stretching mode also aligns along the hydrogen bond. However, the vector of the N-H bending mode is mainly unaffected (see Sect. 7.3).

In face C spectra the O-H stretching band is less pronounced, but shows a strong polarization dependence. It appears at a vertical polarization. Therefore, vertically

Figure 7.14.: Proposed average conformation and orientation of a norephedrine molecule according to face B of enantiopure norephedrine.

oriented O-H hydrogen bonds with inclination towards the direction of measurement can be assumed. The asymmetric and symmetric N-H stretching bands as well as the N-H bending fundamental and overtone are present for both directions of polarization, but are more intense in the horizontally polarized spectrum. This points at rather horizontally aligned N-H hydrogen bonds. The C-C_{aromatic,3} is more pronounced in the spectra of face C, while the intensity of the C-C_{aromatic,4} stretching band is more or less equal for both polarizations. This leads to the inconsistent conclusion of a horizontally oriented C-C stem and a diagonally oriented phenyl ring. The truth is probably somewhere in between as depicted in Fig. 7.13.

The proposed orientations of face A and C correspond to a nearly 90° rotation around the *z* axis. The two orientations might correspond to similar faces of crystals which grew slightly screwed to each other. But, the fact that the two N-H stretching bands behave differently upon polarization points rather at the formation of different polymorphs. The orientations of face B and C can be obtained by a 90° rotation around the *y* axis. Therefore, face B and C might belong to different faces of analogous crystals. However, the morphologies are different.

The N-H stretching and bending positions which are the same for all three faces deviate only little from the positions observed for racemic norephedrine (see Fig. 7.2). A similar hydrogen bonded network and a similar conformation of the monomer units can therefore be assumed. The mismatch of the proposed orientations and the irregular habit of the sublimated crystals points at a disordered crystal structure or at the formation of polymorphs.

7.4.2. Racemic Norephedrine

Racemic norephedrine (Fig. 7.9) melts at 102°C under ambient pressure (according to the supplier, see Tab. 7.1). There is no evidence that it is hygroscopic.

Crystal Structure

Racemic norephedrine crystallizes in the monoclinic space group $P2_1/c$ by slow evaporation of a solution of chloroform (CSD REF Code: NOREPH01) [89, 172]. It contains four molecules in the unit cell ($Z=4$) and one molecule in the asymmetric unit ($Z'=1$). Norephedrine molecules of the same chirality are connected via O-H...N hydrogen bonds (1.9 Å, green dots and circles) more or less along the crystallographic b axis (see Fig. 7.15 and Fig. 7.19 later on). Every molecule is connected to one opposite enantiomer by two reciprocal weak N-H...O hydrogen bonds of 2.3 Å length along the a/c bisector (purple dots and circles). By these two interactions infinite zigzag strands of $\cdot[\cdot\text{O-H}\cdots\text{N-H}\cdot]\cdots$ hydrogen bonds along the c axis are formed (yellow highlight). Every molecule is part of two neighboring counterpropagating zigzag strands. In such a strand the O-H...N hydrogen bonded molecules have the same chirality, while the N-H...O bonds connect opposite enantiomers. The hydrogen bonded layers are connected by π -interactions between the phenyl groups.

Crystallization

In order to sublime racemic norephedrine a freshly prepared 1:1 mixture of (1*S*,2*R*)- and (1*R*,2*S*)-norephedrine was used. In a first attempt, crystals already sublimated without tempering the bottom of the cell at a pressure below 1 mbar with the use of the air conditioner (18–20°C) as in the case of enantiopure norephedrine (see Sect. 7.4.1). FTIR spectra (not shown) are equivalent to those of the enantiopure substance. This can either be explained by the formation of enantiopure crystals or by differences between the enantiopure and racemic substance which are too small for the applied resolution.

Another 1:1 mixture of (1*S*,2*R*)- and (1*R*,2*S*)-norephedrine which was prepared in a separate flask and reevacuated every week over a period of two months behaved differently. In this case the sublimation temperature was 40°C. Crystals obtained by this procedure grew into polycrystals as well as into single platy crystals with

Figure 7.15.: Schematic view of the hydrogen bond network in racemic norephedrine. The O-H...N hydrogen bonds are marked with green dots and the weaker N-H...O hydrogen bonds with smaller purple dots. An infinite cooperative zigzag strand is highlighted in yellow. The phenyl rings pointing up are filled in black, whereas phenyl rings pointing down are represented by open circles. The second NH is not depicted, because it is not involved in hydrogen bonds. It also has a nonvanishing projection onto the depicted plane. The configuration of the norephedrine molecules is given.

varying profiles (as was the case for the enantiopure compound, see Sect. 7.4.1). Both crystal types led to the same spectra shown in Fig. 7.16. Differences to the spectra of the enantiopure crystals in Figs. 7.10 and 7.11 appear for a variety of bands. The formation of a hydrate can be excluded since no additional strong O-H stretching band is present. It can be assumed that racemic crystals were present. The formation of an enantiopure polymorph is also possible but less likely. The spectral differences between the enantiopure and the racemic compound will be discussed in Sect. 7.4.3. It was not possible to measure spectra of the other faces. This was due to the frequently polycrystalline nature and due to the variable profile of the single crystals, making an assignment to specific faces difficult.

ND/OD-deuterated racemic norephedrine crystals were obtained using the pre-treated 1:1 mixture of (1*S*,2*R*)- and (1*R*,2*S*)-norephedrine. A spatula tip of the pestled 1:1 mixture was dissolved in 10 drops of D₂O in the open sublimation cell and heated to 30°C. After cooling the solution down to room temperature the cell was closed and evacuated. A solid substance with undefined habit crystallized from the solution. Crystalline strings with a defined direction of growth were used for FTIR polarization measurements (see Fig. 7.17). A visual picture of the measured section of the crystal is shown above the spectra.

Sublimation of the ND/OD-deuterated racemic norephedrine at 45°C led to platy crystals with variable profiles (triangular–hexagonal) as well. Polarization spectra are equivalent to the ones measured using the crystals obtained directly from the solution (see Fig. 7.17). It can be noticed that a partial exchange of deuterium by hydrogen from ND to NH and from OD to OH took place during the sublimation process. The N-H and O-H stretching bands as well as the band at 2422 cm⁻¹ and the region around 1450 cm⁻¹ increase, while the N-D and O-D stretching bands decrease compared to the spectra recorded using crystals from the solution.

A comparison of nondeuterated and ND/OD-deuterated polarization spectra (Figs. 7.16 and 7.17) of racemic norephedrine exhibits similarities in the C-H stretching region and in the behavior of the N-H and N-D as well as the O-H and O-D stretching bands. Thus, it is likely that analogous faces had been measured. All spectra are therefore denoted Face A.

Figure 7.16.: Racemic norephedrine polarization FTIR spectra of face A. The arrows show the direction of the electric field vector. The visual pictures of the measured crystal are shown above the corresponding spectra. Band positions are given in cm^{-1} .

FTIR Spectra

The assignments of the experimental bands of racemic norephedrine are summarized in Tab. 7.10. The N-H and O-H modes are assigned according to the quantum chemical predictions and the preliminary spectral considerations in Sect. 7.3. The experimental bands are also assigned by the comparison of nondeuterated and ND/OD-deuterated pseudonorephedrine spectra as well as by comparison with the spectral positions of the other investigated phenylpropanolamines.

A comparison of the spectra of the ND/OD-deuterated crystals obtained from a solution and by sublimation (Fig. 7.17) reveals an N-H/D bending mode of partly deuterated norephedrine at 1452 cm^{-1} . The band intensifies after the ND/OD-deuterated substance is exposed to humidity during the sublimation process analogous to the localized N-H and N-D stretching bands. The experimental position is also in agreement with the predicted wavenumbers of an $\text{N-DH}\cdots\text{O}$ and an $\text{N-HD}\cdots\text{O}$ bonded amine group (see Sect. 7.3). The N-D bending mode of fully ND/OD-deuterated norephedrine appears at 1211 cm^{-1} (not shown).

The aromatic C-H and the $\text{C-C}_{\text{aromatic}}$ wavenumbers are in agreement with

Figure 7.17.: ND/OD-deuterated racemic norephedrine polarization FTIR spectra of face A. Crystals were obtained from a solution of D₂O (bottom, sol) and by sublimation (top, subl). The arrows show the direction of the electric field vector. The visual pictures of the measured crystals are shown above the corresponding spectra. The crystal obtained from the solution extended beyond the measured section which is displayed. Band positions are given in cm⁻¹.

Table 7.10.: Assignments of experimental band maxima in the FTIR microscopic spectra of nondeuterated (Fig. 7.16) and ND/OD-deuterated racemic norephedrine of face A (Fig. 7.17), FTIR-ATR spectra (without ATR correction, Fig. 7.2) as well as calculations of the relaxed monomer unit taken from the crystal structure (Mon_{crystal}) on the B3LYP/6-311++G(3df,2p) level. All wavenumbers are given in cm⁻¹. The stretching and bending vibrations are indicated as ν and δ and the symmetric and asymmetric vibrations with sym and asym. Tentative assignments and bands without assignment are labeled with a question mark (?).

the spectral positions of methyl mandelate, mandelic acid, and the other phenylpropanolamines in this Chapter. A tentative assignment of the aliphatic C-H stretching modes is performed after the determination of the molecular orientation in agreement with the assignments of the other phenylpropanolamines in this Chapter.

Fig 7.16 shows a strong dependence of the N-H and O-H stretching bands on the direction of polarization. The O-H and both N-H stretching band intensities are complementary and thus the transition dipole moments of these modes are approximately perpendicular to each other within face A (see Supplement F) and more or less aligned with the polarizer grid position. A similar but less pronounced contrast is found for the N-D and the O-D stretching bands (see Fig. 7.17). Quantum chemical calculations of the isolated relaxed crystal monomer ((1*R*,2*S*)-norephedrine) predict nearly parallel transition dipole vectors of the asymmetric N-H stretching mode and the O-H stretching vibration, while the one of the symmetric N-H stretching mode is perpendicular (see Supplement F). The transition dipole vectors of the N-H stretching modes cannot be predicted well using monomer calculations. The vectors of both N-H stretching modes tend to align along the N-H \cdots O hydrogen bond as shown for ethylamine in Sect. 7.3. The remaining polarization contrast between the N-H and O-H stretching bands can partly be explained by a rotation of the O-H group during structure optimization (see Fig. 7.9). The angle between the OH group and the bisector of the NH₂ group decreases by 18° (from 122° to 104°). Furthermore, the O-H \cdots N and N-H \cdots O hydrogen bonds are nearly orthogonal to each other in the crystal structure (Figs. 7.15 and 7.19) [89]. It can therefore be assumed that also the vibrational transition dipole vectors are nearly orthogonal to each other which would match the above mentioned experimental observations. The same is true for the N-D (2486 cm⁻¹ and 2370 cm⁻¹) and O-D stretching bands. The bands at 3278 cm⁻¹ and at 2422 cm⁻¹ can be assigned to localized deuterium bonded modes of partly deuterated norephedrine as in the case of enantiopure norephedrine (see Sect. 7.4.1). They show the same polarization behavior as the asymmetric and symmetric modes.

A strong dependence on the direction of polarization is also found for the bands at 1608 cm⁻¹, 1500 cm⁻¹, and 1481 cm⁻¹. All of these bands are intense for a horizontal polarization in analogy to the N-H stretching bands. The band at 1608 cm⁻¹ is due to an overlap of the C-C_{aromatic,1} stretching and the N-H bending mode. The N-H bending band vanishes almost completely after deuteration revealing a less

intense band at 1603 cm^{-1} . This band is only caused by the $\text{C-C}_{\text{aromatic},1}$ stretching since the N-D bending is shifted towards lower wavenumbers upon deuteration. The $\text{C-C}_{\text{aromatic},1}$ stretching band seems to intensify for a horizontal polarization. But since the sublimated crystals are not fully deuterated (the N-H bending mode might lead to an increase of intensity in the region of 1603 cm^{-1}) and because there are contributions of atmospheric water vapor, the intensity differences are not reliable. The bands at 1500 cm^{-1} and 1481 cm^{-1} might be due to a combination of the $\text{C-C}_{\text{aromatic},3}$ stretching and a mixed bending mode of the O-H, the α - and β -acidic C-H groups (denoted OH in the right part of Fig 7.18). The mixed O-H, α - and β -acidic C-H mode is predicted at 92 cm^{-1} lower wavenumbers than the $\text{C-C}_{\text{aromatic},3}$ mode, but it might appear at higher wavenumbers due to a blue shift caused by the hydrogen bonds within the crystal. After deuteration both bands vanish exhibiting the former presence of an O-H or N-H mode. A band appearing at 1495 cm^{-1} can clearly be assigned to the $\text{C-C}_{\text{aromatic},3}$ stretching mode. The two absorptions at 1500 cm^{-1} and 1481 cm^{-1} are only observed for racemic norephedrine and not for enantiopure norephedrine or the other phenylpropanolamines investigated in the present work. A coupling of the $\text{C-C}_{\text{aromatic},3}$ stretching and the mixed O-H/C-H $_{\alpha}$ /C-H $_{\beta}$ bending mode probably causes a splitting towards higher and lower wavenumbers.

