Chapter 1

Introduction

1.1 Neuronal exocytosis

Neuronal communication requires fast exocytosis of synaptic vesicles. Synaptic vesicles (SVs) possess a large variety of trafficking proteins in different copy numbers and are filled with neurotransmitters in the lumen [119]. SVs function as transporters of neurotransmitters and release their neurotransmitters by rapid fusion with the presynaptic plasma membrane triggered by calcium influx upon arrival of an action potential [62,63,139].

Filled SVs translocate to the active zone, in which SVs target the plasma membrane (docking) and prepare themselves for fusion (priming). The priming state involves protein-protein interaction as well as protein-lipid interaction (priming). Subsequently, they fuse with the plasma membrane initiated by the local increase of the intracellular calcium concentration (fusion, see Figure 1.1) [62,113,117].

After fusion, new empty SVs are reformed from the plasma membrane by clathrin coated vesicle fission, a process termed endocytosis [45]. The new SVs are recycled by fusion with the early endosome and regenerated by budding from the early endosome [113]. The regenerated SVs are refilled with neurotransmitters triggered by an electrochemical gradient (NT uptake) and proceed to a new round of the exo- and

endocytosis (Figure 1.1) [113].

Figure 1.1: Synaptic vesicle cycle [113]. Neurotransmission is mediated by fusion of synaptic vesicles with the plasma membrane. During this process, neurotransmitters are released from the vesicle lumen into the synaptic cleft. After fusion, new SVs are reformed from the plasma membrane by endocytosis. Empty vesicles are recycled from the early endosome by endosome fusion and regenerated by budding from the early endosome. The vesicles are then filled with neurotransmitters (NT uptake) and are available for neurotransmission. Before fusion, the vesicles dock to the plasma membrane and proceed to the priming state, at which point the vesicles are ready for fusion. The fusion occurs when the calcium channels are opened upon arrival of an action potential.

1.2 The role of SNARE proteins in exocytosis

Neuronal exocytosis is mediated and regulated by a series of proteins, among which SNARE (soluble *N*-ethylmaleimide-sensitive-factor attachment receptor) proteins play a central role. The formation of a ternary complex of SNARE proteins is

crucial for the overall process and the SNARE complex itself is the minimal machinery of neuronal membrane fusion [17,20,62,102,138]. In neuronal exocytosis, the SNARE complex consists of synaptobrevin 2 (Sb2), syntaxin 1A (Sx1A) and synaptosomal-associated protein 25 (SNAP25).

Sb2 is a vesicular SNARE protein [119], whereas Sx1A and SNAP25 are located in the plasma membrane and form a complex [34,38]. The core of a SNARE complex is a bundle of four α -helices, each of them being a so-called SNARE motif [114]. Sb2 and Sx1A each provide one motif and SNAP25 contributes two (Figure 1.2).

The SNARE complex has a highly conserved layer structure; each of the layers consists of four amino acid side chains which interact with each other. Due to the composition of the layer structure, SNARE proteins are also classified as Q-SNAREs (Sx (Qa) and SNAP25 (Qb and Qc)) and R-SNARE (Sb, see Figure 1.3) [36]. The SNARE assembly proceeds from the cytosolic N-terminus to the membrane anchored C-terminus (zippering hypothesis) [48,91].

Figure 1.2: Four-helix-bundle of the core SNARE complex [114]. Sb: Synaptobrevin (blue). Sx: Syntaxin (red). Sn1: SNAP-25(N) (green). Sn2: SNAP-25(C) (green).

At the stage of the docked intermediate, SNARE proteins form the *trans*-complex, in which the C-terminal transmembrane domains of the proteins are in separate membranes. During fusion, the *trans*-complex converts into the *cis*-complex form, in which both transmembrane domains of Sx1A and Sb2 come together in the same membrane, and stimulates membrane merging [63]. The *cis*-complex is inactive for the further membrane fusion and can be disassembled by AAA+ ATPase protein NSF (*N*-ethylmaleimide-sensitive factor) [77] and its cofactor SNAP proteins (soluble NSF at-

Figure 1.3: Layer structure of the ternary SNARE complex [36]. Synaptobrevin (blue), Syntaxin (red) and SNAP-25 (green) assemble a helix-bundle with a conserved layer structures, in which the +8 layer is the last layer before the C-terminal linker region and the +7 layer is the first layer at the N-termini.

tachment proteins) [22] under ATP hydrolysis.

The SNARE disassembly will be discussed later in Section 1.4. The disassembled Sx and SNAP25 furthermore form the acceptor complex upon invocation by SM (Sec1/Munc-18) family proteins and are available for the further vesicle docking and fusion (Figure 1.4) [63]. SM proteins are not included in this study.

Figure 1.4: The SNARE conformational cycle during vesicle docking and fusion [63]. Three Q-SNAREs (Qa, Qb and Qc) localized in the plasma membrane and one R-SNARE localized in the synaptic vesicles form a fusion machinery. Vesicles are docked to the plasma membrane by SNARE interaction, forming a loose *trans*-SNARE complex. At the priming stage associated with other late regulatory proteins, SNAREs assemble to a tight *trans*-complex and are prepared for fusion. Upon arrival of an action potential, SNAREs fully assemble to the *cis*-conformation and promote membrane fusion. The *cis*-SNARE-complex is not active for fusion and is disassembled by AAA+ ATPase protein NSF with its cofactor α -SNAP under ATP hydrolysis. The disassembled Q-SNAREs are transformed into the active acceptor complex by SM proteins (Sec1/Munc18-related proteins) and can further take part in membrane fusion.

1.3 Calcium sensor protein: synaptotagmin-1

Neuronal exocytosis is triggered by the influx of calcium: Synaptic vesicles are docked at the plasma membrane but do not undergo fusion until an action potential causes a transient increase in the intracellular calcium concentration. The calcium influx is sensed by synaptotagmin-1 (Syt1, 65 kDa) [19, 37, 79], which is linked to the synaptic vesicle by their transmembrane domains (aa 58-79) in about seven copies [119]. Syt1 possesses two calcium binding C2 domains, referred to as C2A (aa 140-265) and C2B (aa 271-421), which are connected to the transmembrane domain by a long (61 residue) flexible linker [37]. C2A binds three and C2B two calcium ions (Figure 1.5) [37, 95]. Syt1 binds to the acidic phospholipids of the membrane in the presence of calcium [3, 13, 42, 56, 59, 73, 95]. C2B contains a polybasic lysine patch (aa 324-327) proximal to the calcium binding site and has a specific affinity to phosphatidylinositol-4,5-bisphosphate (PiP2) in a calcium independent manner (Figure 1.5) [6, 73, 104, 134, 141]. The polybasic stretch also binds phosphatidylserine (PS). Moreover, Syt1 interacts with syntaxin and SNARE-complex-containing syntaxin in the absence of calcium [6, 19, 21, 69, 125], albeit the binding is influenced to a limited degree by calcium [19, 101].

Syt1 is well known as capable to increase the rate of exocytosis by several orders of magnitude [96], but the molecular mechanism is still unclear. Two different priming models are presently being discussed. In the first model, a partial SNARE assembly is formed and arrested at this state, which is assumed to be caused by either an energy barrier or interaction with complexin or synaptotagmin. After receiving calcium, Syt1 may (i) bind to the SNARE complex and the plasma membrane (PiP2, PS), displace the inhibitory complexin and promote the full SNARE zippering [111, 134, 135]; or (ii) bind to the plasma membrane, induce curvature stress close to the membrane contact area and lower the energy barrier [61, 78, 82]; (iii) alternatively cross-link the vesicle membrane and the plasma membrane and promote fusion by compensating the membrane charge [3]. The second model proposes tethering/docking of the vesicle to the plasma membrane by Syt1 *trans*-binding to PiP2 contained in the plasma membrane

without SNARE assembly. Calcium activates both C2 domains and thus cross-linking of the membrane to further promote the SNARE assembly. Hereby, Syt1 functions as distance regulator [111,141].

To dissect the molecular mechanism of Syt1, SNARE-mediated fusion was performed using reconstituted liposomes. Contradictory effects of Syt1 have been reported. Several studies have shown that tethering/docking of Syt1 to the plasma membrane promotes SNARE assembly [61,78]. However, tethering was not observed as a separate intermediate because of the presence of the SNARE proteins. Inhibition of fusion has also been observed in several fusion experiments with SNAREs and Syt1 [67,111]. This led to further complications in the study, because Syt1 may also bind in *cis* to the vesicular membrane and *cis*-binding competes with *trans*-binding. Since *trans*-binding of Syt1 is required by all of the different fusion models, a balance between *cis*- and *trans*-binding may play an essential role in neurotransmission. Therefore, this study will focus on the *cis*- and *trans*-membrane interaction of Syt1.

Figure 1.5: 3D structure of synaptotagmin-1. [95] Synaptotagmin-1 possesses one transmembrane domain and two C2 domains, called C2A and C2B. All the three domains are linked subsequently to each other by two flexible linkers. The C2A domain binds three calcium ions, while the C2B domain binds two calcium ions. Mutant (K326,327A) of the calcium independent binding site of C2B is shown as “KAKA” (blue). S342C shows the position of the cysteine mutant, at which the fluorescence dye can be attached (green).

1.4 NSF and α -SNAP

NSF (*N*-ethylmaleimide-sensitive factor) belongs to the AAA+ ATPase family and its function in neuronal exocytosis is to accomplish disassembly of the SNARE complex under ATP hydrolysis [81, 115]. NSF consists of two AAA+ domains, referred to as D1 domain (aa 206-477) and C-terminus D2 domains (aa 478-744), and one N-terminus domain (aa 1-205) [118, 137]. For disassembly, NSF forms a homo-hexamer [39, 40, 49] and provides the energy for disassembly by its D1 domain, while the C-terminus D2 domain is mainly responsible for the hexamerization [84].

NSF does not bind to the SNARE complex directly. To transfer the energy from the ATP hydrolysis to the SNARE complex, NSF must interact with its cofactor α -SNAP (soluble NSF attachment proteins) [22], which consists of fourteen subsequent α -helices [80, 132] and connects the SNARE complex and the NSF hexamer with two more copies of itself [131]. Altogether, NSF hexamer, three α -SNAPs and one SNARE complex form an complex, called 20S complex or 20S particle [40, 49, 57, 131]. The N-termini of the NSF hexamer attach to the α -SNAPs at their C-termini [8, 84, 136] and energy is transferred to the SNARE complex via interaction of the N-terminus of α -SNAP with the C-terminal side of SNARE complex near the membrane [52]. To process the SNARE disassembly, α -SNAP has to attach to the membrane through the hydrophobic loop located at its N-terminus (Figure 1.6) [132]. The disassembly is promoted by the conformation change of the NSF hexamer concerted with the ATP hydrolysis. This movement is transferred to the SNARE complex and the membrane by α -SNAPs [49, 115].