The band at 1452 cm^{-1} is rather independent of the direction of polarization for both the nondeuterated and the ND/OD-deuterated racemic norephedrine. Only a slight increase in intensity can be observed for a horizontal polarization. This band is probably caused by a combination of the C-H $_3$ bending and the $\text{C-C}_{\text{aromatic},4}$ stretching modes.

An assignment of the molecular orientation of racemic norephedrine within the crystal is difficult since it was not possible to measure more than one face and because of the effect of hydrogen bonding on the relative direction of vibrational transition dipole vectors of the N-H and O-H and the N-D and O-D stretching bands (see above). The measured face of racemic norephedrine (face A) most likely corresponds to a view between the crystallographic a and c axes (a/c). In this a/c view the hydrogen bonded network of O-H \cdots N and N-H \cdots O connected strands is most pronounced. It can be assumed that these two rather strong interactions determine the direction of the crystallization growth. A comparison of experimental (non-deuterated and deuterated) polarization FTIR-spectra of face A and oriented gas model polarization spectra of the a/c view is shown in Fig. 7.18. There is a good

agreement between the intensity ratios of the O-H stretching band as well as the N-H bending and the mixed O-H/C-H $_{\alpha}$ /C-H $_{\beta}$ bending mode. This supports the assignment of face A to the *a/c* view. A mismatch with regard to the intensity ratios of the N-H stretching band can be noticed. As discussed above, this discrepancy results from the influence of the N-H \cdots O hydrogen bond within the crystal which itself is nearly orthogonal to the O-H \cdots N hydrogen bond. A mismatch of the experimental and simulated N-H stretching band is therefore expected. The C-C $_{\text{aromatic},3}$ mode does not appear in the spectra, while the intensity of the C-C $_{\text{aromatic},4}$ band is equal for both polarizations. It can be inferred that the C-C stem points into the direction of the radiation with the phenyl ring being intermediate a horizontal and vertical position which is the case in the *a/c* view. Overall, there is some evidence that face A corresponds to the *a/c* view. In order to verify this assumption measurements of the two other faces would be needed.

The C-H stretching region is more complicated. The aromatic C-H stretching modes appear at similar wavenumbers as in the spectra of methyl mandelate and mandelic acid (see Tabs. 7.4 and 7.10) but the aliphatic C-H stretches are more red shifted as predicted by the monomer calculations (see Supplement F). An assignment by comparing the predicted and experimental sequence is not possible due to the presence of additional bands, probably caused by overtones of the C-H bending modes. Nonetheless, the polarization behavior provides some hints for a tentative assignment. The methyl group is horizontally aligned in the proposed orientation (see Fig. 7.19). Therefore, the symmetric stretching band should be more intense in the horizontally polarized spectra such as the band at 2954 cm $^{-1}$. However, the band at 2954 cm $^{-1}$ does not appear in the spectra of enantiopure norephedrine. The symmetric methyl stretching mode is therefore tentatively assigned to the band at 2920 cm $^{-1}$. Note, that the experimental and predicted polarization behavior do not match. The C-H $_{3,\text{asym}2}$ mode has a vertically aligned transition dipole vector and matches the behavior of the band at 2979 cm $^{-1}$. The other asymmetric methyl mode points into the direction of measurement with a contribution in the vertical direction. Its polarization behavior fits the band at 3028 cm $^{-1}$. Nonetheless, this mode is assigned to the band at 3004 cm $^{-1}$ since it matches the assignments in the spectra of the other phenylpropanolamines. Also, the scaled position is in better agreement with the band at 3004 cm $^{-1}$. The vibrational transition dipole vectors of the acidic C-H modes are predicted to align more or less along the C-H bond (see Supplement F). Therefore, the α -acidic C-H stretching mode should appear for both

Figure 7.18.: Comparison of experimental and oriented gas model polarization spectra without deuteration (B3LYP/6-311++G(3df,2p) level) of face A of racemic norephedrine. The nondeuterated spectra (top, black), the ND/OD-deuterated spectra (center, green), and oriented gas model spectra (bottom, blue) are shown. Harmonic wavenumbers are scaled by a factor of 0.966 to account for anharmonicity. Assigned bands in the left part are stretching modes. The aromatic, asymmetric (asym1 and asym2), symmetric, and acidic C-H stretching modes (α and β) are indicated. The N-H bending, several C-C_{aromatic} stretching (abbreviated C-C_x), and the mixed O-H/C-H _{α} /C-H _{β} bending modes (abbreviated O-H) are shown in the right part.

Figure 7.19.: Molecular orientation of racemic norephedrine along the three crystal faces. The crystal structure was taken from Ref. [89]. The configurations of the individual molecules are labeled. The shape of the frames does not imply a crystal habit. Green circles mark selected O-H \cdots N and purple circles N-H \cdots O hydrogen bonds.

polarizations. It is assigned to the band at 2866 cm^{-1} . The β -acidic mode has a vertically aligned transition dipole, but shows predominantly into the direction of measurement. It is assigned to the band at 2844 cm^{-1} . The unassigned bands in Tab. 7.10 probably belong to overtone or combination modes of the C-H group.

7.4.3. Comparison of Enantiopure and Racemic Norephedrine

There are spectral differences for enantiopure and racemic norephedrine microcrystals and powder (see Figs. 7.20 and 7.2) as a result of different crystal structures, itself a manifestation of chirality recognition. Toda et al. investigated the racemic crystal formation of a powdered (1*S*,2*R*)- and (1*R*,2*S*)-norephedrine mixture via IR spectroscopy in Nujoll mull and by X-ray structure analysis [165]. They found a shift of 5 cm^{-1} from 3335 cm^{-1} (enantiopure norephedrine) to 3330 cm^{-1} (racemic compound) and no shift for the band at 3270 cm^{-1} . They incorrectly assigned these bands to the O-H and not to the N-H stretching vibration. Within this project the asymmetric N-H stretching band shifted from 3338 cm^{-1} to 3332 cm^{-1} (see Fig. 7.20 as well as Tabs. 7.8 and 7.10) in the FTIR spectra of the microcrystals. Thus, a comparable red shift of 6 cm^{-1} was found. The symmetric N-H stretching band slightly blue shifts from 3271 cm^{-1} in the enantiopure case to 3273 cm^{-1} in the spectra of racemic norephedrine. In Ref. [165] no shift is reported. The symmetric N-H stretching mode is slightly more intense in the ATR spectra of the racemic compound (Fig. 7.2).

Further spectral differences between enantiopure and racemic norephedrine can be noticed in the O-H, C-H, and C-C stretching as well as O-H, N-H, and C-H₃ bending region (see Figs. 7.2 and 7.20). These differences will not be discussed in detail. However, it should be emphasized, that in the case of the racemic compound the O-H stretching band has more intense contributions at lower wavenumber which points at stronger O-H hydrogen bonds. Also, the higher intensity of the N-H bending band of the enantiopure compound as well as the appearance of the mixed O-H bending band at 1481 cm^{-1} in the spectra of the racemic compound are noteworthy.

An indication of the chirality recognition is also the difference in temperature used for the sublimation. In order to crystallize the enantiopure compound a temperature range of $18\text{--}20^\circ\text{C}$ was used. On the other hand, the racemic compound crystallized at 40°C which is significantly higher. Also, the melting temperature of racemic norephedrine ($\sim 100^\circ\text{C}$) is significantly higher than the melting temperature of enantiopure norephedrine ($\sim 50^\circ\text{C}$). It can be assumed that the racemic crystals are more stable than the enantiopure compound. This assumption could be verified by measuring the relative vapor pressures via mass spectrometry as performed in the case of methyl mandelate (Chapter 5).

A study of lattice energies using Dreiding II force field of seven homochiral and

Figure 7.20.: Comparison of racemic (rac) and enantiopure (enant) norephedrine polarization FTIR spectra. The arrows show the direction of the electric field vector.

7. *Phenylpropanolamines*

racemic neuroactive substances (e.g., ephedrine derivatives) suggests van der Waals interactions to be the major force for chiral discrimination [189]. Electrostatic and hydrogen bonding energies are assumed to have a minor influence although they are difficult to estimate.

7.5. Pseudonorephedrine

Enantiopure pseudonorephedrine (Fig. 7.21) is a white powder which melts at 76°C (according to the supplier, Tab. 7.1). There is no evidence that it is hygroscopic.

Crystal Structure

(1*S*,2*S*)-Pseudonorephedrine was crystallized as block-like crystals by vapor diffusion from ethyl acetate and hexanes (CSD REF Code: GEVNEB) [90]. The determined space group is $P2_1$ (see also Ref. [172]). Pseudonorephedrine contains two molecules in the unit cell ($Z=2$) and one molecule in the asymmetric unit ($Z'=1$). Infinite strands of $\cdots[\cdots\text{O}-\text{H}\cdots\text{N}-\text{H}\cdots]$ hydrogen bonded zigzag chains ($\text{O}-\text{H}\cdots\text{N}$: 2.0 Å, $\text{N}-\text{H}\cdots\text{O}$: 2.5 Å) are formed along the crystallographic a axis (see Fig. 7.26 later on). Every molecule is part of two hydrogen bonded strands which are aligned parallel along the b axis. In a third dimension van der Waals interactions of the phenyl and the methyl groups take place.

Crystallization

Pseudonorephedrine sublimates at substrate temperatures around 35°C within minutes. The habit of the crystals is tabular. The rotation spectra in Fig. 7.22 of two microcrystals show that there are clear differences concerning the C-H and C-C_{aromatic} stretching bands of face A and of face B and C. These differences can be used to

Figure 7.21.: Frozen and relaxed monomer units taken from the crystal structure of pseudonorephedrine [90] as well as the most stable monomer (assumed, B3LYP/6-311++G(3df,2p) level). Centers of chirality are marked with an asterisk (*).

Figure 7.22.: Enantiopure pseudonorephedrine FTIR spectra obtained after rotation of crystals showing type A and type B spectra. Rotating the crystal interconverts the spectral types A and B and exhibits a spectrum of type C. The visual pictures of the measured crystals are shown above the corresponding spectra. The saturation of the spectra is substantial.

assign spectra to face A. On the other hand, the spectra of face B and C are quite similar. Subtle differences in the intensity of the O-H stretching and the contour of the region below 2000 cm^{-1} can be used to tentatively distinguish spectra of face B and C. The distribution of crystals growing on face A, B, and C was found to be largely equal. In Fig 7.23 FTIR polarization spectra of face A and B are shown.

In order to obtain ND/OD-deuterated pseudonorephedrine the pestled compound (tip of spatula) was dissolved in 8 drops of D_2O in the unclosed sublimation cell. The cell was heated up to 35°C to accelerate the solvation process. After cooling back to room temperature the cell was closed and evacuated. ND/OD-deuterated pseudonorephedrine started to crystallize due to the evaporation of D_2O to a crystal size of 0.05–1 mm within minutes. Crystals obtained by this procedure had a platy habit. Polarized FTIR spectra of the crystals are shown in Fig. 7.24. In the case of the crystals obtained from solution no correlation between the face (habit) and the type of spectra was possible. The denominations Face A and Face B were made after comparison with spectral types of sublimated crystals.

Sublimated ND/OD-deuterated pseudonorephedrine crystals were grown by us-

ing the crystals obtained after evaporation of D_2O . Spectra of sublimated ND/OD-deuterated pseudonorephedrine crystals are shown in Fig. 7.25. The assignment of spectral types to faces was performed by comparing the habit of the ND/OD-deuterated and nondeuterated crystals. Spectra shown in Figs. 7.24 and 7.25 were recorded in the closed sublimation cell (not on the removed CaF_2 substrate).

FTIR Spectra

The assignments of the experimental bands are summarized in Tab. 7.11 for non-deuterated and in Tab. 7.12 for ND/OD-deuterated pseudonorephedrine. The N-H and O-H stretching and the (mixed) bending modes are assigned according to the quantum chemical predictions and the preliminary spectral considerations in Sect. 7.3. The experimental bands are also assigned by comparison of non-deuterated and ND/OD-deuterated pseudonorephedrine spectra. In analogy to norephedrine, also the N-H bending overtone is assigned.

The aromatic C-H and the $\text{C-C}_{\text{aromatic}}$ wavenumbers are in agreement with the spectral positions of methyl mandelate, mandelic acid, and the other phenyl-

Figure 7.24.: ND/OD-deuterated enantiopure pseudonorephedrine polarization FTIR spectra crystallized from D_2O solution of type A and B. The arrows show the direction of the electric field vector. The visual pictures of the measured crystals are shown above the corresponding spectra. The visual picture of the crystal exhibiting a type B spectrum was multiplied by a factor of 0.5. Band positions are given in cm^{-1} .

propanolamines in this Chapter. The assignment of the aliphatic C-H stretching modes will be performed after determination of the molecular orientation on the basis of their polarization behavior. Also, the assignments of the mixed modes will be confirmed by their polarization behavior.

The bands at $3355/3354\text{ cm}^{-1}$ and $3288/3290\text{ cm}^{-1}$ in Fig. 7.23 can be assigned to the asymmetric and the symmetric N-H stretching modes. Two bands at 2503 cm^{-1} and $2420/2418\text{ cm}^{-1}$ appear in the N-D stretching region of ND/OD-deuterated pseudonorephedrine obtained out of the solution (Fig. 7.24). These bands are caused by the asymmetric and the symmetric N-D stretching modes. After sublimation of the ND/OD deuterated compound two further bands at 3336 cm^{-1} and 3307 cm^{-1} arise in the N-H stretching region and one further band at 2443 cm^{-1} in the N-D stretching region (Fig. 7.25). These bands can be assigned to localized N-H and N-D stretching modes of partly deuterated pseudonorephedrine (see Sect. 7.3). The more intense and more red shifted band at 3307 cm^{-1} is caused by the hydrogen bonded N-H, while the band at 3336 cm^{-1} probably corresponds to the free N-H stretching mode. In the N-D stretching region only the bonded N-D band at 2443 cm^{-1} is present. An explanation will be given in Sect. 7.8.

The N-H and O-H stretching bands are present in the spectra of both face A and B for both polarizations (see Fig. 7.23). Thus, the O-H and N-H hydrogen bonds are visible in both orientations. The symmetric aromatic C-H stretching band at 3101 cm^{-1} appears only in the vertically polarized spectrum of face B. The C-C stem is thus not visible in the orientation of face A, while it is vertically oriented in the case of face B (see Supplement F). The $\text{C-C}_{\text{aromatic},1}$ and $\text{C-C}_{\text{aromatic},2}$ stretching bands at 1601 cm^{-1} and 1585 cm^{-1} are overlayed by the N-H bending mode. The resulting broad band is present in the spectra of face A and B. It almost vanishes after deuteration (see Figs. 7.24 and 7.25) revealing the contribution of the $\text{C-C}_{\text{aromatic},1}$ and $\text{C-C}_{\text{aromatic},2}$ stretching modes. Their polarization dependence is in agreement with the orientation of the C-C stem stated above. Furthermore, it can be inferred that the α -acidic CH group is horizontally aligned in Face A and B. The broad band around 1600 cm^{-1} in the nondeuterated pseudonorephedrine spectra decreases almost completely in the vertically polarized spectra of face A (Fig. 7.23). A decrease in intensity can also be observed in the horizontally polarized spectra of face B. Since most contributions belong to the N-H bending mode, it can be inferred that the amine group is rather horizontally aligned in the case of face A and more or less vertically aligned in the case of face B. The $\text{C-C}_{\text{aromatic},3}$ stretching band

appears in the horizontally polarized spectra of face A. It is highest in intensity in the case of a vertical polarization of face B which is in agreement with a vertical orientation of the C-C stem. The C-C_{aromatic,4} band at 1450 cm⁻¹ and 1452 cm⁻¹ is present in all spectra of face A and B. It has an unusually high intensity in the spectra of face A. This increase can be explained by two C-H₃, a mixed C-H₃/C-H_β, and a mixed O-H/C-H_α/C-H_β bending mode at the same spectral position. The slight intensity decrease upon deuteration (see Fig. 7.24) supports the additional assignment of the O-H/C-H_α/C-H_β bending mode to the band at 1450/1452 cm⁻¹.

The spectral differences appearing upon polarization can be used to fix the molecular orientation of face A to a view along the crystallographic *c* axis and face B to a view along the crystallographic *b* axis (see Fig. 7.26). Since there is no noticeable change in conformation due to structure optimization (see Fig. 7.21), monomer calculations should predict the experimental behavior to a reasonable extent.

A comparison of experimental face A and face B spectra with oriented gas model spectra is shown in Fig. 7.27. As expected the red shift of the O-H and N-H stretching modes is underestimated. Good agreement can be noticed for the experimental and predicted intensity ratios of the O-H stretching mode. There is a lack of agreement between the experimental and oriented gas model intensity of the N-H stretching band of face B. In the spectra measured using a vertical polarization the N-H stretching bands are clearly visible, while the simulation predicts them to have no intensity. The weakness of the N-H stretching transition moments can lead to unexpected aggregation-induced reorientations of the dipole moment derivatives [183]. The molecular orientation of face B is shown in Fig. 7.26. It can be seen that the N-H...O hydrogen bonds are almost perfect horizontally aligned. Therefore, also by comparison of the molecular orientation and crystal face no N-H stretching bands would be predicted for a vertical polarization. The mismatch might result from a turned orientation than the proposed one or from polymorphism. Reasonable agreement can be noticed in the lower part of Fig. 7.26 showing that the assignment of face A to a view along the crystallographic *c* axis and of face B to a view along the crystallographic *b* axis is trustworthy.

The knowledge of the molecular orientation and the polarized spectra can be used to assign the bands in the aliphatic C-H stretching region. A comparison of experimental and oriented gas model polarization spectra of the C-H stretching region is shown in the upper part of Fig. 7.27. There is good agreement of the position and polarization behavior of the methyl stretching bands in the ND/OD-deuterated and

Figure 7.26.: Molecular orientation of pseudonorephedrine along the three crystal faces. The crystal structure was taken from Ref. [90]. The continuous frames mark the observed faces, whereas the unobserved face is dash-framed.

Figure 7.27.: Comparison of experimental and oriented gas model polarization spectra without deuteration (B3LYP/6-311++G(3df,2p) level) of face A (left) and face B (right) of pseudonorephedrine. The nondeuterated spectra (top, black), the ND/OD-deuterated spectra (center, green), and oriented gas model spectra (bottom, blue) of nondeuterated (solid line) and ND/OD-deuterated (dashed line) are shown. Harmonic wavenumbers are scaled by a factor of 0.966 to account for anharmonicity. Assigned bands in the two upper parts are stretching modes. C-H stretching modes are indicated. The N-H bending, $C-C_{\text{aromatic},1}$, and $C-C_{\text{aromatic},2}$ (abbreviated N-H+), other $C-C_{\text{aromatic}}$ stretching modes (abbreviated $C-C_x$), $C-H_3$ bending modes, a mixed $C-H_3/C-H_\beta$ bending mode (abbreviated $C-H_{3,\beta}$), and a mixed $O-H/C-H_\alpha/C-H_\beta$ bending mode (abbreviated O-H) are shown in the lower part. The asterisk (*) marks the experimental position of the $C-C_4$ bending mode, both $C-H_3$ bending modes, the mixed $C-H_3/C-H_\beta$ bending mode, and the mixed $O-H/C-H_\alpha/C-H_\beta$ bending mode.

the oriented gas model spectra (scaled by a factor of 0.966, see Chapter 3). Thus, the bands at $2997/2994\text{ cm}^{-1}$, $2970/2972\text{ cm}^{-1}$, and $2933/2935\text{ cm}^{-1}$ can unambiguously be assigned to two asymmetric and the symmetric methyl stretching bands. Also, the polarization behavior of the bands at 2860 cm^{-1} and 2844 cm^{-1} is in good agreement with the predicted direction of the vibrational transition dipole vector of the α - and β -acidic C-H stretching modes. Only, in the case of the vertically polarized spectrum of face B the experimental and predicted behavior of the β -acidic mode deviates. Since, the β -acidic C-H bond is more or less horizontally aligned in the molecular orientation of face B (matches the experimental behavior), the strong intensity in the oriented gas model spectrum is probably an artifact of the rotation method. The scaled red shift of the α -acidic mode is slightly under- and the one of the β -acidic slightly overestimated.

The band at $2877/2879\text{ cm}^{-1}$ cannot be assigned to a C-H stretching mode. It is probably caused by C-H bending overtone. The same is true for the more red shifted bands at 2806 cm^{-1} and 2798 cm^{-1} in the ND/OD-deuterated spectra.

7.6. Ephedrine

Enantiopure anhydrous ephedrine (Fig. 7.28) is a white powder which melts at 37–39°C (according to the supplier, Tab. 7.1). It is a hygroscopic substance. The enantiopure hemihydrate melts at 39–43°C. It is a white to clear substance.

FTIR-ATR spectra have only been recorded for the hemihydrate of ephedrine (see Fig. 7.2). It has not been possible to measure FTIR-ATR spectra of the anhydrous compound. The ephedrine sample used for the measurements was stored in a bottle which had been opened a few months before. Probably, the sample was hydrated in the bottle. Remeasurements with a fresh substance should be carried out.

Crystal Structures

In the case of ephedrine, the crystal structures of anhydrous (1*R*,2*S*)-ephedrine (E-AH) and (1*R*,2*S*)-ephedrine hemihydrate (E-H) are available [91, 172]. The crystal structure of anhydrous ephedrine crystallized from an alcoholic solution was solved by Collier et al. (CSD REF Code: EPHE) [91]. They report a needle-like habit with the *a* axis representing the fastest growth direction. Anhydrous ephedrine crystallizes in the space group $P2_12_12_1$ (see also Ref. [172]). There are four molecules in the unit cell ($Z=4$) and one molecule in the asymmetric unit ($Z'=1$). O-H···N hydrogen bonds

Figure 7.28.: Frozen and relaxed monomer units taken from the crystal structure of anhydrous ephedrine [91] as well as the most stable monomer [82, 85, 87] (B3LYP/6-311++G(3df,2p) level). Centers of chirality are marked with an asterisk (*).

Figure 7.29.: Schematic view of the hydrogen bond network in ephedrine hemihydrate. The O-H \cdots N hydrogen bonds are marked with green dots, N-H \cdots O hydrogen bonds with purple dots, and O-H \cdots O hydrogen bonds with blue dots. A finite cooperative hydrogen bonded strand is highlighted in yellow. Black atoms are above, gray atoms in, and light gray atoms beyond the plane of the water molecules. The ephedrine molecules are reduced to the OH and NH group connected by a straight line.

(2.0 Å) which run along the crystallographic c axis connect the molecules along the a axis (see Fig. 7.32 later on). The strands are connected by π -interactions of the phenyl and the methyl group.

Malone and Parvez reported the space group $B22_12$ for ephedrine hemihydrate in 1978 [172]. A reassignment of platy ephedrine hemihydrate crystals obtained from an aqueous solution led a correction of the space group to $C222_1$ by Collier et al. in 1978 (CSD REF Code: EPHEDH04) [91]. Ephedrine hemihydrate has 8 ephedrine and 6 water molecules in the unit cell. In the asymmetric unit there are one ephedrine and one water molecule as unraveled by X-ray and neutron studies [91, 172, 190]. Two ephedrine molecules form dimeric units which are connected by two O-H \cdots N hydrogen bonds (1.9 Å) along the crystallographic c axis (see Fig. 7.29 and Fig. 7.34 later on). These dimers are linked together by O-H \cdots O hydrogen bonds along the a axis with water being a double proton donor (2.0 Å). It connects the ephedrine dimers to chains. As visualized in Fig. 7.29, there are cooperative (blue and green) and anti-cooperative hydrogen bonds (purple). The chains are held together by π -stacking of two phenyl rings and van der Waals interactions of a phenyl and a methyl group.

Crystallization

In the case of the sublimation experiments only one sublimated polycrystal of anhydrous ephedrine was obtained. It consisted of tabular single crystals. All other sublimation attempts led to a condensation of droplets at the upper window (above 18°C). At temperatures below 18°C nothing happened. It is conceivable that the obtained polycrystal grew on powder of ephedrine sticking on the upper CaF₂ substrate. But this is rather unlikely since the CaF₂ windows had been cleaned before every measurement. Also, as stated above, the powder probably consisted of ephedrine hemihydrate and not the anhydrous compound. The recorded polarized FTIR spectra of the anhydrous ephedrine crystal are shown in Fig. 7.30.