Disassembly of the SNARE complex increases the number of free SNARE proteins, and thus plays a positive role for vesicle priming [18, 66, 120, 133]. On the other hand, free α -SNAP has been shown to inhibit the vesicle fusion in *Drosophila* [4] and the exocytosis of dense-core vesicles in PC12 cells [9]. However, how this inhibition of membrane fusion occurs is remaining unclear.

Figure 1.6: Membrane attachment site of α -SNAP in the presence of the SNARE complex [132]. The yeast Sec17 (α -SNAP) from Baker's yeast is structured as fourteen subsequent α -helices ($\alpha 1$ - $\alpha 14$) and consists of a hydrophobic loop localized between the $\alpha 1$ - and $\alpha 2$ -helices. The loop attaches to the membrane when α -SNAP binds the SNARE complex (Synaptobrevin 2, Syntaxin 1a and SNAP-25), and facilitates the disassembly of the SNARE complex by NSF.

1.5 Fluorescence correlation spectroscopy

1.5.1 Fluorescence correlation spectroscopy (FCS)

Fluorescence correlation spectroscopy (FCS) is a technique with single molecule level resolution, which is used in this study to temporally characterize the molecular dynamics of biomolecules *in vitro* in terms of concentration, diffusion time, and interaction with other biomolecular components [5,31,76,98].

The core of FCS is not the characterization of the individual fluorescence event itself—as in time-correlated single photon counting (TCSPC)—but rather the temporal fluctuation of the total fluorescence intensity $I(t)$ [31,74,75] caused by rotational- or translational diffusion [29,75], population of the triplet state [14,25,130], chemical reactions or interactions [46,47,50,93], Förster Resonance Energy Transfer (FRET) [121,129]. The fluctuation of a single molecule’s emission can be observed only when the sample is strongly diluted, so that the diffusion of a single particle into (on) and out of (off) the effective volume cannot be neglected. The ideal sample concentration for FCS measurements is from subnanomolar to submicromolar.

To analyze experimental data, the photons collected by the detector are added up in time intervals of 5 μs each and a temporal fluorescence trace $I(t)$ is constructed from these intervals. The fluctuation can be described as [31,50]:

$$\delta I(t) = I(t) - \langle I(t) \rangle \quad (1.1)$$

where the $\langle I(t) \rangle$ is the mean fluorescence intensity $I(t)$ over the entire time of the experiment ($0 - T$). Autocorrelation is a characterization of data or functions in terms of the “self-similarity”, in this case of the signal I at time t , $I(t)$, compared to the signal I at a time shift $t + \tau$, $I(t + \tau)$ (Figure 1.7). The autocorrelation is computed as [31,50]:

$$G(\tau) = \frac{\langle I(t) \cdot I(t + \tau) \rangle}{\langle I(t) \rangle^2} - 1 = \frac{\langle \delta I(t) \cdot \delta I(t + \tau) \rangle}{\langle I(t) \rangle^2} \quad (1.2)$$

Figure 1.7: Fluorescence autocorrelation-spectroscopy. The autocorrelation function of a fluorescence signal $I(t)$ provides a quantitative measure of the similarity of this very signal with an instance of itself $I(t + \tau)$ shifted by a temporal offset τ . A schematic fluorescence trace $I(t)$ and its time-shifted traces $I(t + \tau_x)$ ($x = 0 - 3$) are shown above (left). The autocorrelation $G(\tau)$ is calculated by multiplication of $I(t)$ with $I(t + \tau)$ over the entire trace (purple line), averaging the results and normalizing by the square of the average intensity. For $\tau = 0$, $G(0) = \frac{1}{N}$ and at half of the decay $\tau = \tau_D$. The temporal offset τ , also referred to as the “correlation time”, is the abscissa value and is usually represented in log scale (right).

In this study, the liposomes and the SVs diffuse in a three-dimensional Brownian motion and the analytical expression of the autocorrelation function hence is [76]:

$$G(\tau) = \frac{1}{\langle C \rangle \cdot \pi^{3/2} \cdot w_0^2 \cdot z_0} \cdot \left(1 + \frac{4D\tau}{r_0^2}\right)^{-1} \cdot \left(1 + \frac{4D\tau}{z_0^2}\right)^{-1/2} \quad (1.3)$$

In this equation, $\langle C \rangle$ is the average of the particle concentration in the effective focal volume V_{eff} , while $\pi^{3/2} \cdot w_0^2 \cdot z_0$ is V_{eff} as calculated by the integration of the emission distribution over the focal volume V . D represents the molecular diffusion coefficient of the particle, and w_0 and z_0 the radius of the focal volume in lateral and axial directions, respectively. The focal volume is a property of the setup (laser beam and objective).

The time-independent part of this function can be expressed as $\frac{1}{N}$, where N is the average particle number in V_{eff} and can be calculated as $N = \langle C \rangle \cdot V_{eff}$. The diffusion time τ_D , for which a particle stays in the focal volume, is inversely proportional to the diffusion coefficient D [30]:

$$\tau_D = \frac{w_0^2}{4D} \quad \tau_{D,z} = \frac{z_0^2}{4D} \quad (1.4)$$

τ_D is the diffusion time in the lateral direction and $\tau_{D,z}$ in the axial direction. With these diffusion times, Equation 1.3 can be reformed as [50]:

$$G(\tau) = \frac{1}{N} \cdot \left(1 + \frac{\tau}{\tau_D}\right)^{-1} \cdot \left(1 + \frac{\tau}{\tau_D} \cdot \frac{w_0^2}{z_0^2}\right)^{-1/2} \quad (1.5)$$

The ratio of $\frac{w_0}{z_0}$ is a property of the experimental setup and was determined directly using immobilized gold beads ($\varnothing = 20$ nm) on a micro-XYZ-stage for this study by Dr. W. H. Pohl [92]. The reflection of the laser beam by the gold beads can be observed only within the focal volume. The value of $\frac{w_0}{z_0}$ for the water immersion objective used in this study (UPlanSApo 60x/1.2w, Olympus) is 0.25 [92].

The time dependent part of the correlation function approaches unity at $\tau = 0$, and thus the ordinate value gives the reciprocal of the particle number within the effective volume:

$$G(0) = \frac{1}{N} \quad (1.6)$$

At $\tau = \tau_D$, the time dependent part of the autocorrelation function is about 0.5, neglecting the reciprocal square root, so that the diffusion time τ_D can be read off at the half-value of the decay. Figure 1.7 shows a schematic of the autocorrelation curve.

1.5.2 Fluorescence cross-correlation spectroscopy (FCCS)

In case of two-color experiments, two different dyes are used for labeling the sample particles, either in two different groups of sample components or at different positions of the same sample particles. The two dyes are excited simultaneously either with two (one-photon excitation, OPE) lasers or with a single (two-photon excitation, TPE) laser. Using fluorescence cross-correlation spectroscopy (FCCS), the number of interacting particles N_x which accordingly emit both colors from spatial proximity after, for instance, fusion or tethering, can be determined. It should be noted at this point, that the interaction of the spatially close emitters might impact on the characteristics of the emission (fluorescence lifetime and intensity). However, for the immediate treatment of FCCS in this subsection, these effects shall not be considered. The FCCS function is analogous to the FCS function, so that a similarity comparison is performed between the separated fluorescence traces of two colors [50, 107]:

$$G_{RG}(\tau) = \frac{\langle \delta I_R(t) \cdot \delta I_G(t + \tau) \rangle}{\langle I_R(t) \rangle \cdot \langle I_G(t) \rangle} \quad (1.7)$$

$G_{RG}(\tau)$ is the amplitude of the cross-correlation. $I_R(t)$ and $I_G(t)$ are the intensity functions of the separate red and green channels (Figure 1.8).

Equation 1.5 is fitted to the cross-correlation data and, from the resulting $G_{RG}(0)$, the multicolor particle number N_x can be calculated as [99]:

$$G_{RG}(0) = \frac{N_x}{(N_R + N_x) \cdot (N_G + N_x)} \quad (1.8)$$

N_R and N_G are the numbers of the free red and green emitters, respectively.

The sum of N_i ($i = R, G$) and N_x can be calculated from the autocorrelation of the

respective channel:

$$N_R + N_x = N_R(0) = \frac{1}{G_R(0)} \quad (1.9)$$

$$N_G + N_x = N_G(0) = \frac{1}{G_G(0)} \quad (1.10)$$

N_x can subsequently be obtained as:

$$N_x = G_{RG}(0) \cdot N_R(0) \cdot N_G(0) \quad (1.11)$$

Figure 1.8: Fluorescence cross-correlation-spectroscopy. The FCCS concept is analogous to FCS but with two separate fluorescence channels (left). From the results of FCCS (blue solid line) and of FCS for each color (red and green dash lines), the number of the particles with both red and green dyes N_x can be calculated (right).

1.5.3 Two-photon excitation (TPE)

FCS measurements require a low sample concentration (nM) and a small detection volume, so that a fluctuation of the individual dye's emission can be observed clearly.

The latter can be achieved using an objective with high numerical aperture (NA, NA = 1.2 in this study) in a confocal microscope [100], minimizing the lateral extent of the excitation beam to several 10^2 nm. Furthermore, a pinhole is needed to limit the axial dimension of the focal volume. Alternatively, two-photon excitation (TPE), due to its excitation property, can be used for FCS to reduce the excitation volume and thus the effective volume of the focus [10,23,27,55].

During two-photon excitation, the fluorescence dye absorbs, in one excitation process, two photons of theoretically double the wavelength used for one-photon excitation within a sub-femtosecond time range (Figure 1.9a) [44]. To achieve this, a pulsed laser is required for drastically increasing the photon density in the focus area. The excitation probability is proportional to the square of the laser's intensity, so that only the middle part of the focal volume can be excited. The distribution of the emission light depends on the laser beam and the objective, and can be approximated as a 3D-Gaussian. Thus the effective excitation volume is decreased by a factor of $\sqrt{2}$ in each direction for TPE:

$$\text{OPE: } V_{eff} = \pi^{3/2} \cdot w_0^2 \cdot z_0 \quad (\text{Page 13, Subsection 1.5.1}) \quad (1.12)$$

$$\text{TPE: } V_{eff} = \left(\frac{\pi}{2}\right)^{3/2} \cdot w_0^2 \cdot z_0 \quad (1.13)$$

and the diffusion time is accordingly shorter by a factor of two in each direction (Figure 1.9b):

$$\text{OPE: } \tau_D = \frac{w_0^2}{4D} \quad \tau_{D,z} = \frac{z_0^2}{4D} \quad (\text{Page 13, Equation 1.4}) \quad (1.14)$$

$$\text{TPE: } \tau_D = \frac{w_0^2}{8D} \quad \tau_{D,z} = \frac{z_0^2}{8D} \quad (1.15)$$

The typical V_{eff}^{OPE} for OPE is about 1 fl.