A single crystal of ephedrine hemihydrate was obtained from an aqueous solution. The crystal has a platy habit. Fig. 7.31 shows the visual picture and the polarization FTIR spectra of this crystal. Ivanova et al. recorded linear polarized and nonpolarized IR spectra of ephedrine hemihydrate (grown by slow evaporation from an aqueous solution at room temperature) [191]. The differences to ATR and crystal spectra measured in this work might be due to the KBr pellet technique they used.

For both, the anhydrous and the ephedrine hemihydrate, only one face of one crystal has been measured. The observed faces are arbitrarily denoted Face A. No ND/OD deuteration experiments were carried out for ephedrine (neither anhydrous nor hemihydrate).

FTIR Spectra

The vibrational assignments of ephedrine anhydrate and ephedrine hemihydrate are summarized in Tab. 7.13. The assignments of the N-H and O-H stretching and the mixed C-H₃/N-H bending modes are performed by comparison of experimental and predicted wavenumbers (see also Sect. 7.3).

In the ephedrine hydrate spectra an O-H stretching band pattern appears less red shifted than in the spectra of the other investigated phenylpropanolamines. It is caused by the crystal water which acts as a double proton donor for weaker O-H...O hydrogen bonds and as a double proton acceptor for N-H...O hydrogen bonds (see Sect. 7.3). Cooperative and anti-cooperative effects more or less cancel each other out and additionally cause a less red shifted O-H stretching band [130, 192]. The water O-H stretching band shows contributions to lower wavenumbers (3421 cm⁻¹)

Figure 7.30.: Enantiopure anhydrous ephedrine polarization FTIR spectra. The arrows show the direction of the electric field vector. The visual pictures of the measured crystal are shown above the corresponding spectra. Band positions are given in cm^{-1} .

Figure 7.31.: Enantiopure ephedrine hemihydrate polarization FTIR spectra. The arrows show the direction of the electric field vector. The visual pictures of the measured crystal are shown above the corresponding spectra. Band positions are given in cm^{-1} .

at a vertical polarization which can be assigned to the symmetric stretch. The asymmetric contribution appears at higher wavenumber (3460 cm^{-1}) for the horizontal polarization. In the ATR spectrum of ephedrine hemihydrate (Fig. 7.2) a broad band at $3200\text{--}2200\text{ cm}^{-1}$ is present which can be assigned to the O-H stretching mode of ephedrine. The O-H bending mode of water appears at 1647 cm^{-1} . The shoulder of the N-H stretching band probably results from an asymmetric coupling of the two NH groups bonded to the same water molecule.

The aromatic C-H and C-C_{aromatic} stretching bands of ephedrine anhydrate and hydrate are assigned according to observations made in the case of methyl mandelate, mandelic acid, and the other phenylpropanolamines in this Chapter. The tentative assignment of the aliphatic C-H stretching modes is performed on the basis of the pseudonorephedrine and pseudoephedrine assignments and the predictions. Note, that the predicted C-H stretching positions of ephedrine hemihydrate deviate from the predictions of the other phenylpropanolamines. Nonetheless, the experimental positions are tentatively assigned in analogy.

Face A of anhydrous ephedrine probably corresponds to a view along the crystallographic *b* axis as depicted in Fig. 7.32. But since spectra of the other two faces are missing the assignment cannot be verified. Fig. 7.33 shows a comparison between the experimental spectra of face A and the oriented gas model spectra of a view along the crystallographic *b* axis. There is reasonable agreement regarding the intensity changes of the experimental and simulated N-H and C-C_{aromatic} stretching bands. One might notice that the experimental intensity change of the O-H stretching band does not agree with the simulated one. In Fig. 7.32 the hydrogen bonds in the view of face A are depicted. The O-H...N hydrogen bonds run more or less along the *c* axis. Thus, one would predict the O-H stretching mode to be excited at a vertical polarization as it is the case in the experimental spectra. The discrepancy of experimental and simulated behavior results from a slight rotation of the O-H group during the monomer relaxation. In Fig. 7.28 a comparison of a frozen and a relaxed monomer is displayed showing the structural modification upon relaxation. The C_{aromatic}-C-O-H dihedral angle changes by ca. 30° (from 99° to 67°). This rotation of the O-H group has an effect on the direction of the calculated transition dipole vector. The divergence of experimental and simulated intensity changes of the O-H stretching band in Fig. 7.33 can therefore be explained.

In the lower wavenumber region good agreement between experimental and oriented gas model polarization spectra can be found for the C-C_{aromatic,1}, C-C_{aromatic,3},

7. Phenylpropanolamines

Figure 7.32.: Molecular orientation of anhydrous ephedrine along the three crystal faces. The crystal structure was taken from Ref. [91]. The continuous frame marks the observed face, whereas the unobserved faces are dash-framed.

Figure 7.33.: Comparison of experimental (top, black) and oriented gas model (bottom, blue) polarization spectra (B3LYP/6-311++G(3df,2p) level) of face A of anhydrous ephedrine. Assigned bands in the left part are stretching modes. The C-C_{aromatic} stretching modes (abbreviated C-C_x), mixed C-H₃/N-H bending modes (abbreviated C-H₃ and 1, 2, 4 for the individual modes), a mixed N-H/C-H₃ bending mode (abbreviated N-H), and a mixed O-H/C-H₃ bending mode (abbreviated O-H) are shown in the lower part. The question mark (?) labels an unassigned band.

and C-C_{aromatic,4} stretching modes. These bands appear at 1603 cm⁻¹, 1491 cm⁻¹, and 1448 cm⁻¹. The mixed C-H₃/N-H bending modes and the mixed C-H₃/N-H bending mode cannot unambiguously be assigned. For the assignment performed in Fig. 7.33 and in Tab. 7.13 the calculated order was used. The above mentioned modes are predicted to be more intense at a vertical polarization. This is in good agreement with the experimental vertically polarized spectrum. Here, several bands appear in the region from 1500–1400 cm⁻¹. All in all, Fig. 7.33 shows that it is justified to assume the molecular orientation depicted in Fig. 7.32.

A further indication for the proposed molecular orientation is the consistency of interactions within the crystal and the habit of the grown crystal. As described above a polycrystal consisting of tabular single crystals was obtained. The strongest interaction is the O-H...N hydrogen bond followed by N-H...O hydrogen contacts. These are located in the *ac* plane. Therefore, it can be concluded that face A corresponds to a view along the *b* axis. Nevertheless, spectra of the other faces would be valuable.

An assignment of the molecular orientation of ephedrine hemihydrate is more difficult. According to the comparison of habit and interactions one would expect that face A corresponds to a view along the crystallographic *b* axis. In this view the hydrogen bond network is most pronounced (see Fig. 7.34). However, the crystal was not obtained by sublimation but from an aqueous solution. Therefore, external interactions might have an influence on the crystallization growth and on the crystals habit. The conclusion of the analysis of the polarization spectra is different. Face A does not correspond to a view along the crystallographic *b* axis. As can be seen in Fig. 7.31 there is a striking change in intensity in the case of the O-H bending mode of the water molecule appearing at 1647 cm⁻¹. The direction of the vibrational transition dipole vector of this mode runs along the crystallographic *b* axis. Therefore, it cannot be excited in the view along the *b* axis. The symmetric aromatic C-H stretching mode exhibits some intensity in the horizontally polarized spectrum. A rather diagonal orientation of the C-C stem with the phenyl plane less visible can be inferred since the vibrational transition dipole vector deviates by about 30° from the C-C_{aromatic} axis (see Supplement F). This would match a view along the crystallographic *b* axis. However, this orientation is already excluded.

Interestingly, both the C-C_{aromatic,3} and the C-C_{aromatic,4} stretching band at 1487 cm⁻¹ and 1454 cm⁻¹ are quite high in intensity for both directions of polarization. It can be assumed that the reason is an underlying mixed band with con-

Figure 7.34.: Molecular orientation of ephedrine hemihydrate along the three crystal faces. The crystal structure was taken from Ref. [91]. The continuous frame marks the observed face, whereas the unobserved faces are dash-framed.

tributions of the OH (or NH) group which also causes a shift to lower and higher wavenumbers respectively compared to the positions in the spectra of the other phenylpropanolamines. An ND/OD-deuteration of ephedrine hemihydrate might help to solve this question and to unravel the assignment of the C-H stretching modes. With this information the molecular orientation might more confidently be assigned.

7.7. Pseudoephedrine

7.7.1. Enantiopure Pseudoephedrine

Enantiopure pseudoephedrine (see Fig. 7.35) is a white powder which melts at 116–120°C (according to the supplier, Tab. 7.1). There is no evidence that it is hygroscopic.

Crystal Structure

(1*S*,2*S*)-pseudoephedrine crystallizes in the space group $P2_12_12_1$ (CSD REF Code: PSEPD) [92,172]. It contains four molecules in the unit cell ($Z=4$) and one molecule in the asymmetric unit ($Z'=1$). The molecules are held together by isolated O-H \cdots N hydrogen bonds (1.9 Å) which are aligned in a zigzag manner along the crystallographic b axis (see Fig. 7.40 later on). The hydrogen bonded chains are connected by weak aromatic C-H \cdots O interactions (2.2 Å) along the a axis and by van der Waals interactions of the phenyl and the methyl group in another dimension. The formation of needle-like racemic pseudoephedrine crystals was reported by Duddu et al. and characterized by its X-ray diffraction pattern [173].

Figure 7.35.: Frozen and relaxed (1*S*,2*S*)-monomer units taken from the crystal structure of enantiopure pseudoephedrine [92] as well as the most stable monomer [82, 86, 87] (B3LYP/6-311++G(3df,2p) level). Centers of chirality are marked with an asterisk (*).

Crystallization

Enantiopure pseudoephedrine crystals were obtained in a temperature range of 30°C to 45°C. The tabular crystals exhibit two types of spectra (see Fig. 7.36) with similar abundance. It is possible to assign the two spectral types to two different faces of the crystals by rotating the crystal. As can be seen in Fig. 7.37 rotating a crystal showing spectra of face A leads to the spectral type of face B and vice versa. The rotation experiments also exhibit spectra corresponding to face C of the crystal.

ND/OD-deuterated crystals were obtained from a solution of a tip of spatula of enantiopure pseudoephedrine in 15 drops of D₂O. The solution was heated up to 55°C and cooled down to room temperature in the open sublimation cell. The cell was subsequently evacuated. During the evacuation process platy crystals grew into a polycrystal in the solution. Polarization FTIR measurements were carried out on monocrystalline fragments of the polycrystal which are shown in Fig. 7.38. Spectra of two different faces A and B were obtained.

Sublimated ND/OD-deuterated crystals grew on top of the cell after heating it up to 35°C. Monocrystals with a tabular habit were obtained. Polarization FTIR spectra measured of the two faces A and B correspond to those measured using the polycrystals from the solution (see Figs. 7.38 and 7.39).

A comparison of the spectra and visual pictures of the nondeuterated and the ND/OD-deuterated enantiopure pseudoephedrine crystals (Figs 7.36 and 7.39) shows similarities in the C-H and C-C_{aromatic} stretching region as well as in the habit of the crystals. Face A and face B belong to analogous faces of the nondeuterated and the ND/OD-deuterated crystals. FTIR spectra of face A and B of enantiopure pseudoephedrine (see Figs. 7.36, 7.38, and 7.39) can easily be distinguished by the intensity of the O-H and O-D stretching bands which are much higher in the case of face B.

FTIR Spectra

The vibrational assignments are summarized in Tabs. 7.14 and 7.15. The assignments of the N-H and O-H stretching and the mixed N-H/C-H₃ bending modes are performed by comparison of experimental and predicted wavenumbers (see also Sect. 7.3) and by the behavior upon the ND/OD-deuteration. The N-D stretching position will be addressed below. The tentative assignments of the N-H/C-H₃ and C-H₃/N-H bending modes are supported by further considerations after determin-

Figure 7.36.: Enantiopure pseudoephedrine polarization FTIR spectra of face A. The arrows show the direction of the electric field vector. The visual pictures of the measured crystals are shown above the corresponding spectra. Band positions are given in cm^{-1} .

Figure 7.37.: Enantiopure pseudoephedrine FTIR spectra obtained after rotation of crystals showing type A and type B spectra. Rotating the crystal interconverts the spectral types A and B and exhibits oversaturated spectra of type C. The visual pictures of the measured crystals are shown above the corresponding spectra.

Figure 7.38.: ND/OD-deuterated enantiopure pseudoephedrine polarization FTIR spectra of face A and B. Crystals were obtained from a solution of D_2O . The arrows show the direction of the electric field vector. The visual pictures of the measured crystals are shown above the corresponding spectra. The visual picture of the crystal showing face A was cut at the long axis of the crystal. Band positions are given in cm^{-1} .