For our two-photon confocal microscope, the lateral radius w_0 was determined using the fluorescence dye Rhodamine Green (RG) with a known diffusion coefficient $D_{RG} = 2.8 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$ [24,100] and calculated using equation 1.15. The V_{eff}^{TPE} was calculated with equation 1.13 and the value is about 0.3 fl, which perfectly confirmed the expected decrease in detection volume by a factor of $\sqrt{8}$ ($\sqrt{2}$ in each direction) compared to OPE.

Figure 1.9: OPE compared with TPE in terms of the excitation module and the effective volume. a. Jablonski-diagram for OPE and TPE. b. Schematic of the effective excitation volume by OPE (green) and TPE (red).

Two-photon excitation allows simultaneous excitation of two fluorescence dyes with one laser beam and protects the biological sample against denaturation throughout most of the path of the laser beam due to its low photon energy and its small excitation volume.

1.5.4 Förster resonance energy transfer (FRET)

Förster resonance energy transfer (FRET) is a non-radiative energy transfer between a donor fluorophore and an acceptor fluorophore. The donor is excited to its electronically excited state, transfers the energy to the acceptor nearby and thus excites the acceptor [41]. In this process, the donor fluorescence is quenched and only the acceptor is able to fluoresce (Figure 1.10). For FRET to occur, the spectra of the donor emission and the acceptor absorption need to overlap, the distance between the donor and the acceptor has to be relatively short (10-100 Å), and relative dipole-dipole orientations have to be favorable for coupling [122].

In general, the experimentally observable rate constant k_{exp} of the decay of the

Figure 1.10: Jablonski-diagram of FRET donor and acceptor. As the excited state's energy is transferred from the donor to the acceptor, donor emission is quenched and acceptor fluorescence enhanced.

donor's (D) and acceptor's (A) respective S_1 state populations is a sum of the fluorescence (Fl) rate constant and other rate constants, for instance internal conversion (IC), intersystem crossing (ISC):

$$k_{exp}^D = k_{Fl}^D + k_{IC}^D + k_{ISC}^D \quad (1.16)$$

$$k_{exp}^A = k_{Fl}^A + k_{IC}^A + k_{ISC}^A \quad (1.17)$$

If FRET occurs, the depletion of the donor's electronically excited state is accelerated:

$$k_{exp}^{D'} = k_{Fl}^D + k_{IC}^D + k_{ISC}^D + k_{FRET} \quad (1.18)$$

The fluorescence quantum efficiency can be calculated as k_{Fl}/k_{exp} and the observed fluorescence lifetime τ_{exp} is the inversion of the emission rate constant k_{exp} . Thus, the donor emission count rate and lifetime τ_D decrease under FRET.

The FRET distance is the donor-acceptor-distance at which the FRET quantum efficiency k_{FRET}/k_{exp} is 50% [11]. FRET is, of course, most pronounced below this distance. In the Syt1 tethering experiment, the liposomes were labeled with either 1% TR-DHPE or 1.5% OG-DHPE in such a way that upon fusion the distance between TR and OG is about 7 nm. According to a previous study using TR-OG FRET pair [23,55], FRET can be observed upon fusion. Figure 1.11 shows the excitation and emission spectra of TR

and OG.

Figure 1.11: Excitation and emission spectra of TR-DHPE and OG-DHPE.

1.6 Outline of this Study

This study focuses on the functional mechanism of Syt1 with the particular emphasis on the *cis*- and *trans*-membrane interaction of Syt1. To achieve this, molecular requirements for the calcium dependent and independent binding properties are investigated using reconstituted liposomes with a sensitive tethering assay based on two photon-fluorescence cross correlation spectroscopy (TP-FCCS). Tethering is measured between the liposomes bearing Syt1 and the liposomes containing acidic phospholipids, in this case phosphatidylserine (PS) and phosphatidylinositol-4,5-bisphosphate (PIP₂), under the influence of calcium. The host liposomes of Syt1 contain either no acidic phospholipids or 20% PS to obtain either *trans*- or *cis*-binding. Furthermore, interaction between membrane anchored Syt1 and membrane anchored SNARE proteins (Syntaxin 1A (Sx1A), a 2:1 complex consisting of two Sx1A and one SNAP-25, and a ternary complex consisting of Sx1A, SNAP-25 and Synaptobrevin 2 (Sb2) lacking transmembrane domain) is tested. To investigate the binding function of different binding sites, mutants at C2A and C2B domains of the full-length Syt1 are used instead of the wild-type Syt1. In addition, cross-linking mediated by soluble Syt1 (aa 1-97) is measured to complete the study by comparison with the previous publications.

Associated with the Syt1 project, two preliminary measurements are performed in this study, aimed at characterizing the mouse synaptic vesicle (SVs) by average protein mass, and monitoring the chromaffin granules (CGs) docking with the large liposomes mediated by partial SNARE assembly arrested by α -SNAP. Purified mouse SVs are labeled with FM 1-43 fluorescence dye and measured with fluorescence correlation spectroscopy (FCS) to determine the vesicle number. Combining the protein concentration of the same sample, an average vesicular mass of proteins can be calculated. This experiment introduces a nice comparison with the previous study of rat SVs and establishes a vesicular base for the further characterization of the composition of proteins as well as lipids in a single vesicle manner.

Using FCCS tethering assay, a stable docked state between CGs and large liposomes can be monitored for the first time. α -SNAP is reported to be able to inhibit CG fusion by the lipid mixing assay. Here, docking can be observed under the same conditions. This observation suggests a partial assembly model of the SNARE complex mediated by α -SNAP, which inhibits CG fusion, but not CG docking.

Chapter 2

Materials and Methods

2.1 Materials

2.1.1 Chemicals

All the standard chemicals used in this study were purchased from the following companies: Sigma (Deisenhofen, Germany), Sigma-Aldrich (St. Louis, USA), AppliChem (Darmstadt, Germany), Merck (Darmstadt, Germany), Roth (Karlsruhe, Germany), Biorad (Richmond, USA), Serva (Heidelberg, Germany), Boehringer (Ingelheim, Germany), Fluka (Switzerland) and Anatrace (USA). The column material Sephadex G50 was purchased from GE Healthcare (Freiburg, Germany) and the molecular weight protein standards (SM0671) was purchased from MBI Fermentas (St. Leon-Rot, Germany).

2.1.2 Phospholipids

All the phospholipids used in the tethering experiments were purchased from Avanti Polar Lipids Inc. (Alabama, USA), except Texas Red phosphatidylethanolamine and Oregon Green phosphatidylethanolamine, which were purchased from Invitrogen

Molecular Probes (see Table 2.1).

Abbreviation	Phospholipid	Company
PC	L- α -Phosphatidylcholine	Avanti Polar Lipids
PE	L- α -Phosphatidylethanolamine	Avanti Polar Lipids
PS	L- α -Phosphatidylserine	Avanti Polar Lipids
PI	L- α -Phosphatidylinositol	Avanti Polar Lipids
PiP2	Phosphatidylinositol-4,5-bisphosphate	Avanti Polar Lipids
TRPE	Texas Red-PE	Invitrogen Molecular Probes
OGPE	Oregon Green-PE	Invitrogen Molecular Probes
NBD-DOPE	1,2-dioleoyl- <i>sn</i> -glycero-3-phosphoethanolamine- <i>N</i> -(7-nitrobenz-2-oxa-1,3-diazol-4-yl)	Avanti Polar Lipids
Rhodamine-DOPE	1,2-dioleoyl- <i>sn</i> -glycero-3-phosphoethanolamine- <i>N</i> -lissamine rhodamine B sulfonyl ammonium salt	Avanti Polar Lipids

Table 2.1: Phospholipids used for reconstitution of liposomes.

2.1.3 Proteins

All the protein constructs used in this study were from *Rattus norvegicus*. The proteins were cloned in the pET28a (Novagen) vector and expressed in *Escherichia coli* strain BL21 (DE3) except the Δ N complex, in which syntaxin 1A (Sx1A) (183-288) and synaptobrevin 2 (49-96) were cloned in pET Duet-1 (Novagen), and SNAP 25A was cloned in pET28a.

Expression constructs of the full-length synaptotagmin-1 (Syt1) (1–421) and of the soluble domain of Syt1 (97–421), have been described elsewhere [111]. Also the

following calcium mutants of the full-length Syt1 have been described earlier [111]: a*B (D178, 230, 232A), Ab* (D309, 363, 365A), a*b* (D178, 230, 232, 309, 363, 365A), and KAKA mutant (K326, 327A). The constructs for the neuronal SNAREs were the SNARE motif of syntaxin 1A with its transmembrane domain (183–288), a cysteine-free variant of SNAP-25A (1–206), and synaptobrevin 2 without its transmembrane domain (1–96). The Syt1 (97–421) single cysteine variant (S342C) was obtained after first removing the single native cysteine (C278S) and then introducing a point mutation at position 342.

All proteins were expressed in *Escherichia coli* strain BL21 (DE3) (Novagen) and purified using Ni²⁺-nitrilotriacetic acid beads (Ni-NTA, GE Healthcare) followed by ion exchange chromatography (IEXC) on the Aekta system (GE Healthcare) as described in the literature [91, 111], with a few modifications. The Syt1 single cysteine variant (97–421, S342C) was further labeled with Alexa Fluor 488 C5 maleimide. This was done by first dialyzing the proteins against the AF-labeling buffer (page 28, Table 2.3). The dialyzed protein solution was then incubated with the fluorophore for 2 h at RT and separated from the free dye using a Sephadex G50 superfine column. The labeling efficiency was about 40% [111, 140, 141]. Sx1A (183–288) and synaptobrevin 2 (1–96) were purified by IEXC in the presence of 15 mM CHAPS. The binary complex (2:1) containing Sx1A (183–288) and SNAP-25A (1-206) was assembled from purified monomers and subsequently purified by IEXC in the presence of 1% CHAPS. The ΔN complex was co-expressed with pET Duet-1 and pET28a vectors and purified by IEXC with 50 mM n-octyl- β -D-glucoside [91]. The ternary SNARE complex consisting of Sx1A (183–288), SNAP-25A and synaptobrevin 2 (1–96) was generated by incubating of the binary complex and synaptobrevin 2 (1–96) in a ratio of 1:2 over night at 4°C. The excess synaptobrevin 2 was removed with Sephadex G50 superfine column during liposome reconstitution.

All the SNARE proteins including different SNARE complexes, and α -SNAP and its mutants were provided by Dr. Alexander Stein and Dr. Yongsoo Park (neurobiology department) [33, 35, 91, 105, 111, 128, 132]. Full-length Syt1 (Syt1/1-421/PET28a/NdeI-XhoI/His) was cloned by the neurobiology department and expressed in this study.

CHAPTER 2. MATERIALS AND METHODS

The expression and purification were described in page 30, subsection 2.2.1. The Syt1 purification protocol was modified from the publications and the dissertation of Dr. Alexander Stein [95, 111]. The mutants of the full-length Syt1 and the soluble Syt1 were provided by Dr. Geert van den Bogaart [111, 140, 141]. The sequences of all the proteins are given in Table 2.2.

Abbreviation	Protein	Sequence	
Sb ¹⁻⁹⁶	Synaptobrevin 2 1-96	1-96	[35]
SNAP25A	SNAP 25A	1-206, C84, 85, 90, 92S	[33]

2.1.6 Software

The software products used for data analysis were MATLAB 2009b (The MathWorks, Inc.), Origin 8.6G (MicroCal Inc.), Microsoft Office Suite 2010 (Microsoft Corp.) and SigmaPlot (Systat Software Inc.).

2.2 Methods

2.2.1 Expression and purification of synaptotagmin-1

Synaptotagmin-1 (Syt1) was cloned in the pET28a vector (Novagen) and transformed via heat shock in the expression cell *Escherichia coli* strain BL21 (DE3, Novagen, see page 22, subsection 2.1.3). Transformation was performed with the standard pro-

tolocol of the neurobiology department. To check the expression condition, four 50 ml cultures were prepared in the TB-medium containing 30 $\mu\text{g}/\text{ml}$ kanamycin. The cultures grew under shaking at 37°C until OD = 0.8–1.0. The expression was started with IPTG inducing at a concentration of 0.5 mM and performed either at 37°C or at 22°C for 3 h as well as over night (ON).

The expression was checked with SDS-PAGE (Figure 2.1). The best condition for the Syt1 expression was at 22°C for at least 3 h after IPTG inducing. After expression, the culture was centrifuged (4000 RPM, 15 min, 4°C) and the pellet was resuspended with a little amount of extraction buffer (all buffers used in this subsection see page 26, Table 2.3). The resuspended cell was kept at -20°C.

Figure 2.1: Expression test of Syt1 under different conditions. Each 50 ml TB-KANA-culture (30 $\mu\text{g}/\text{ml}$) was incubated at 37°C until OD = 0.8–1.0. The expression was started with 0.5 mM IPTG and performed under different conditions (shown on the gel picture). The sample in the middle (“no IPTG”) was taken before adding IPTG.

Syt1 was purified with immobilized metal ion affinity chromatography (IMAC) followed by Ion Exchange Chromatography (IEXC). The resuspended cell pellet was thawed and filled with the same amount of extraction buffer with 10% sodium cholate, lysozyme (f.c. 1 mg/ml), PMSF 1 mM, MgCl_2 (f.c. 1 mM) and a few crumbs of DNase I were added to the cell solution and the mixture was incubated under stirring for 30 min at RT. The lysate was furthermore homogenized with 4 x 40 strokes using ultra-

sound (large Tip, 50% duty cycle, microtip limit) and incubated for 15 min at RT. The solution was centrifuged at 15000 G for 30 min (SLA-1500).

The supernatant was carefully collected and mixed with 9 ml Ni-NTA-Agarose slurry (for a culture of 6 l). The lysate-Ni-NTA mixture was incubated for 3 h at 4°C on the rolling incubator. The mixture was filled into 50 ml Falcon tubes and centrifuged at 3000 U for 10 min (Beckman J6-MI). The supernatant was removed into a bottle (Qiagen) and the Ni beads were resuspended in a small amount of supernatant and filled into a large column. The filled column was washed with 300 ml of the washing buffer. Finally, Syt1 was eluted with the elution buffer in five fractions (5 x 10 ml). The eluates were directly mixed with DTT (f.c. 1 mM). After a rough concentration determination (Bradford) the concentrated fractions were pooled together and mixed with 50 μ l thrombin (1 U/ μ l) per 10 ml of volume to cleave the histidine tag. The protein solution was dialyzed in at least 10 times the volume of sample with the desalting buffer at 4°C overnight. All the purification steps and the thrombin cleavage itself were checked with SDS-PAGE (Figure 2.2a).

Thrombin and other proteins were furthermore removed with IEXC using a MonoS 5/5 HR column on the Aekta purification system. After loading the protein solution onto the column, elution was programmed as first a prewash with 70% buffer A and 30% buffer B (page 27, Table 2.3) for two column volumes, followed by increasing buffer B's fraction from 30% to 100% for five column volumes. Finally the column was washed using 100% buffer B for two column volumes. All of these eluates were retrieved as sets of separate fractions of 2 ml each. The concentrated fractions were checked using SDS-PAGE (Figure 2.2b). The purification yielded ca. 1 mg protein per 6 l of culture.

Figure 2.2: Purification of Syt1 with immobilized metal ion affinity chromatography and ion exchange chromatography. a. Purification steps using Ni-NTA beads: the pellet after cell lysis (pell), the supernatant of the lysate (Sup), the flow-through after binding on the Ni-NTA beads (Fl), washing the column with the wash buffer (W), the most concentrated fractions checked with Bradford Kit (F2 and F3) and the proteins after thrombin cleavage and dialysis (F2* and F3*). b. Purification with IEXC: protein input (F2* and F3*) and IEXC output (IEXC).

2.2.2 Determination of the protein concentration

2.2.2.1 UV absorption

The concentrations of the SNARE proteins, Syt1 and α -SNAP were determined with UV absorption spectroscopy (280 nm) [28,88]. The molar extinction coefficient ϵ of a protein with amino acids sequence number n could be calculated as Equation 2.1 [43]:

$$\epsilon_{\text{Protein}}^{280} = n_{\text{Tyr}} \cdot \epsilon_{\text{Tyr}}^{280} + n_{\text{Trp}} \cdot \epsilon_{\text{Trp}}^{280} + n_{\text{Cys}} \cdot \epsilon_{\text{Cys}}^{280} \quad (2.1)$$

$$\begin{aligned} \text{In water: } \epsilon_{\text{Tyr}}^{280} &= 1490 \text{ mM}^{-1}\text{cm}^{-1} \\ \epsilon_{\text{Trp}}^{280} &= 5500 \text{ mM}^{-1}\text{cm}^{-1} \\ \epsilon_{\text{Cys}}^{280} &= 125 \text{ mM}^{-1}\text{cm}^{-1} \end{aligned}$$

The concentration of a homogenous protein solution with extinction coefficient ϵ could be calculated using Lambert-Beer law (Equation 2.2), in which c is the protein concentration and d is the thickness of the light path.

$$Abs = \epsilon \cdot c \cdot d \quad (2.2)$$

The protein concentration was measured using a Nanodrop Spectrometer (ND-1000, Thermo Scientific) and the extinction coefficients of the proteins were taken from the program "ProtParam tool" [32].

2.2.2.2 Bradford assay

By protein purification with Ni-NTA beads (page 30, subsection 2.2.1) the concentration of the different fractions of the eluates were checked tentatively with a Bradford Kit (Biorad) [15]. The Bradford assay is a sensitive photometric method for quantitative determination of the protein concentration under a denaturated condition in $\mu\text{g}/\text{ml}$ range. Coomassie brilliant blue G-250 is a triphenylmethane dye which can mainly

bind to the alkaline amino acids and then turns from its cationic – to its anionic state. The absorption can be observed at 595 nm. To qualitatively test the protein concentration, 10 μl of each protein solution were mixed with 800 μl ddH₂O and 200 μl Bradford reagent 5x (Biorad, USA).

2.2.2.3 Modified Lowry-Peterson protein determination

For determination of the protein concentration of the SVs, the SV samples were treated according to a modified Lowry-Peterson method [90]. Bovine serum albumin (BSA) was used as the standard in different concentrations in the range of 0–40 μg . A series of different dilutions of the SV samples (1:2, 1:5, 1:10 and 1:20) and the standards were filled up with ddH₂O to an end volume of 1 ml. The solutions were incubated with 100 μl DOC (Deoxycholic acid, 0.15%) for 10 min at RT. TCA (Trichloroacetic acid, 72%) was added to the solutions to precipitate the proteins. The mixtures were incubated for 10 min on ice and centrifuged for 10 min at 13 000 rpm at 4°C. The pellets were dissolved and incubated in 750 μl Lowry solution III (page 28, Table 2.3, same for the Lowry solution IV) and 250 μl ddH₂O for 30 min at RT. Finally, the samples were mixed with 75 μl of Lowry solution IV and incubated for 45 min at RT. The absorbance was measured at 750 nm using a Novaspec II photometer (Par-macia Biotech, Germany). This part of the experiment was performed by Dr. Saheeb Ahmed (neurobiology department).

2.2.3 Determination of Rhodamine Green concentration with UV absorption spectroscopy

To determine the mouse SVs concentration using FCS, a standard fluorescence dye Rhodamine Green (RG) of known concentration (10 nM) was used to analyze the data by directly comparing particle numbers. RG was solved in PBS (Sigma) and the concentration of RG was determined by UV-absorption spectroscopy (Cary 5E, Varian). The molar extinction coefficient of RG is $\epsilon_{RG} = 75000 \text{ M}^{-1}\text{cm}^{-1}$ at 502 nm [72]. The

concentration was calculated using Equation 2.2.

2.2.4 SDS-PAGE

The purification steps of proteins were checked using SDS-PAGE (Sodium dodecyl sulfate polyacrylamide gel electrophoresis) [68]. The recipes for the tricine gels are listed in Table 2.5 [108]. 3.4 ml separating gel mixture (10%) was poured between the glass plates (0.8 mm separation) and ca. 1 ml collecting gel mixture was added on top of the separating gel until the chamber was full. A comb with either 10 or 15 wells was inserted directly into the collecting gel solution and could be removed after about 5 min, when the polymerization was finished. The protein samples were mixed with 5x sample buffer (see page 27, Table 2.3, same with the following buffers) and heated to 90°C for 10 min. Of each sample, 10 μ l were loaded into the gel pockets. The gel tank was filled with the cathode buffer in the middle and the anode buffer outside the gel. It took about 25 min to pull the sample through the collecting gel using 60 Volts and the electrophoresis was promoted at 120 Volts until the blue color of the samples ran out of the gel. For staining, the gel was dipped into the coomassie staining solution, heated for 5 s in a microwave and rocked for 5 min. To destain the gel, the coomassie staining solution was carefully removed and the gel was incubated in the coomassie destaining solution for another 5 min. The gel could be furthermore destained in water overnight.

Component	Collecting gel	Separating gel
Acrylamide 30%	200 μ l	1.66 ml
Gel buffer	375 μ l	1.68 ml
ddH ₂ O	925 μ l	570 μ l
Glycerol 50%	-	1.06 ml
TEMED	2 μ l	3 μ l
APS 10%	10 μ l	25 μ l

Table 2.5: Tricine (Schägger)-gels.