Figure 7.39.: ND/OD-deuterated enantiopure pseudoephedrine polarization FTIR spectra of of face A and B. Crystals were obtained by sublimation. The arrows show the direction of the electric field vector. The visual pictures of the measured crystals are shown above the corresponding spectra. Band positions are given in cm^{-1} .

ing the molecular orientation later on. The aromatic C-H and C-C_{aromatic} stretching bands are assigned according to observations made in the case of methyl mandelate, mandelic acid, and the other phenylpropanolamines in this Chapter. The aliphatic C-H stretching modes will be assigned after the determination of the molecular orientation of the two faces.

In the nondeuterated spectra only one N-H stretching band appears (as expected), whereas there seem to be two N-D stretching bands at 2475 cm⁻¹ and 2434/2436 cm⁻¹ in the ND/OD-deuterated spectra. They result from a Fermi-resonance of the N-D stretching fundamental and the N-D bending overtone at 1226 cm⁻¹ (not shown) [194]. The assignment is supported by their polarization behavior and by their behavior upon deuteration.

Polarization FTIR spectra of face A clearly show a dependence of the N-H and O-H stretching bands on the direction of polarization. Both bands gain intensity with a polarization parallel to the long crystal axis. Thus, a horizontal alignment of the isolated O-H...N hydrogen bonds and of the N-H axis can be assumed. In the case of face B the N-H and O-H stretching bands are high in intensity for both directions of polarization. This behavior matches a diagonal alignment of the O-H...N hydrogen bonds and the N-H group. Since the intensities of the N-H and O-H stretching bands are higher in intensity in the spectra of face B, the O-H...N hydrogen bonds and the N-H axis are more visible in the orientation of face B. The C-C_{aromatic} stretching bands only show subtle differences between face A and B spectra. The C-C_{aromatic,1}, C-C_{aromatic,3}, and C-C_{aromatic,4} stretching bands are present in both face A and B spectra with nearly equal intensities for both polarizations. The C-C_{aromatic,1} and C-C_{aromatic,3} are more intense in the face A spectra. Therefore, a diagonal orientation of the C-C stem and the C-N-C-C-C_{aromatic} backbone can be assumed for both faces with a better visibility in the case of face A (see Supplement F). The appearance of the symmetric aromatic C-H stretching in all spectra and for all polarizations supports this conclusion. The C-C_{aromatic,2} stretching band at 1583 cm⁻¹ appears only in face B spectra. This points at a better visibility of the α - and β -acidic C-H axes in the orientation of face B since the vibrational transition dipole vector of the C-C_{aromatic,2} stretching mode is parallel to these axes (see Supplement F).

The polarization behavior of the N-H and O-H stretching bands as well as the subtle differences in the C-C_{aromatic} stretching region can be used to infer the molecular orientation within the crystals. Face A corresponds to a view along the crystallo-

7. Phenylpropanolamines

Table 7.14.: Assignments of experimental band maxima in the FTIR microscopic spectra of enantiopure pseudoephedrine of face A, face B, face C (Fig. 7.36), FTIR-ATR spectra (without ATR correction, Fig. 7.2), IR-DFG Vapor Phase (Gas, Ref. [193]) as well as calculations of the relaxed monomer unit taken from the crystal structure (Mon_{crystal}) on the B3LYP/6-311++G(3df,2p) level. All wavenumbers are given in cm^{-1} . The stretching and bending vibrations are indicated as ν and δ and the symmetric and asymmetric vibrations with sym and asym. Tentative assignments and bands without assignment are labeled with a question mark (?).

graphic c axis, whereas face B can be assigned to the a axis as depicted in Fig. 7.40. Comparisons of the experimental nondeuterated and ND/OD-deuterated as well as the oriented gas model spectra are shown in Fig. 7.41. It can be seen that there is a good agreement regarding the intensity ratios of a variety of bands. There is a good match between the intensity ratios of the O-H as well as N-H stretching bands of face A and B. Also, the increase and decrease of the C-C_{aromatic} stretching bands are in agreement between experiment and simulation. The region between 1500 cm⁻¹ and 1400 cm⁻¹ appears to be more complicated. There are contributions of the C-C_{aromatic,3} and C-C_{aromatic,4} stretching modes as well as several mixed N-H/C-H₃ and mixed C-H₃/NH bending modes.

Further evidence for the assignment of face A to view c and face B to view a is the consistency of interactions and habit of the crystals. As can be seen in Fig. 7.40 and as described above the O-H...N hydrogen bonded chain runs along the crystallographic b axis and determines the growth direction. It therefore corresponds to the long crystal axis of the tabular crystals. The other growth directions are determined by C-H...O contacts along the a axis and by van der Waals interactions. Therefore, the crystal habit is in agreement with the assignment of the molecular orientation.

The experimental and predicted polarized spectra of the two faces can now be used to assign vibrational modes in the aliphatic C-H stretching region (see Tabs. 7.14 and 7.15). In Fig. 7.41 a tentative assignment is performed on the basis of the experimental and predicted polarization behavior. Also, the predicted wavenumbers of the methyl and N-methyl C-H stretching modes (scaled by a factor of 0.966, see Chapter 3) match the observed band positions. In the case of the α -acidic mode the relative shift is under- and in the case of the β -acidic C-H stretching mode it is overestimated as observed for pseudonorephedrine (see Sect. 7.5). This leads to a change of the sequence of the symmetric N-methyl and the β -acidic mode. In order to unravel the positions of the asymmetric1 N-methyl and the asymmetric2 methyl C-H stretching modes, further evaluations are needed. They are both preliminarily assigned to the shoulder at 2968 cm⁻¹. However, it is rather unlikely that both modes actually correspond to this band. The positions of the methyl and the acidic C-H stretching bands match the assignments made in the case of pseudonorephedrine.

Figure 7.40.: Molecular orientation of enantiopure pseudoephedrine along the three crystal faces. The crystal structure was taken from Ref. [92]. The continuous frames mark the observed faces, whereas the unobserved face is dash-framed.

Figure 7.41.: Comparison of experimental and oriented gas model polarization spectra without deuteration (B3LYP/6-311++G(3df,2p) level) of face A (left) and face B (right) of enantiopure pseudoephedrine. The non-deuterated spectra (top, black), the ND/OD-deuterated spectra (center, green), and oriented gas model spectra (bottom, blue) are shown. Harmonic wavenumbers are scaled by a factor of 0.966 to account for anharmonicity. Assigned bands in the upper part are stretching modes. C-H stretching modes are indicated. The C-C_{aromatic} stretching (abbreviated C-C_x), mixed N-H/C-H₃ bending (abbreviated N-H_x), mixed C-H₃/N-H bending (abbreviated C-H_{3,x}), mixed (N-H/C-H₃)₁ bending (abbreviated 3), a mixed (N-H/C-H₃)₂, and the mixed (C-H₃/NH)₂ bending modes (abbreviated 4) are shown in the lower part.

7.7.2. Racemic Pseudoephedrine

Racemic pseudoephedrine (see Fig. 7.35) is a white powder. Its melting temperature is 119°C [173]. So far, the crystal structure of racemic pseudoephedrine has not been determined.

Crystallization

In order to crystallize racemic pseudoephedrine a 1:1 mixture of (1*S*,2*S*)- and (1*R*,2*R*)-pseudoephedrine was pestled and filled into the sublimation cell. The crystallization was performed using a temperature range of 35°C to 50°C (Tab. 7.1). Platy monocrystals as well as polycrystals consisting of needles were obtained. Polarization spectra of two different faces are shown in Fig. 7.42. The spectra can be assigned to the racemic compound since the N-H stretching position of 3301/3300 cm⁻¹ differs compared to the one of the enantiopure compound at 3319/3318 cm⁻¹ (Fig. 7.36) showing that chirality recognition is taking place.

Figure 7.42.: Racemic pseudoephedrine polarization FTIR spectra of face A and face B. Spectral artifacts are caused by the needle-like habit and the small aperture. The arrows show the direction of the electric field vector. The visual pictures of the measured crystals are shown above the corresponding spectra. Band positions are given in cm⁻¹.

Figure 7.43.: Racemic pseudoephedrine FTIR spectra of needle-like crystals. The spectrum of face A was obtained after rotation of a crystal growing on face B. The visual pictures of the measured crystals are shown above the corresponding spectra. Artifacts are caused by the needle-like habit and the small aperture.

Further comparisons of enantiopure and racemic pseudoephedrine will be made in Sect. 7.7.3.

The racemic pseudoephedrine crystals mainly grew on face A but in approximately 5% also face B was observed. In Fig. 7.43 the FTIR spectra of a crystal initially showing face A and after rotation showing face B are depicted. Fig. 7.42 shows polarized FTIR spectra of face A and B.

ND/OD-deuterated racemic pseudoephedrine was obtained from a solution of a 1:1 mixture of (1*S*,2*S*)- and (1*R*,2*R*)-pseudoephedrine in D₂O. In order to dissolve the powdered mixture the open sublimation cell was heated up to 60°C and the solution manually stirred. Afterwards, the solution was cooled down to room temperature (22–24°C). Then the sublimation cell was evacuated. During the evacuation process the racemic compound started to crystallize. Polycrystals formed from single crystals of a needle-like to platy habit were obtained. Polarization FTIR spectra are shown in Fig. 7.44. Sublimation at 40°C led to polycrystals constituted of needle-like single crystals. FTIR spectra of these sublimated ND/OD-deuterated racemic pseudoephedrine crystals show spectral similarities to the one of face A

Figure 7.44.: ND/OD-deuterated racemic pseudoephedrine polarization FTIR spectra of face A and face B crystallized from a solution of D₂O. The arrows show the direction of the electric field vector. The visual pictures of the measured crystals are shown above the corresponding spectra. Band positions are given in cm⁻¹.

obtained from the solution (not depicted). Again, two N-D stretching bands and only one N-H stretching band seem to be present as it is the case in the spectra of enantiopure pseudoephedrine.

FTIR Spectra

The assignments of the experimental bands are summarized in Tabs. 7.16 and 7.17. The N-H and O-H stretching bands are assigned by comparison of the experimental and predicted wavenumbers (see also Sect. 7.3) and by their behavior upon ND/OD-deuteration. There is a Fermi-resonance of the N-D stretching fundamental with the N-D bending overtone with positions at 2466 and 2430 cm⁻¹ (fundamental at 1226 cm⁻¹, not shown). The aromatic C-H and C-C_{aromatic} stretching bands are assigned according to the observations made in the case of methyl mandelate, mandelic acid, and the other phenylpropanolamines in this Chapter.

The crystal structure of racemic pseudoephedrine has not been published so far. Information regarding the average molecular orientation can only be obtained by analysis of the present FTIR polarization spectra. The proposed orientations are

Table 7.16.: Assignments of experimental band maxima in the FTIR microscopic spectra of racemic pseudoephedrine of face A, face B (Fig. 7.42), and FTIR-ATR spectra (without ATR correction, Fig. 7.2). Figure 7.45.: Schematic layout of a pseudoephedrine molecule oriented according to face A and B. Note, that this simplistic view does not reflect the dimensionality correctly and that it does not include all functional groups.

depicted in Fig. 7.45. Note, that it is only a simplistic scheme which does not reflect the dimensionality correctly and which does not include all functional groups.

The N-H stretching band at $3301/3300\text{ cm}^{-1}$ is more red shifted than the ones of ephedrine anhydrate at 3313 cm^{-1} and of enantiopure pseudoephedrine at $3319/3318\text{ cm}^{-1}$ which do not form intermolecular N-H hydrogen bonds within the crystal structure (see Sect. 7.7.1). The position of the N-H stretching band of racemic pseudoephedrine is closer to the N-H stretching band of ephedrine hemihydrate at 3296 cm^{-1} which does form N-H...O hydrogen bonds. The N-H stretching band of racemic pseudoephedrine is also more intense than the one of enantiopure pseudoephedrine (see Fig. 7.2). Therefore, it can be assumed that N-H hydrogen bonds, which are stronger than in the enantiopure case, are formed in the crystal structure of racemic pseudoephedrine.

The O-H and N-H stretching bands appear for both faces which is in contrast to the needle-like habit but in agreement with the platy habit. The O-H stretching band is slightly more intense and broader for face B. In the case of a vertical polarization of face A it almost vanishes. In contrast, the N-H stretching band is slightly more intense in the case of face A spectra. It decreases in intensity in the case of a horizontal polarization of face A. Therefore, a nearly horizontal alignment of the O-H hydrogen bonds and a rather vertical alignment with good visibility can be assumed for the N-H hydrogen bonds of face A. There is a good visibility of the horizontally oriented O-H hydrogen bond and a more diagonal alignment of the N-H hydrogen bond in the orientation of face B.