2.2.5 Reconstitution of liposomes

2.2.5.1 Reconstitution of small liposomes

For the Syt1 tethering experiments, the liposome was reconstituted using size exclusion chromatography as described in earlier papers [105, 138] with the following modifications. All the lipids components were solved in the chloroform/methanol solution (page 25, Table 2.3, the following buffers in this subsection analogously) and mixed with their composition for the liposome. The lipid solution was dried to a lipid film with nitrogen gas or with a rotary evaporator if larger amounts were used. The lipid film was resolved in HPCholate5 buffer to a final lipid concentration of 27 mM. 16.7 μ l lipid mixture were added with protein at a protein:lipid ratio of 1:1000 or 1:750. The lipid protein mixture was filled with HPCholate1.5 buffer to a final volume of 50 μ l. The liposomes were formed by detergent removal using a Sephadex G50 econo column (GE Healthcare, Biorad). The running buffer for the column was HP150. The collected liposome volume was about 250 μ l. The radius of the liposome was about 20 nm [138]. Figure 2.3 shows a schematic of the size exclusion chromatography. All the lipid compositions used in this study are listed in Table 2.6.

Figure 2.3: Size exclusion chromatography using sephadex G50 econo column to reconstitute small liposomes. The lipid mixture was separated by the sephades 50G column to three phases: the removed detergent (top), the remaining free lipids and proteins (center) and the formed liposomes (bottom).

2.2.5.2 Reconstitution of large unilamellar vesicles

Large unilamellar vesicles (LUVs) were prepared for fusion and docking experiments with purified chromaffin granules (CGs) by reverse phase evaporation and

Liposome	PC	PE	TRPE	OGPE	PS	Cholesterol	PIP2
TR	70	19	1	0	0	10	0
TRPS	50	19	1	0	20	10	0
TRPS5	65	19	1	0	5	10	0
TEPS12	58	19	1	0	12	10	0
OG	70	18.5	0	1.5	0	10	0
OGPS	50	18.5	0	1.5	20	10	0
OGPIP	49	18.5	0	1.5	20	10	1

Table 2.6: Lipid composition of the liposomes in the Syt1 tethering experiments. Numbers are given in mol%.

extrusion through polycarbonate membranes with a pore size of 100 nm [23, 55, 89]. The lipid composition of the liposome was PC:PE:PS:Cholesterol:PI:PIP2:NBD-DOPE:Rhodamine-DOPE = 45:12:10:25:4:1:1.5:1.5. The size of the LUVs was verified by light scattering. The ΔN complex or the 2:1 complex (page 24, Table 2.2) were inserted into the preformed LUVs at a protein:lipid ratio of 1:500 using detergent *n*-octyl- β -D-glucoside followed by an overnight dialysis [23, 55]. This reconstitution was part of the investigation project of Dr. Yongsoo Park (neurobiology department).

2.2.6 Purification of mouse and rat SVs

Purification of mouse and rat synaptic vesicles was described previously [53, 85] and the isolation procedure was optimized by Dr. Saheeb Ahmed in his PhD thesis [1]. This purification protocol allows a one brain isolation of SVs within 24 h and had an optimized yield and purity.

After differential centrifugation the SVs were separated from the brain and isolated by means of size-exclusion chromatography (Sephacryl S-1000 Superfine HR, GE Healthcare, Germany). Elution was monitored at a wavelength of 280 nm. The purity of the SV isolation was checked by a dotblot assay [64]. The average size of the SVs was

determined by cryo electron microscopy and the average diameter of the SVs found to be around 40 nm. The purified SVs were eluted using a HB-100 buffer (page 28, Table 2.3) and the most concentrated fraction was used directly for the FCS measurement (see page 11, subsection 1.5.1) without centrifugation to determine the vesicle concentration. All the mouse and rat SV purifications were performed by Dr. Saheeb Ahmed.

2.2.7 Purification of chromaffin granules (CGs)

Purification of CGs was described previously [89]. CGs were separated from the bovine adrenal medullae by differential centrifugation and were isolated and purified with a continuous sucrose density gradient from 0.3 M to 2.0 M (SW41T1 rotor, 27 000 rpm, 1 h). The purified CGs were collected from fraction 16 (pellet) and the purity was checked by western blotting [89]. The purified CGs were resuspended in CG buffer (see page 25, Table 2.3). The average diameter of CGs was about 167 nm determined by the cryo-electron microscopy data. All the CGs were provided by Dr. Yongsoo Park.

2.2.8 Two-photon confocal fluorescence microscopy setup

To simultaneously excite two different colors of liposomes, 22 mW of the output power of a Chameleon titanium-sapphire laser (Coherent, USA) was used for two-photon excitation. The 800 nm, 87 MHz laser beam was expanded using a lens system and coupled to an IX71 inverted microscope (Olympus, Germany), reflected to the top of the microscope by a dichroic mirror DC1 (715 DSCPXR, AHF, Germany) and focused by a UPlanSApo 60x/1.2w water immersion objective (Olympus, Germany). The emitted photons passed through the objective and the dichroic mirror DC1.

Scattered light from the excitation beam was blocked by a two-photon rejection filter 2P-SP (E700SP2, AHF, Germany). The emission was collimated using a second lens system and reflected into the detection side of the setup using an ultrabroad band

dielectric mirror M (650–1130 nm, Newport, USA). The emission was furthermore split by a second dichroic mirror DC2 (590 DCXR, AHF, Germany), filtered in each direction by a bandpass filter BP1/BP2 (HQ 645/75 and HQ 535/50; AHF, Germany) and focused with a lens (either L1 or L2, respectively) to an avalanche photodiode (APD1 or APD2, respectively; SPCM-AQR-13, Perkin-Elmer, Canada; see Figure 2.4 a). The TTL (transistor-transistor-logic) signals from the APD were analyzed using a 4-channel router (PRT 400, PicoQuant GmbH, Germany) and a TCSPC (time-correlated single photon counting) card (TimeHarp200, PicoQuant GmbH, Germany) and saved in PicoQuant’s TTTR (time-tagged time-resolved) format. The correlation was processed using a home-made program (provided courtesy Matthias Grunwald).

Figure 2.4 b shows a schematic of the focus volume for two-photon excitation. The black line indicates the laser beam, and the dark red ellipse marks the excited effective volume V_{eff} of two-photon excitation (TPE). Only the samples inside V_{eff} can be excited while the surrounding volume remains dark. The effective volume of two-photon excitation in this study was approx. 0.3 fl.

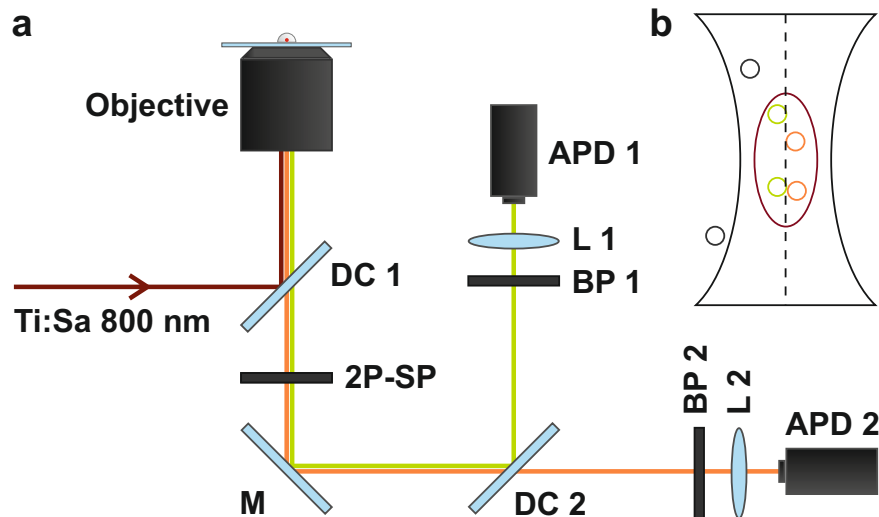

Figure 2.4: Confocal fluorescence microscopy setup for two-photon excitation. a. The pulsed 800 nm Ti:Sa laser beam is reflected to the objective using a dichroic mirror (DC1) and the emission passes through the objective using the same pathway. The scattered light of the laser beam is blocked by a two-photon rejection filter (2P-SP). The emission light is reflected to the detection side by an ultrabroad band dielectric mirror (M) and split by a second dichroic mirror (DC2) to finally arrive at one of two avalanche photodiodes (APD1 or APD2) after having been filtered by a bandpass filter (BP1 or BP2) and focused by a lens (L1 or L2). b. The dark red ellipse marks the V_{eff} of the TPE.

Chapter 3

Results

3.1 *Cis-* and *trans*-membrane interaction of synaptotagmin-1

Synaptotagmin-1 (Syt1) possesses two conserved calcium-binding domains—C2A and C2B—, which serve as partial calcium coordination sites [37,95]. The C2 domains mediate calcium-dependent binding to both SNARE proteins [7,19,21,125] and acidic membrane lipids, with a specific affinity for the membrane lipid phosphatidylinositol-4,5-bisphosphate (PIP₂) [3,6,13,42,56,59,73,95,104,134]. Separated from the calcium binding pocket, the Syt1 also possesses a poly-basic lysine stretch in C2B domain, which binds to anionic membranes containing phosphatidyl-serine (PS) or PIP₂ in a calcium-independent manner [6,19,73,104,134,141]. The 3D-structure of Syt1 is shown in Figure 1.5.

However, it is not yet clear how exactly these binding activities contribute to the acceleration of exocytosis [96]. Recent studies suggested that Syt1 may not only bind *trans* to the plasma membrane but also *cis* to its own membrane [67,111]. Using full-length Syt1 and its mutants, in which either the Ca²⁺ binding C2 domains or the Ca²⁺ independent binding site in C2B domain were disrupted, a structural requirement of the *cis*- and the *trans*-binding under the influence of PS/PIP₂ and SNAREs was dis-

sected with a sensitive tethering assay based on FCS and FCCS (see page 44, subsection 3.1.1). No SNARE proteins are inserted in the host membrane of Syt1, so that tethering will be observed in a stable state without undergoing fusion.

3.1.1 Tethering assay based on FCS and FCCS

The tethering experiments were performed with a two-photon confocal microscope (page 39, subsection 2.2.8) and the data were analyzed using FCS (page 11, subsection 1.5.1) and FCCS (page 14, subsection 1.5.2) techniques. Figure 3.1 shows a schematic of the tethering experiment data. The different percentages (0%, 50%, and 100%) in Figure 3.1 reflect the particle number of tethered liposomes N_x (page 15, equation 1.11) divided by the total number of the green liposomes N_g (page 15, equation 1.10):

$$\text{Tethering} = \frac{N_x}{N_g} \cdot 100 \quad (3.1)$$

The result was corrected by substituting a small percentage of the tethering experiment with Syt1-TR and OG liposomes containing no PS or, in the case of the binding assay, the TRPS and OGPS liposomes in HP150 buffer, respectively.

Figure 3.1: Schematic of typical FCCS curves in the tethering assay. Red and green liposomes are in 1:1 ratio. The red and green lines are the FCS measurement for each liposome color and the blue line is the simultaneous FCCS measurement. All three liposome pictures contain two red and two green particles.

For the experiments, Texas Red (TR) and Oregon Green (OG) labeled small liposomes (page 37, subsection 2.2.5.1) were first measured with FCS at a 1:20 dilution to check their concentrations. Using HP150 buffer (for all buffers see page 25, Table 2.3) the liposomes were diluted to a stock solution with about 100 liposomes in the excitation volume for each color. The tethering experiment was performed in either EGTA buffer or Calcium buffer. The experiment was started directly after mixing (vortex) 90 μl buffer and 5 μl of each the red and green liposomes at RT. Each droplet (20 μl) measurement took 72 s and the data trace was split into six fragments for the correlation. Each measurement set was repeated at least once with fresh liposomes and buffer. All the results were obtained by averaging of two fresh preparations with the error bar marking the range of the respective data points obtained. Figure 3.2 shows two sets of experimental data, one from an experiment under no-tethering conditions and one from an experiment under full-tethering conditions.

Figure 3.2: Example FCCS data from the tethering experiments. a. Control experiment with OGPS and TR liposomes without Syt in EGTA buffer (no-tethering conditions). b. Tethering experiment with OGPS and Syt1-TR liposomes in calcium buffer (full-tethering conditions).

3.1.2 *Cis*- and *trans*-interaction of Syt1 to the acidic lipid membrane

To investigate the membrane interaction of Syt1 (WT), full-length Syt1 and its mutants (*a**B, *Ab**, *a***b** and KAKA) were reconstituted into red TR liposomes in a protein:lipid ratio of 1:1000. Tethering was measured with the protein-free green OG liposomes using FCCS under two-photon excitation. In the *a**B and *Ab** mutants, either one or both C2 domains (*a**, *b**) were disrupted, so that one or both C2 domains cannot bind calcium and thus to the acidic phospholipids. In the KAKA mutant, the polybasic stretch of the C2B domain was mutated by two of the lysine residues, and the mutant cannot bind to PiP2 or PS without presence of calcium. Figure 3.3 shows the domain structures of Syt1 and the mutants used.

Figure 3.3: Domain structures of Syt1 and its mutants used in this experiment.

The TR liposomes contain 1 mol% TRPE and either 0 mol% (TR) or 20 mol% PS (TRPS) whereas all the OG liposomes contain 1.5 mol% OGPE and 20 mol% PS (OGPS). One population of the OG liposomes was reconstituted with an additional 1 mol% PiP2 (OGPiP). All of the liposome compositions are listed in Table 2.6, on page 38.

The first set of experiments was tethering between the Syt1 (WT) bearing TR liposomes and protein-free OGPS liposomes in either the absence or the presence of 100 μ M CaCl₂ [111]. A tethering efficiency of 73% was observed with calcium whereas the tethering was reduced to 20% without calcium (Figure 3.4a, WT). The experiments were repeated with mutants of Syt1. *a**B and *Ab** showed similar results as the WT,

i.e. calcium almost doubled the tethering to more than 85%. The double mutant a^*b^* did not show a calcium dependence, whereas the KAKA mutant tethered the OGPS liposome exclusively in the presence of calcium, as expected [3, 60, 141] (Figure 3.4a, a^*B , Ab^* , a^*b^* and KAKA). In agreement with previous observations, the calcium-independent tethering is mediated by the polybasic lysine stretch of the C2B domain [3, 141]. In all experiments with mutants, a small increase in tethering was observed compared to the respective WT experiment under the same conditions. One possible explanation for this increase is an enhanced membrane interaction due to the removal of charges.

The KAKA mutant possesses only calcium-dependent binding sites and the binding was inhibited when calcium was chelated with 500 μ M EGTA. To check the binding specificity of the calcium, the tethering experiment with the KAKA mutant was repeated with an extra 1 mM ATP/MgCl². Mg²⁺ did not influence membrane tethering. A control experiment was performed with protein-free TR liposome. No tethering was observed in both the absence and presence of calcium, which indicated that the tethering was dependent on Syt1 only (Figure 3.4a, Control). Fusion was monitored by lifetime analysis of OG. Because TR and OG form a FRET pair (page 17, subsection 1.5.4 [23]), a reduction of the OG lifetime indicates lipid mixing of the liposomes. No major change in lifetime was observed and thus it was concluded that fusion did not occur.

To analyze whether PiP₂ enhances membrane tethering, the *trans*-tethering experiments described above were repeated using OGPiP liposome as target liposome (Figure 3.4b). No major differences were observed in all these tethering experiments. According to a previous study, a high percentage of PS could reduce the PiP₂ effect in the binding assay between the labeled Syt1 and the labeled liposomes [95].

To investigate whether *cis*-binding of Syt1 to its own membrane affects its tethering activity, the entire tethering experiments in Figure 3.4 a and b were repeated using Syt1 bearing the TRPS liposome instead of the TR liposome. Most strikingly, the presence of 20% PS almost completely inhibited the membrane tethering under all conditions (Figure 3.4c and d).

To examine the the lower boundary of this *cis*-binding effect, the PS percentage in the host liposomes was lowered to 12% (TRPS12) and 5% (TRPS5). 12% PS is the typical PS composition in a native rat synaptic vesicle [119]. Similarly, *cis*-preventing was observed in the tethering experiment with Syt1 WT (Figure 3.5a). The *cis*-binding could finally be inhibited using 5% PS in TR liposome in the presence of calcium or PiP2 (Figure 3.5b). Here, the calcium-dependent *trans*-binding was recovered to the maximum binding rate, whereas the calcium independent tethering only appeared if the target membrane contained 1% PiP2.

These unexpected results suggested a different binding model between Syt1 and liposomes compared with the findings of previous studies, which had shown that soluble C2AB domains were able to cluster liposomes containing acidic phospholipids in the presence of calcium [3,60,141]. When comparing these results, it is conceivable that membrane anchorage reduces the mobility of the C2 domains in such a way that *cis*-binding alone already exhausts both binding sites of C2A and C2B, and that therefore no C2 domain is available for *trans*-binding. To shed light on this issue, we carried out further tethering experiments using a soluble C2AB domain (97–421). These results are laid out in the next subsection.

Figure 3.4: Liposome tethering mediated by membrane-anchored Syt1. Tethering was measured using TP-FCCS in the absence (black) or the presence (red) of 100 μ M CaCl₂. The donor liposomes contain either 0% or 20% PS, while the acceptor liposomes contain either 20% PS or both 20% PS and 1% PiP2. a. Tethering experiment using wild-type Syt1 (WT) and its mutants. Except for the a*b* mutant, calcium drastically increases the tethering rate in all the other cases. The KAKA mutants bind acceptor vesicles only in the presence of calcium. b. Tethering experiment in the presence of PiP2 in the acceptor vesicle confirming the results in the first set of the experiments (a). c. *Cis*-binding mediated by PS in the donor vesicle. Tethering was observed neither for Syt1 nor for any of its mutants. d. *Cis*-binding in the presence of PiP2 in the acceptor vesicle could still be observed. All control experiments were performed with protein-free donor vesicles.

Figure 3.5: Syt1 mediated membrane tethering in the presence of 12% and of 5% PS in the *cis*-membrane. Tethering was measured in the absence (black) and the presence (red) of 100 μM CaCl_2 . a. 12% PS prevented tethering under all conditions. b. With 5% PS in the Syt1 liposome membrane, tethering required either the presence of calcium or PiP2 in the target membrane.

3.1.3 The soluble C2AB domain of Syt1 is able to cluster liposomes at a saturating concentration

The C2AB (97-421) fragment and its single cysteine mutant AF-C2AB labeled with alexa fluor 488 were used to cross-link the TR and OG liposomes containing 20% PS. The domain structures are shown in Figure 3.6.

Figure 3.6: Domain structures of the soluble C2AB domain and its Alexa Fluor 488 labeled mutant.

Different C2AB dilutions ranging from 50 nM to 860 nM were used to cluster the green and red liposomes under 100 μM calcium. All experiments were started by adding the C2AB domain into the liposome mixture. Clustering could be observed only upon addition of elevated C2AB concentrations. The first evident clustering was determined with 215 nM C2AB (Figure 3.7). No clustering was observed below this

concentration even after 30 min of incubation. The clustering was reversible by adding 2 mM EGTA after clustering. The experiments with either EGTA or calcium alone, as well as with C2AB in EGTA buffer are shown as negative controls (Figure 3.7).

Figure 3.7: Clustering of liposomes mediated by soluble C2AB domain. Columns 1-3: negative controls. Columns 4-8: clustering experiment using soluble C2AB domain of Syt1 of the concentration from 50 nM to 860 nM. Column 9: clustering mediated by 430 nM C2AB could be reverted using 2 mM EGTA.

It is essential to determine the concentration of soluble C2AB relative to the liposome required to cross-link the liposomes and to find the reason for the absence of clustering at low concentrations. A binding experiment was performed in which Alexa Fluor 488 labeled C2AB fragments (AF-C2AB) were added to the TRPS liposome containing 20% PS (Figure 3.8) and the binding was measured with FCCS, which is capable of monitoring free and bound liposomes separately under the same condition. The lowest non-clustering concentration (50 nM) and the lowest clustering concentration (215 nM) of AF-C2AB were added to the TRPS liposome (Figure 3.8a). Both experiments resulted in a high efficiency of soluble AF-C2AB binding to the liposome.

All the results were calculated as the ratio of bound liposome relative to the entire liposome. At 215 nM, when clustering began to be observable, all the liposomes were bound with AF-C2AB. The binding could be reversed by adding 1 mM EGTA.

Figure 3.8: Binding assay of soluble C2AB labeled with alexa fluor 488 to TRPS liposome containing 20% PS. Binding was measured by TP-FCCS. a. Calculated as fraction of the bound liposomes with AF-C2AB. b. Columns 1-4, calculated as fraction of bound AF-C2AB fragments with liposome. b. Columns 5-6, binding was competed by unlabeled C2AB fragments in two different concentrations.

The difference between calcium-dependent clustering and binding indicates that a saturation of binding could be necessary to achieve clustering. To verify this finding, the data from the very same experiments were used to calculate the fraction of bound AF-C2AB fragments among the total number of AF-C2AB fragments (Figure 3.8b). Contrary to the liposome binding rate, more than 60% of the fragments were bound to the liposomes at 50 nM AF-C2AB whereas only 30% binding rate was achieved at 215 nM. The binding was calcium-dependent and could be inhibited with 1 mM EGTA (Figure 3.8b, columns 1-4).