The quality of the nondeuterated spectra in the lower wavenumber region is poor

due to the needle-like habit and a small aperture. Nonetheless, the comparison to the ND/OD-deuterated spectra shows the influence of mixed N-H/C-H₃ bending modes between 1500 cm⁻¹ and 1350 cm⁻¹. The mixed modes appear at higher wavenumber for a vertical polarization and at lower wavenumber in the case of a horizontal polarization of both face A and B. The behavior of the C-C_{aromatic} stretching bands is most pronounced in the ND/OD-deuterated spectra. The C-C_{aromatic,1} stretching band at 1602 cm⁻¹ appears in all spectra but the vertically polarized one of face B (see Fig. 7.44). In this case the C-C_{aromatic,2} stretching band at 1584 cm⁻¹ is present. The C-C_{aromatic,3} and C-C_{aromatic,4} bands appear in all spectra. Thus, the C-C stem is diagonally aligned with the phenyl ring being turned within the orientation of face A. In the case of face B the plane of the phenyl ring is visible and the C-C stem horizontally aligned. These conclusions are supported by the presence of the symmetric aromatic C-H stretching modes in all spectra except the vertically polarized spectrum of face B.

The proposed orientations in Fig. 7.45 may be converted into each other by a 90° rotation around the y-axis. There are some deviations which are only minor. All in all, the conclusions are in agreement with each other. A diagonally bisected crystal might exhibit a more pronounced polarization behavior of the C-C_{aromatic} stretching bands. Therefore, it might reveal further information regarding the molecular orientation within the racemic pseudoephedrine crystal.

7.7.3. Comparison of Enantiopure and Racemic Pseudoephedrine

Sublimated crystals of pseudoephedrine show effects of chirality recognition. They are most pronounced in the position and intensity of the N-H stretching band (see Tabs. 7.14 and 7.16 as well as Figs. 7.2 and 7.46). It is red shifted by 18 cm^{-1} from 3319 cm^{-1} to 3301 cm^{-1} for the racemic compound. For comparison, the position of the N-H stretching band of anhydrous ephedrine is 3313 cm^{-1} and 3296 cm^{-1} for ephedrine hemihydrate. This rather large shift points at different hydrogen contacts of the NH group. Probably, the red shift results from shorter and stronger $\text{N-H}\cdots\text{O}$ hydrogen contacts in the crystal structure of racemic pseudoephedrine as assumed in Sect. 7.7.2. Further differences are apparent in the case of the O-H stretching band and in the region of the mixed N-H/C-H and C-H/N-H bending modes. The bands of the enantiopure compound are more red shifted. It can be assumed that the O-H hydrogen bonds are stronger within the enantiopure crystals. In the racemic crystals a weakening of the O-H hydrogen bonds seems to occur in order to establish stronger N-H contacts.

Different ratios of (1*S*,2*S*)- and (1*R*,2*R*)-pseudoephedrine (1:1, 2:1, 3:1, and 9:1) were sublimated and investigated by FTIR imaging in order to observe the influence of the enantiomeric ratio on chirality recognition. The mixtures were pestled and filled into the sublimation cell. The crystallization was performed using a temperature range of 35°C to 50°C (Tab. 7.1). FTIR images were recorded to differentiate between the enantiopure and the racemic compound. The N-H stretching regions of $3335\text{--}3310\text{ cm}^{-1}$ (Enant) and $3310\text{--}3290\text{ cm}^{-1}$ (Rac) were integrated. Afterwards the integrated area of Enant was subtracted from Rac (Rac–Enant). Fig. 7.47 shows visual pictures as well as FTIR images of the obtained crystals.

In the case of a 1:1 ratio block-like/platy as well as needle-like racemic crystals were obtained. Using a 2:1 ratio led to a polycrystal consisting of racemic needles. In the case of a 3:1 ratio both the enantiopure as well as the racemic compound were sublimated. The polycrystal consists of both compounds and has an undefined habit. Nonetheless, the enantiopure and the racemic compound can be visually distinguished. The enantiopure compound consists of thick, blocky crystals whereas racemic pseudoephedrine crystallizes in the form of needles. In the case of a 9:1 ratio the undefined polycrystal solely consists of the enantiopure compound.

In summary, mixtures of (1*S*,2*S*)- and (1*R*,2*R*)-pseudoephedrine show significant

Figure 7.46.: Enantiopure and racemic pseudoephedrine polarization FTIR spectra. The arrows show the direction of the electric field vector. The visual pictures of the measured crystals are shown above the corresponding spectra. Band positions are given in cm^{-1} . Regions Enant and Rac used for integration are marked in blue and red, respectively.

Figure 7.47.: Chemical images of pseudoephedrine crystals. Different ratios (see upper left corners) of the two enantiopure substances were used. Red colors show the racemic compound. Blue colors show the enantiopure compound.

indication of chirality recognition phenomena. 1:1 and 2:1 mixtures lead to racemic crystals, while at more dissimilar ratios predominantly the enantiopure compound was obtained. A tendency of racemic crystals to grow at slightly higher temperatures was observed. This would lead to the conclusion that the enantiopure crystals are more stable than racemic pseudoephedrine. However, a negative Gibbs free energy ($\Delta G = -0.55 \text{ kcal}\cdot\text{mol}^{-1}$) was determined for the formation of the racemate from opposite enantiomers in the solid state by X-ray powder diffraction [173]. This rather points at a higher stability of the racemate. The slightly higher sublimation temperatures may be influenced by other parameters e.g., pressure and ambient temperature or by kinetic factors. The measurement of the relative vapor pressure via mass spectrometry as performed in the methyl mandelate case can shed further light into this question.

7.8. Spectral Comparisons

A variety of vibrational modes are assigned in the spectra of the sublimated phenylpropanolamines in this Chapter. In this Section, the spectral positions of analogous modes will be compared and analyzed on the basis of the interactions within the crystal structures, the different monomer conformations (Sect. 7.2), and the preliminary spectral considerations made in Sect. 7.3.

O-H/O-D Stretch

Broad and red shifted O-H stretching bands resulting from O-H \cdots N hydrogen bonds are found for all of the investigated phenylpropanolamines in the region of 3300–2300 cm⁻¹. The O-D stretching bands appear in the region of 2600–1800 cm⁻¹ and exhibit a structure which may result from symmetric and asymmetric couplings or from two quantum excitations. Since the O-H stretching bands are red shifted into the region of the C-H stretching bands, unambiguous information about the band structuring is difficult to obtain.

The largest red shift and broadening is found for enantiopure pseudoephedrine and the smallest red shift and broadening in the case of pseudonorephedrine (Fig. 7.2). As summarized in Tab. 7.18, the O-H \cdots N hydrogen bonds in enantiopure pseudoephedrine are mostly isolated whereas in pseudonorephedrine cooperatively strengthened infinite chains of hydrogen bonds are found. Thus, one would expect stronger O-H \cdots N hydrogen bonds in the case of pseudonorephedrine [130, 192], which is in conflict with the observed red shifts.

Table 7.18.: Hydrogen bonds of the OH and NH group formed as a donor (D) and acceptor (A) as well as cooperative patterns involving infinite chains (coop_∞), the cooperativity between two hydrogen bonds (coop₂), and anti-cooperativity (a-coop) in some phenylpropanolamines.

	OH			NH

PE, enant	C-H \cdots O-H \cdots N	D(A)		O-H \cdots N-H	A	

Table 7.19.: Experimental crystal $\tilde{\nu}_{\text{cryst}}$ and predicted monomer positions ω_{mon} (B3LYP/6-311++G(3df,2p)) in cm^{-1} of conformations corresponding to the conformations found in the crystals (Fig. 7.3) ordered in the sequence of the O-H stretching bands (smallest to largest) as observed in the experimental crystal spectra. The experimental crystal wavenumbers have an error of $\pm 50 \text{ cm}^{-1}$.

	Conformation	$\tilde{\nu}_{\text{cryst}}$	ω_{mon}
PNE	AG	≈ 2980	3839
E-AH	AG(a)'	≈ 2950	3842
NE, rac	GG	≈ 2900	3831
PE, enant	AG(b)	≈ 2840	3838
E-H	AG(b)	≈ 2720	3733

The experimental O-H stretching band sequence in the crystal spectra deviates from the sequence of the predicted monomers of conformations corresponding to the structures in the crystal (Tab. 7.19). Therefore, the sequence of the O-H stretching bands cannot solely be explained by conformational differences but by other interactions formed upon crystal aggregation which compete with cooperativity on the hydrogen bond strengths. This is in agreement with the sublimation temperatures of enantiopure pseudoephedrine and pseudonorephedrine being in the same order (Tab. 7.1) and with the H-N and O-N distances of the hydrogen bond being smaller in the isolated case of pseudoephedrine (Tab. 7.2). There may be local reasons, such as the geometrical availability of the free electrons of nitrogen, or more global effects, such as dipole interactions leading to cohesion or packing forces in the crystal structure. Further investigations are needed in order to specify the forces. Probably, a variety of different interactions competing with each other are present.

The O-H stretching band pattern of water in the ephedrine hemihydrate spectra at $3630\text{--}3330 \text{ cm}^{-1}$ is less red shifted and less broadened than the alcoholic O-H stretching bands of the investigated phenylpropanolamines (Fig. 7.2). This is in agreement with the formation of less stable $\text{O-H}\cdots\text{O}$ instead of $\text{O-H}\cdots\text{N}$ hydrogen bonds. The O-H stretching band shows polarization dependent high and low frequency contributions of asymmetric and symmetric modes.

N-H Stretch

Asymmetric and symmetric N-H stretching modes of the primary amines as well as localized N-H stretching modes of partly deuterated primary and nondeuterated secondary amines are assigned in the region of $3360\text{--}3270\text{ cm}^{-1}$. In the case of the primary amines norephedrine (enantiopure and racemic) and pseudonorephedrine a Fermi-resonance of the symmetric N-H stretching fundamental with the N-H bending overtone is found. Ephedrine hemihydrate shows a coupling of the NH groups of two ephedrine molecules leading to an asymmetric and a symmetric N-H stretching band. The N-D stretching bands appear in the spectral region of $2503\text{--}2370\text{ cm}^{-1}$. A Fermi-resonance takes place between the N-D stretching fundamental and the N-D bending overtone in the case of enantiopure and racemic pseudoephedrine.

The N-H stretching bands in the crystal spectra are intensified and red shifted compared to the predicted monomer modes of corresponding conformations but less so than the O-H stretching bands (Supplement F). The intensification of the N-H stretching bands is larger for the more red shifted N-H stretching bands (Fig. 7.2) and thus in agreement with the presence of stronger hydrogen bonds. In the case of the primary amines especially the intensity of the symmetric, or more properly bonded N-H stretch increases with increasing red shift. This is also true for the symmetric N-D stretching bands (Figs. 7.11, 7.17, and 7.24) and in agreement with the predictions (Tab. 7.5).

There is a red shift and intensification of the experimental crystal N-H stretching bands compared to the predicted monomer N-H stretching modes of corresponding conformations which cannot solely be explained by the formation of hydrogen bonds. In the following, the shifts caused by other effects than hydrogen bonds will be estimated. Tab. 7.20 lists the difference between experimental and predicted N-H stretching wavenumbers (average of the asymmetric and symmetric stretch for nonmethylated amines) of ethylamine and ephedrine monomers in the gas phase [82, 195]. The difference between the experimental and the predicted values of -154 cm^{-1} and -165 cm^{-1} reflects the error of the method e.g., anharmonicity. Therefore, a correction shift of -160 cm^{-1} (mean value) is applied on the predicted wavenumbers of the investigated phenylpropanolamines. Their experimental and predicted wavenumbers (uncorrected and corrected) as well as the differences and ratios between the experimental and the corrected predicted wavenumbers are also given in Tab. 7.20. In the case of the primary amines also the average

wavenumber of the asymmetric and the symmetric N-H stretching modes are listed. Deperturbed positions $\tilde{\nu}_0(A)$ (without Fermi-resonance) are estimated from the observed bands $\tilde{\nu}(A)$ and $\tilde{\nu}(B)$ by the following equation [196]:

$$\tilde{\nu}_0(A) = \frac{\tilde{\nu}(A) + \tilde{\nu}(B)}{2} + \frac{\Delta\tilde{\nu}_0}{2} = \frac{\tilde{\nu}(A) + \tilde{\nu}(B)}{2} + \frac{\Delta\tilde{\nu}}{2} \cdot \frac{R-1}{R+1} \quad (7.1)$$

with B being the less intense band at lower wavenumber. $\Delta\tilde{\nu}_0$ and $\Delta\tilde{\nu}$ are the deperturbed and the observed (perturbed) wavenumber differences of $A - B$ and R is the ratio of the integrated intensities $\frac{I(A)}{I(B)}$ of the two modes.

The deviations of -43 to -78 cm^{-1} reflected in ratios of 0.987 – 0.977 between experimental crystal and corrected predicted monomer wavenumbers illustrate the divergence between experiment and prediction after accounting for anharmonicity. They result from intermolecular interactions upon aggregation which are not considered in monomer calculations. The divergence is the largest for racemic norephedrine and pseudonorephedrine (-56 to -78 cm^{-1}) in which the amine group simultaneously acts as a hydrogen bond donor and acceptor and cooperative hydrogen bonds are established (Tab. 7.18). The deperturbed symmetric (bonded) and the asymmetric (free) N-H stretching modes show a similar red shift (70 – 75 cm^{-1}). A red shift of 32 cm^{-1} is predicted for both N-H stretching modes of the methanol-ethylamine-dimethylether complex (Sect. 7.3) which serves as a model case for the influence of $\text{O-H} \cdots \text{N-H} \cdots \text{O}$ hydrogen bonds. Accounting for the predicted red shift of an amine group acting as a hydrogen bond donor and acceptor still leaves a divergence between experiment and prediction of -38 to -43 cm^{-1} for the deperturbed symmetric and the asymmetric mode for norephedrine and pseudonorephedrine.

In the case of ephedrine anhydrate and enantiopure pseudoephedrine the divergence is -58 to -60 cm^{-1} . Here, the NH group only acts as a hydrogen bond acceptor. For the methylethylamine-methanol complexes, in which the amine group is the hydrogen bond acceptor, a red shift of 13 – 20 cm^{-1} is predicted. The divergence between experiment and predictions can thus be corrected to a value of -38 to -47 cm^{-1} .

The smallest divergence is found for the symmetric N-H stretch of ephedrine hemihydrate. Here, the $\text{N-H} \cdots \text{O}$ hydrogen bonds are anti-cooperative and therefore, the N-H stretching band is less red shifted (43 cm^{-1}) compared to the predictions. As discussed in Sect. 7.3, the low lying predicted wavenumber of ephedrine

Table 7.20.: Experimental gas phase $\tilde{\nu}$ and predicted N-H stretching wavenumbers ω of the ethylamine (EA) and the most stable ephedrine monomer (E AG(a)) [82, 195] on the B3LYP/6-311++G(3df,2p) level as well as the difference $\Delta(\tilde{\nu} - \omega)$ in cm^{-1} . Experimental crystal $\tilde{\nu}$, predicted ω (B3LYP/6-311++G(3df,2p)), and predicted N-H stretching wavenumbers corrected by -160 cm^{-1} ω_{corr} as well as the difference between the experimental and predicted wavenumbers $\Delta(\tilde{\nu} - \omega_{\text{corr}})$, the corrected difference between the experimental and predicted wavenumbers $\Delta(\tilde{\nu} - \omega_{\text{corr}})_{\text{corr}}$ in cm^{-1} and the ratio $\frac{\tilde{\nu}}{\omega_{\text{corr}}}$ are listed. An average of the asymmetric and the symmetric N-H stretching wavenumbers (av) of the primary phenylpropanolamines and in some cases deperturbed N-H stretching positions (0) are given.

PE, enant	3319	3539	3379	-60	0.982	-(40-47)

hemihydrate is a result of O-H \cdots (H)N dipole interactions. The resulting red shift of 20 cm⁻¹ (Tab. 7.6) might be overestimated by the quantum chemical calculations and therefore, the monomer prediction of the wavenumber too low in comparison to the other parameters and the other N-H stretching predictions in general. However, the deviation increases to -59 cm⁻¹ for the average of the asymmetric and the symmetric N-H stretching mode. It is then in the same order as the deviations of the other phenylpropanolamines.

Summing up, the corrected red shifts of deperturbed experimental N-H stretching modes compared to the corrected predictions of corresponding modes are in the range of -(38–59) cm⁻¹ (Tab. 7.20). The corrected differences may be caused by local effects, such as aromatic interactions which do not take place in the monomer (experiment and prediction) or by global effects, such as packing forces (see above). Packing constraints are known to cause a red shift as found for the *n*-propanol O-H stretching band in a crystalline argon matrix compared to the gas phase [197].

N-D Stretch

The N-D stretching bands are further red shifted than the N-H stretching positions, as expected. Tab. 7.21 summarizes the experimental and predicted positions of the N-H and N-D stretching modes and the ratios of the N-H and N-D stretching wavenumbers. The observed ratio of 1.339–1.381 shows deviations to both sides of the harmonically approximated ratio of 1.369 ($\sqrt{\frac{\mu_D}{\mu_H}}$). Larger ratios are observed for the symmetric N-H stretching modes (perturbed and deperturbed) of enantiopure and racemic norephedrine. The deviations to the harmonic approximation can be explained by anharmonicity which was found to increase for larger aggregates in the case of the methanol O-H stretching mode [129]. The ratios deviate less for the bonded than the free vibrations. This is surprising since anharmonicity can be expected to increase upon hydrogen bonding [198–200].

The experimental ratios of the N-H and N-D stretching wavenumbers are smaller than the predicted ones (Tab. 7.21). They only deviate by 1–2% with exception of the perturbed symmetric stretch of racemic norephedrine (0.3%). Assuming that the deviations should be in the same order, it is probably due to the Fermi-resonance.

In the spectra of partly deuterated norephedrine (enantiopure and racemic) and pseudonorephedrine also localized N-H and N-D stretching bands are assigned (Tab. 7.21). In all cases the bonded localized N-H and N-D modes are observed.

7. Phenylpropanolamines

Table 7.21.: Experimental $\tilde{\nu}$ and predicted N-H and N-D stretching wavenumbers ω (B3LYP/6-311++G(3df,2p)) of the nondeuterated and deuterated phenylpropanolamines in cm^{-1} as well as the ratio of the N-H and N-D positions of corresponding modes. Deperturbed symmetric N-H and N-D stretching positions (0) are given as well.

	$\tilde{\nu}_{\text{N-H}}$	$\tilde{\nu}_{\text{N-D}}$	$\frac{\tilde{\nu}_{\text{N-H}}}{\tilde{\nu}_{\text{N-D}}}$	$\omega_{\text{N-H}}$	$\omega_{\text{N-D}}$	$\frac{\omega_{\text{N-H}}}{\omega_{\text{N-D}}}$

This is in agreement with the predicted intensity enhancement of the bonded in contrast to the free mode of the partly deuterated ethylamine-dimethylether complex as visualized for the ethylamine-dimethylether predictions in Fig. 7.48 (see also Tab. 7.5).

In the spectra of partly deuterated pseudonorephedrine also the free N-H stretching mode is assigned. The analogous free N-D stretching mode which is predicted to have a similar intensity as the free N-H stretching mode does not appear. The appearance of the free N-H stretching band in the partly deuterated spectra of pseudonorephedrine can be explained by two arguments. First, the free (dangling) deuterium is preferentially exchanged by humidity. Thus, the free N-D stretching mode is depleted first and the free N-H stretching mode emerges preferentially (kinetic exchange argument). Accordingly, if the nondeuterated substance is sublimated in a D₂O atmosphere the free N-D stretching mode should arise from a kinetic point of view (not performed). Secondly, deuterium is the better hydrogen bond donor and N-D...O hydrogen bonds are preferentially established because of the reduced zero point energy destabilization of the librational modes [201, 202]. Therefore, the free N-H stretching band is more likely to appear in the spectra of partly deuterated primary amines than the free N-D stretching mode (no matter if a deuterium-hydrogen or a hydrogen-deuterium exchange takes place). The intensity increase of the free N-H and the intensity decrease of the free N-D stretching mode are indicated by gray arrows in Fig. 7.48.

Next to O-H and N-H stretching also N-H bending bands are assigned by comparison of nondeuterated and ND/OD-deuterated spectra as well as by comparison of experiment and prediction. The N-H bend of the primary amines appears at higher wavenumbers than the mixed modes of the secondary amines, in agreement with the predictions (Tab. 7.7). The assignments of the localized bending modes are confirmed by their polarization behavior in the experimental and oriented gas model spectra. In the case of the secondary amines the comparison of experimental and oriented gas model spectra is not reliable since the vibrational dipole vector changes unpredictably upon hydrogen bonding (Sect. 7.3). The N-H bending overtones are found to couple with the symmetric N-H stretching fundamentals in the case of the primary amines (see above).

The aromatic C-H and the C-C_{aromatic} stretching modes appear at similar positions for all investigated phenylpropanolamines as well as methyl mandelate and mandelic acid. It can be assumed that this is also true for other structurally simi-

Figure 7.48.: Splitting of the N-H and N-D stretching modes of the nondeuterated, fully ND-deuterated, and partly ND-deuterated ethylamine-dimethylether complex. Asym and sym label the asymmetric and symmetric modes and f and b the free and bonded modes. The splittings and the intensities (thickness of bars) reflect the predictions of the methylamine-dimethylether complex (Sect. 7.3). The arrows (widening and narrowing of the bars) indicate the intensity increase and decrease of the free modes upon an asymmetric isotope exchange.

lar substances. Furthermore, the polarization behavior of the symmetric aromatic C-H and the C-C_{aromatic} stretching mode are reliable indicators of the phenyl and the α -acidic CH group and can be used to infer the molecular orientation.

7.9. Conclusions

The polarized FTIR microspectroscopic method was applied to the phenyl-propanolamines norephedrine, pseudonorephedrine, ephedrine, and pseudoephedrine. Chirality recognition was observed for norephedrine and pseudoephedrine crystals. An anhydrate and a hydrate were obtained in the case of ephedrine. It was shown that for sublimated crystals the main direction of growth is determined by the direction of hydrogen bonds. As expected, the strongest interaction determines the direction of growth unlike for crystals obtained from a solution.

It was shown that the O-H stretching red shifts cannot be explained by cooperativity and that therefore competing interactions influence the hydrogen bond strengths. Localized and coupled as well as free and bonded N-H and N-D stretching bands were assigned based on isotope studies and predictions. Also, several localized and mixed N-H stretching and bending modes were assigned. In some cases, the bending overtone was found to couple with the stretching fundamental. Red shifts were explained by different N-H hydrogen contacts as well as by conformational differences. The assignment of the aliphatic C-H stretching bands was difficult and is only preliminary. ND/OD deuteration studies of ephedrine anhydrate and hemihydrate would be helpful for a more confident assignment.

The molecular orientations were inferred on the basis of the experimental and predicted polarization behavior and compared to the crystal structures where available. The polarization behavior of the hydrogen bonded stretching, the symmetric aromatic C-H stretching, and the C-C_{arom} stretching bands were found to be helpful indicators in some cases. A tentative average conformation of the molecules in the unit cell was deduced for enantiopure norephedrine and for racemic pseudoephedrine since the crystal structures are not solved yet.

8. Summary & Outlook

Adaptive aggregation and chirality recognition of sublimated microcrystals were the subjects of this dissertation. The phenomenon of adaptive aggregation was exemplified on the simple model case of the ethanol-water dimer investigated by a combined Raman- and FTIR-jet study. Ethanol was found to exhibit a gauche conformation upon complexation by water because that allows the water to establish a secondary weak hydrogen bond [11, 14, 81]. It would be interesting to see how an increased aliphatic chain influences the hydrogen bonds by introducing competing dispersion interactions [132]. The study of highly polar fluorinated alcohols [133] in combination with water [134] would also be of interest.

For the first time, polarized transmission FTIR microspectroscopy was applied to study conformational and chiral effects of hydrogen bonded sublimated crystals. The method was tested on methyl mandelate [37]. It was found that not the most stable conformation [38] but an energetically less favorable monomer conformation is present in the crystal. Here, adaptive aggregation takes place due to beneficial intermolecular interactions. Chirality recognition studies revealed the formation of a rather rare mixed 3:1 crystal next to the prevalent 1:1 racemate [38]. Both contain the less stable monomer conformation as well. Enantiopure methyl mandelate was used to show the suitability of polarized transmission FTIR microspectroscopy for the inference of the molecular orientation within a crystal and for the assignment of vibrational bands. The polarization behavior and vibrational transition dipole vectors, respectively, of hydrogen bonded O-H stretching, C-H stretching, and C-C_{aromatic} stretching bands were revealed and associated with specific orientations of the hydrogen bonds and certain axes within the molecules.

The method was extended to mandelic acid [37]. Results gained for methyl mandelate were confirmed and the aromatic C-H stretching modes were assigned. Mandelic acid crystallizes in one enantiomeric and two racemic forms [88, 161, 166–168]. The racemate was not studied within the present framework. Its investigations might support the interpretation of further bands at lower wavenum-

bers [20, 164, 165]. Also, the appearance of polymorphism in the case of the racemate is worth to be studied. Further chirality recognition effects might occur for co-crystals of mandelic acid and methyl mandelate [58]. The sublimation of mixed methyl mandelate-mandelic acid crystals was performed without success due to different vapor pressures (see also Ref. [181]). A prior co-crystallization from solution and a subsequent sublimation might be more successful.