From this set of FCCS data, the fraction of bound liposomes and AF-C2AB, as

well as the fraction of free components can be read out easily. With these, the binding constant K_D between liposomes ($[A]$) and AF-C2AB ($[B]$) can be calculated. The binding kinetics can be described by:

and the binding constant K_D is then calculated as:

$$K_D = \frac{[A]_{free} \cdot [B]_{free}}{[AB]} \quad (3.3)$$

The total number of liposomes $[A]_0$ is a sum of the bound liposomes $[AB]$ and the free liposomes $[A]_{free}$. The fraction of bound liposomes can be calculated as:

$$\frac{[AB]}{[A]_0} = \frac{[B]_{free}}{K_D + [B]_{free}} \quad (3.4)$$

In this equation, $\frac{[AB]}{[A]_0}$ can be taken directly from the fraction of bound liposomes in Figure 3.8a (“Bound % of liposome”), and $[B]_{free}$ can be calculated with the AF-C2AB concentration and the fraction bound AF-C2AB in the Figure 3.8b (“Bound % of AF-C2AB”). Using these data, the binding constant K_D can be calculated as in Table 3.1:

$[B]_0$ (nM)	$\frac{[AB]}{[A]_0}$	$\frac{[AB]}{[B]_0}$	$[B]_{free}$ (nM)	K_D (nM)
50	0.5	0.6	20	20
215	0.9	0.3	150.5	16.7

Table 3.1: Binding constant between liposomes and AF-C2AB fragments.

The average K_D is about 18 nM. With Equation 3.4, the binding kinetics between liposomes and AF-C2AB can be computed (Figure 3.9).

Addition of 215 nM AF-C2AB, which is 10-fold over the K_D value, lead to a concentration of 150.5 nM free AF-C2AB fragments after binding to the liposomes. According to the binding kinetics, this high concentration is already within the saturation range of the AF-C2AB. This was also confirmed by the binding experiments using extra amounts of the unlabeled C2AB fragments, in addition to the 50 nM AF-C2AB.

Figure 3.9: Binding kinetics between liposomes (A) and AF-C2AB (B). $[AB]$ is the concentration of bound liposomes with AF-C2AB fragments. $[A]_0$ is the total concentration of free and bound liposomes. The fraction of bound liposomes $\frac{[AB]}{[A]_0}$ can be read off from Figure 3.8a. $[B]_{free}$ is the concentration of free AF-C2AB fragments, which can be calculated as in the Table 3.1. K_D is the binding constant between liposomes and AF-C2AB fragments.

400 nM C2AB substantially competed with AF-C2AB and resulted in a binding rate below 10%, whereas additional 150 nM C2AB reduced the binding rate to 35%, similar as the binding rate using 215 nM AF-C2AB alone (Figure 3.8b, columns 5-6). In conclusion, soluble C2AB fragment clusters liposomes in a calcium-dependent manner and requires the saturation of the binding sites on the membrane surface.

3.1.4 Syt1-SNARE interaction mediated membrane tethering

To investigate the membrane tethering mediated by Syt1-SNARE interaction [7,19,21,125] Syt1 and SNARE proteins were reconstituted separately into TR and OG liposomes. One TR liposome population contained 20% PS to check whether back binding is preferred compared to the Syt1-SNARE interaction. All the SNAREs bearing OG liposomes contained no acidic lipids, so that the *trans*-tethering of Syt1 to PS or PiP2 was ruled out. Three different SNARE combinations were used in this set of experi-

ments: Sx1A (syntaxin-1A, 183–288) alone, a binary 2:1 complex Sx1A-SN25 (syntaxin 1A, 183-288 and SNAP-25, 1-206) and a fully assembled ternary complex Sx1A-SN25-Sb2 (synaptobrevin 2, 1–96, SNAP-25, 1-206 and syntaxin 1A, 183-288). The ternary complex was reconstituted by incubating 2:1 complex and Sb 1-96 in a ratio of 1:2 at 4°C over night, and the mixture was furthermore used for liposome reconstitution. Thus the liposomes of the ternary complex also contained single Sx1A. The protein:lipid ratio for Syt1 was 1:750 and for SNAREs it was 1:1000. All the experiments were performed in either EGTA or 100 μ M calcium buffers.

Efficient tethering of about 40% was observed when Syt1 bearing liposome lacked PS. The tethering was calcium independent except when using Sx1A alone. This result agrees with the findings of previous studies [7,19,21,125], showing that the interaction between Syt1 and Sx1A is enhanced by calcium (Figure 3.10a). Two negative controls were measured using protein-free OG liposomes under the same conditions and with an additional 1 μ M free SNAP25 in the buffer, respectively, to exclude the unspecific tethering caused by SNAP25 (Figure 3.10a, control).

The background tethering measured using TR-liposomes lacking Syt1 was significantly lower than in the tethering experiment (Figure 3.10b), indicating that tethering is mediated by Syt1-SNAREs interaction. The tethering was Syt1-SNARE specific, since the presence of 10 mg l^{-1} BSA could not prevent it. Similarly to subsection 3.1.2, tethering was missing completely when 20% PS was present in the Syt1 liposome (Figure 3.10c).

Since the Syt1-SNARE mediated membrane tethering mainly proceeded in a calcium-independent manner, the question arises whether this tethering is caused by the polybasic stretch of the C2B domain of Syt1. Therefore, all the tethering experiments were repeated using KAKA in which only the calcium-dependent binding sites C2A and C2B are active (Figure 3.10d and e). Both tetherings mediated by SNARE complexes were reduced to the same levels as the non-tethering Syt1 (Figure 3.10d). The calcium enhancement of the tethering mediated by single Sx1A was preserved, but the tethering rate was slightly reduced as compared to the Syt1 WT experiment (Fig-

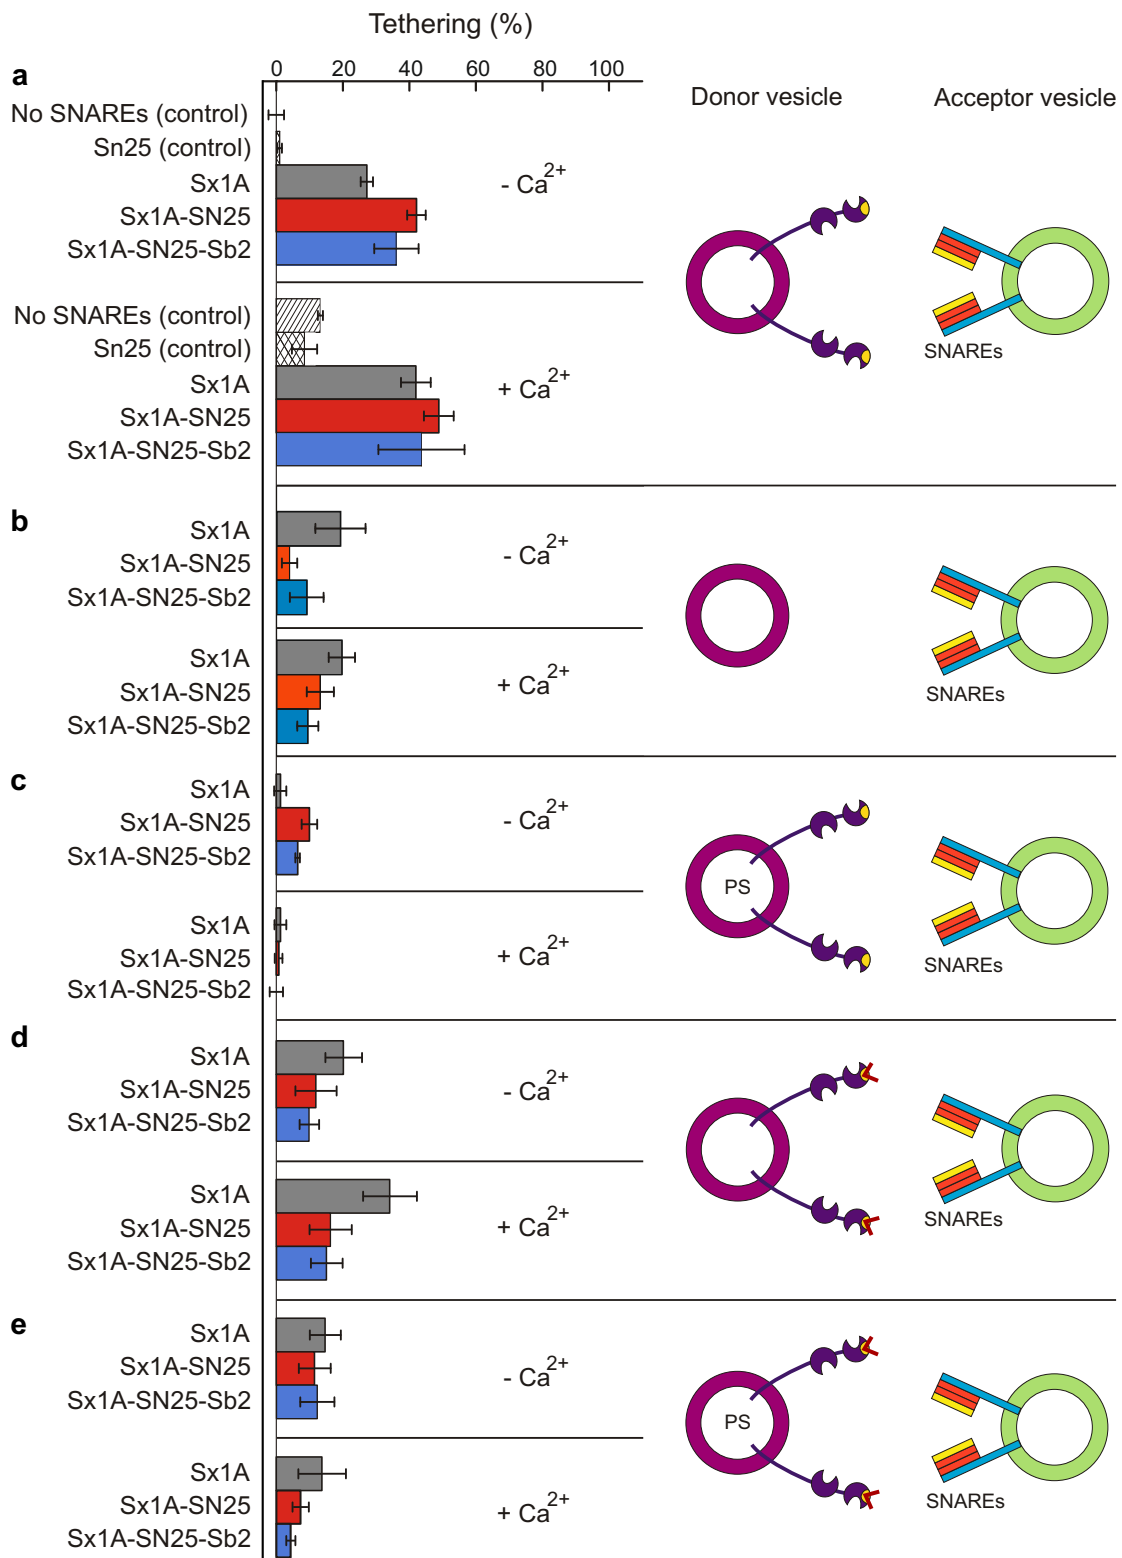

Figure 3.10: Tethering of liposomes mediated by membrane-anchored Syt1-SNAREs interactions. Donor vesicles containing either 0% or 20% PS were reconstituted with Syt1 WT or its KAKA mutant (P:L = 1:750). Acceptor vesicles free of PS were reconstituted with purified recombinant Sx1A (gray), a binary 2:1 complex Sx1A-SN25 (red), or a ternary SNARE complex Sx1A-SN25-Sb2 (blue, P:L = 1:1000). Control measurements were performed either without SNARE or with 1 μ M soluble SNAP-25. Tetherings were carried out in the absence ($- \text{Ca}^{2+}$) or presence ($+ \text{Ca}^{2+}$) of 100 μ M Ca^{2+} . a. Tethering was observed under no PS condition. Ca^{2+} dependency was observed only by acceptor vesicle with Sx1A. b. Background tethering without Syt1 as a control. c. No tethering was determined when Syt1 liposomes contained 20% PS which indicated back binding of Syt1. d and e. Repeated tethering and back binding measurements with KAKA mutant and the determined tetherings reduced to the background level except with Sx1A liposomes which still showed a Ca^{2+} dependency.

ure 3.10d). Presence of PS in the Syt1 liposome significantly reduced the tethering with single Sx1A to the level of the Syt1-lacking background (Figure 3.10e). This KAKA mutant experiment was performed by Sabrina Schroeder and Chao-Chen Lin.