The polarized transmission FTIR microspectroscopic method was also applied to some neuroactive phenylpropanolamines which are structurally similar to methyl mandelate and mandelic acid. The molecular orientation was inferred for most of the investigated substances. In the cases of enantiopure norephedrine and racemic pseudoephedrine no crystal structures were available. A tentative average orientation of the molecules within the unit cell was obtained based on their polarization behavior. Further evaluation of the C-H stretching bands would help to assign the molecular conformation and orientation more accurately. Measurements on block-like racemic pseudoephedrine crystals might provide a better spectral quality. Determining the crystal structure with other techniques would be worthwhile in order to reassess the postulated orientation proposed within this work.

Chirality recognition was observed in the cases of norephedrine and pseudoephedrine. FTIR images were recorded for pseudoephedrine in order to observe the influence of the enantiomeric ratio on chirality recognition. Analogous measurements could be carried out for norephedrine. Mass spectroscopy as it was performed in the case of methyl mandelate would be suitable to determine the relative vapor pressures and phase diagrams of the enantiopure and racemic compounds.

In the case of ephedrine, an anhydrate and a hydrate were obtained. The sublimation of prepared ephedrine hemihydrate might allow the study of other faces. Also, the ND/OD deuteration might shed new light into the interpretation. A spectral comparison might provide valuable information regarding the influence of conformational differences and the integration of water into the crystal structure on the position and intensity of various bands.

Several N-H stretching bands in the spectra of the investigated phenylpropanolamines were assigned. Their red shifts were analyzed in terms of hydrogen bond and conformational influence. Both were found to affect the N-H stretching position. Raman-jet spectroscopy using a heatable nozzle [203, 204] might reveal the isolated monomer spectra of the phenylpropanolamine conformations present in the crystals. With this information, the influence of the conformation on the N-H

stretching position can be further evaluated.

Within the scope of F. Ziegler's Bachelor thesis, the methylxanthines caffeine, theophylline, and theobromine were investigated by the polarization FTIR (not presented in this work). Caffeine was found to crystallize in a needle-like habit. Thus, a small aperture needed to be applied which decreased the spectral quality. Nonetheless, the molecular orientation of one face was determined and C-H stretching bands assigned. The measurements of theophylline and theobromine were repeated by J. Wallbaum and T. Nack in the framework of an internship [152], in which the investigations were extended through recrystallization and deuteration studies. The interpretation of these results is still in progress. Measurements on other methylxanthines e.g., isocaffeine may clarify the interpretation [205, 206].

The experimental results of this work were compared with harmonic monomer calculations. Vibrational crystal phase calculations would be desirable to account for intermolecular interactions [36]. A cooperation was started with R. Tonner on enantiopure methyl mandelate. Preliminary results are encouraging. Anharmonic monomer calculations could be applied as well and compared to experiment and the harmonic calculations.

Deuteration studies were used to support the vibrational assignment in the cases of methyl mandelate and the phenylpropanolamines. Time-dependent isotope exchange studies of deuterated crystals might provide information about the exchange rates [207]. In case of the primary amines it might be possible to observe the kinetics of the bonded versus the free N-D group.

The polarized transmission FTIR microspectroscopic method can be extended to the investigation of polymorphism. As mentioned above, there are two known polymorphs of racemic mandelic acid which are worth to be studied. The methylxanthines caffeine and theophylline also show polymorphism [208–213] and exist as anhydrides and hydrates [214–216]. Also, the investigation of unknown polymorphs which do not crystallize by standard crystallization methods is of interest [170].

The sublimation cell constructed and tested within this work can be further improved. The CaF₂ crystals within the windows of the sublimation cell were randomly oriented. The influence of the preferential growth direction should be investigated with an oriented CaF₂ substrate [149]. Interactions between the windows and the substrate might change the preferred face exhibited by the microcrystals. The application of the ATR technique can be extended to crystals. An ATR ob-

jective could improve the spatial resolution of the microscopic measurements by a factor of five. A higher resolution would open the possibility to analyze and characterize even smaller crystals in the range of a few micrometers. Remeasurements of the methylxanthines with this technique would be worthwhile. Since the ATR device needs to be in contact with the sample, a new sublimation cell with a sealed opening for the ATR crystal would need to be constructed. In order to investigate less volatile substances higher sublimation temperatures need to be applied. A heating plate which can achieve higher temperatures would be needed.

During the course of the studies conducted for this dissertation, a macro jet setup for the imaging of jet expansions was newly constructed and tested. The jet-images will provide information of the spatial distribution of different monomer conformations and clusters within the jet expansion. This provides information of conformational preferences and conditions for adaptive aggregation which might be valuable for the further improvement of the sublimation experiments. The project is continued by J. Zischang [217].

The oriented monomer units need to be compared with the ones of the crystal structure since the angles for the rotation are not correctly calculated in every case. If the orientation of the relaxed monomer deviates from the one within the crystal structure, the rotation can be manually performed.

D. Jet Parameters and Experimental Conditions

D.1. Filet-Jet Parameters

Table D.1.: Parameters of the FTIR-jet for the mixed alcohol-water systems.

Optic-Parameters	
Source Setting	Tungsten
Beamsplitter	CaF ₂
Detector	InSb 2 mm
Channel	X1
Aperture	3.5 mm
Opt. filter setting	4000–2860 cm ⁻¹
Scanner velocity	80 kHz
Stabilization delay	2 s
Delay before measurement	0 s
Gain	on
Signal enhancement	auto
Reference enhancement	auto
Resolution	2.0 cm ⁻¹
Acquisition-Parameters	
Wanted high frequency limit	15800 cm ⁻¹
Wanted low frequency limit	0 cm ⁻¹
Acquisition mode	Single-Sided Fast-Return
Correlation mode	–
Low pass filter	–
High pass filter	–
FT-Parameters	
Frequency limits	15800–0 cm ⁻¹
Phase correction mode	Mertz
Phase resolution	16 cm ⁻¹
Zero filling factor	4
Apodization function	Norton-Beer-Medium

D. Jet Parameters and Experimental Conditions

Table D.2.: Experimental FTIR-jet conditions for the mixed methanol-water and for the mixed ethanol-water system. ϑ denotes the saturator temperature. Also given are the opening times of the mixing valves.

	methanol-water	ethanol-water
$\vartheta(\text{alcohol})/^{\circ}\text{C}$	−15	−10
$\text{time}_{\text{open}}(\text{alcohol})/\text{s}$	0.1	0.4
$\text{time}_{\text{closed}}(\text{alcohol})/\text{s}$	4.08	2.4
$\vartheta(\text{water})/^{\circ}\text{C}$	+5	+5
$\text{time}_{\text{open}}(\text{water})/\text{s}$	0.92	1.04
$\text{time}_{\text{closed}}(\text{water})/\text{s}$	1.88	1.8
$\text{time}_{\text{open}}(\text{helium})/\text{s}$	3.32	2.72
$\text{time}_{\text{closed}}(\text{helium})/\text{s}$	0.1	0.1

E. Quantum Chemical Predictions of the Mixed Alcohol-Water Clusters

Table E.1.: Differences between the experimental $\tilde{\nu}_{\text{ww}}(\text{exp})$ and the calculated harmonic wavenumber $\omega_{\text{ww}}(\text{th})$ in cm^{-1} for the water and the deuterated water dimer on different levels. For the larger basis sets, the difference approaches twice the expected O-H oscillator anharmonic constant, as it should.

$\tilde{\nu}_{\text{ww}}(\text{exp}) - \omega_{\text{ww}}(\text{th})$	B3-S	MP2-S	MP2-M	MP2-L
$(\text{H}_2\text{O})_2$	-48	-152	-138	-161
$(\text{D}_2\text{O})_2$	-5	-76	-71	-88

Table E.2.: Shifted MP2-S/MP2-M average of predicted Raman and IR wavenumbers $\tilde{\nu}$ in cm^{-1} as well as relative Raman and IR intensities (σ'_{rel} in $10^{-36} \cdot \text{m}^2 \cdot \text{sr}^{-1}$ and I_{rel} in $\text{km} \cdot \text{mol}^{-1}$, respectively) for pure and mixed dimers and trimers in the methanol-water system. A methanol mole fraction of $x_{\text{m}}=0.75$ for the Raman and of $x_{\text{m}}=0.50$ for the IR case is assumed. For the scaling procedure, see Chapter 4.

E. Quantum Chemical Predictions of the Mixed Alcohol-Water Clusters

Table E.11.: Dissociation energies without (D_e) and with zero point energy correction (D_0) in $\text{kJ}\cdot\text{mol}^{-1}$ of pure and mixed ethanol-water dimers for dissociation into e_t and w (values for dissociation into e_g and w are given in parentheses). Also, calculated wavenumbers ($\omega(\text{th})$) in cm^{-1} , scattering activities (A_{Raman}) in $\text{\AA}^4\cdot\text{u}^{-1}$, scattering cross sections (σ') in $10^{-36}\cdot\text{m}^2\cdot\text{sr}^{-1}$, and IR intensities (I_{IR}) in $\text{km}\cdot\text{mol}^{-1}$ of the donor (D) and acceptor (A) symmetric (*sym*) and asymmetric (*asym*) O-H stretching vibration on different levels are listed. The S basis set does not predict the correct order.

F. Quantum Chemical Predictions of the Investigated Microcrystals

F.1. Methyl Mandelate

Table F.1.: Predicted harmonic wavenumbers ω in cm^{-1} and intensities I in $\text{km}\cdot\text{mol}^{-1}$ of a methyl mandelate monomer unit relaxed from the crystal structure ($\text{Mon}_{\text{crystal}}$) and the most stable methyl mandelate monomer ($\text{Mon}_{\text{stable}}$) on the B3LYP/6-311++G(3df,2p) and MP2/6-311++G(2d,p) level. The stretching and bending vibrations are indicated as ν and δ and the symmetric and asymmetric vibrations with sym and asym.

Figure F.1.: Fundamental stretching (ν) and bending modes (δ) of a methyl mandelate monomer along the crystallographic b axis (B3LYP/6-311++G(3df,2p) level). The relaxed monomer was taken from the crystal structure of enantiopure methyl mandelate (see Chapter 5) [38]. The direction of the vibrational transition dipole vectors (yellow, unit length) as well as the displacement vectors of each mode (blue) are indicated.

Figure F.2.: Fundamental stretching (ν) and bending modes (δ) of a methyl mandelate monomer along the crystallographic a axis (B3LYP/6-311++G(3df,2p) level). The relaxed monomer was taken from the crystal structure of enantiopure methyl mandelate (see Chapter 5) [38]. The direction of the vibrational transition dipole vectors (yellow, unit length) as well as the displacement vectors of each mode (blue) are indicated.

F.2. Mandelic Acid

Table F.2.: Predicted harmonic wavenumbers ω in cm^{-1} and intensities I in $\text{km}\cdot\text{mol}^{-1}$ of a mandelic acid monomer unit relaxed from the crystal structure ($\text{Mon}_{\text{crystal}}$) on the B3LYP/6-311++G(3df,2p) (B3LYP) and MP2/6-311++G(2d,p) (MP2) level (see Figs. F.3 and F.4). The stretching vibrations are indicated as ν and the symmetric vibration with sym.

Curriculum Vitae

Personal Information

Name	Marija Nedić
Date of Birth	04 th of August 1982
Place of Birth	Hamburg

Academic Education

Since Feb 2009	Ph.D. thesis at the Institute of Physical Chemistry, Georg-August-Universität Göttingen under the supervision of Prof. Dr. Martin A. Suhm Title of thesis: Adaptive Aggregation and Chirality Recognition of Neuroactive Substances and their Building Blocks: A Vibrational Spectroscopic and Microscopic Study
Dec 2008	1. Staatsexamen für das Lehramt an Gymnasien with the subjects Chemistry and Philosophy Title of thesis: „Der kleinste Schnaps der Welt“– Experimentell und theoretische Untersuchungen zu kleinen Alkohol-Wasser-Clustern
Oct 2003 – Dec 2008	Studies of Lehramt an Gymnasien with the subjects Chemistry and Philosophy, Georg-August-Universität Göttingen
Apr 2003 – Sep 2003	Studies of Lehramt an Gymnasien with the subjects Chemistry and German, Christian-Albrechts-Universität zu Kiel

School Education

2002	Allgemeine Hochschulreife (Abitur)
1993–2002	Gymnasium Hummelsbüttel in Hamburg
1989–1993	Grundschule Flughafenstraße in Hamburg