All the results reported in this section were summarized in a recent publication [123].

3.2 Characterization of mouse synaptic vesicles by average protein mass

Neuronal exocytosis requires fusion of synaptic vesicles (SVs) with the presynaptic membrane. Characterization of the SVs in terms of protein contents and lipid composition as well as SNARE-mediated membrane fusion and neurotransmitter uptake is essential to understand the fusion process and the storage of neurotransmitters. Biological and physical characterization of the rat SVs was done by Takamori *et al.* in

2006 [119]. A detailed picture of the SVs including the quantified mass, composition and copy number of the respective proteins and lipids as well as the size and density per single vesicle was obtained (Figure 3.11).

Figure 3.11: Molecular model of an average SV. [119]

The mouse is one of the standard species of animal experiments and shares common ancestry with the rat. Thus, it is a natural extension of the previous study, to characterize the protein and lipid structures of the mouse SVs at a single vesicle level. In the following subsections, a vesicle counting assay based on TP-FCS is described to determine the SV particle concentration, which is essential for characterizing all the biological properties of a single vesicle. Furthermore, combining the protein concentrations determined by means of a modified Lowry-Peterson method, an average mass of proteins per mouse SV compared to that of the rat could be calculated.

3.2.1 Synaptic vesicle labeling with FM 1-43 dye

FM dyes are widely used as outer membrane labeling dyes in monitoring endo- and exocytosis, vesicle trafficking, and vesicle fusion in various systems [2, 12, 16, 54, 124]. FM 1-43 and its derivatives harbor a water-soluble cationic head group and a membrane permeable hydrophobic tail, while their double bond central region carries the fluorescent properties. The membrane association of the FM dyes is reversible.

FM 1-43 (*N*-(3-triethylammoniumpropyl)-4-(4-(dibutylamino) styryl) pyridinium dibromide) is almost non-fluorescent in an aqueous solution but shows an increased fluorescence of more than 40-fold intensity upon binding to liposomes [97].

To characterize the mouse SVs, they were tagged in the FCS measurement using the FM 1-43 dye. The labeling protocol was modified from the previous paper [119]. 10 μM FM 1-43 dye was mixed with the same volume of purified SV solution, which was collected directly from size-exclusion chromatography, so that the final concentration of the FM dye was 5 μM . Incubation was performed for at least 2 min on ice. Figure 3.12 shows two fluorescence traces taken from two measurements of 10 s each, with either 5 μM FM 1-43 alone or FM-SV-mixture, in which FM dye had a final concentration of 5 μM and SV sample was 1:1 diluted by mixing with the FM dye solution. The SVs were clearly labeled with the FM dye.

3.2.2 Concentration determination of SVs using TP-FCS

The concentration of the SVs was determined using two photon confocal microscopy at 40 mW and calculated with fluorescence correlation technique (FCS). The experimental setup was as described previously (page 39, subsection 2.2.8) with a few modifications. Only one APD detector (APD 2) was used to collect either RG or FM 1-43 fluorescence. Hence, a second dichroic mirror (DC 2) was not included for this measurement, but instead Bandpass filters HQ535/50 as well as HQ645/75 were used to select the emission of either RG or FM dye.

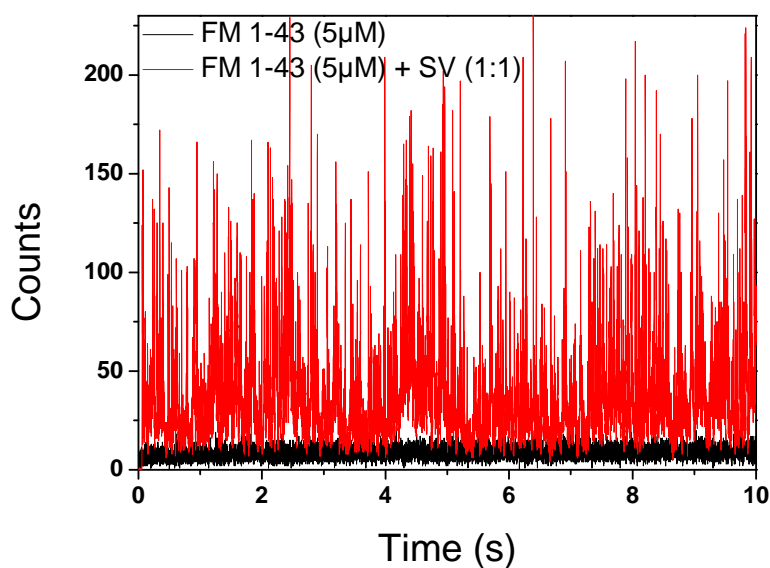

Figure 3.12: SV labeling with FM 1-43 dye. SVs were incubated with the FM 1-43 dye for 2 min on ice with a final concentration of 5 μM FM dye (red); a background trace of 5 μM FM 1-43 is shown as comparison (black).

The most concentrated SV fraction collected from the size exclusion chromatography (see page 38, subsection 2.2.6) was freshly labeled with FM 1-43 membrane dye (see page 59, subsection 3.2.1). The homogeneity of the SVs was controlled by measuring diffusion time. At least two SV dilutions with a final FM concentration of 5 μM were measured (Figure 3.13), and each dilution was measured at least twice with fresh droplets. Every measurement took 6×10 s. The particle number of SVs in the effective volume was calculated with equation 1.6, by $N_{SV} = 1/G(0)$.

A standard RG fluorescence dye solution with a concentration of 10 nM (page 35, subsection 2.2.3) was used to calculate the concentration of the SVs. With the particle number N_{RG} of RG the concentration of SVs could be calculated as $c_{SV} = 10 \text{ nM} \cdot \frac{N_{SV}}{N_{RG}}$. The final concentration was an average of all the dilutions and the error bar was taken to be the standard deviation of all the measurement fragments combined. The data set will be shown in subsection 3.2.4 in combination with the protein concentration.

Figure 3.13: FCS measurement of rat SVs in three dilutions compared to FM 1-43 background. All three dilutions were measured in the presence of 5 μM FM 1-43 (red, green and blue line). 5 μM FM 1-43 is shown as background (black).

3.2.3 Background correction due to the dark FM fluorescence

Although the free FM 1-43 dye is almost non-fluorescent [97], its emission at the high concentration used in this experiment was still detectable. To eliminate this “dark” background, a new calculation of the correlation function considering the experimentally observed fluorescence $I^{exp}(t)$ was developed.

The “dark” emission of 5 μM FM 1-43 was approximately a constant f independent of time. Assuming that only a small part of the excess FM 1-43 dye was attached to SVs, the experimentally observed fluorescence intensity $I^{exp}(t)$ could be calculated as the sum of the labeled SV fluorescence $I(t)$ and the FM’s near constant emission f . The average of the experimentally obtained fluorescence could then be written in the form

of a sum of the average fluorescence of labeled SVs $\langle I(t) \rangle$ and the FM constant f :

$$I^{exp}(t) = I(t) + f \quad (3.5)$$

$$\langle I^{exp}(t) \rangle = \langle I(t) \rangle + f \quad (3.6)$$

According to equations 1.1 and 1.2, the fluorescence correlation function can be written as:

$$G(\tau) = \frac{\langle (I(t) - \langle I(t) \rangle) \cdot (I(t + \tau) - \langle I(t) \rangle) \rangle}{\langle I(t) \rangle^2} \quad (3.7)$$

Combining all three preceding equations, the experimentally determined correlation is related to the pure labeled SV signal by the following equation:

$$\begin{aligned} G^{exp}(\tau) &= \frac{\langle (I^{exp}(t) - \langle I^{exp}(t) \rangle) \cdot (I^{exp}(t + \tau) - \langle I^{exp}(t) \rangle) \rangle}{\langle I^{exp}(t) \rangle^2} \\ &= \frac{\langle ((I(t) + f) - (\langle I(t) \rangle + f)) \cdot ((I(t + \tau) + f) - (\langle I(t) \rangle + f)) \rangle}{(\langle I(t) \rangle + f)^2} \end{aligned} \quad (3.8)$$

The numerator of the function results in the same as in equation 3.7, and $G^{exp}(\tau)$ can be cast into a new form of $G(\tau)$ multiplied with a constant factor:

$$G^{exp}(\tau) = G(\tau) \cdot \frac{\langle I(t) \rangle^2}{(\langle I(t) \rangle + f)^2} = G(\tau) \cdot \frac{(\langle I^{exp}(t) \rangle - f)^2}{\langle I^{exp}(t) \rangle^2} \quad (3.9)$$

Thus, the autocorrelation $G(\tau)$ of labeled SVs can be calculated with the experimentally obtained correlation $G^{exp}(\tau)$ and a correction factor

$$G(\tau) = G^{exp}(\tau) \cdot \frac{\langle I^{exp}(t) \rangle^2}{(\langle I^{exp}(t) \rangle - f)^2} \quad (3.10)$$

In the experiment, the average fluorescence intensity $\langle I^{exp}(t) \rangle$ is measured in units of photon counts per second. 5 μM FM 1-43 was measured separately to obtain the background constant f . The calculated correction factor to $G^{exp}(\tau)$ was determined to be approximately 1.5.

3.2.4 Comparing the mass of proteins per vesicle of mouse and rat SVs

If the particle concentrations of SVs were known, many biological properties could be calculated at the level of a single vesicle. Combining the protein concentration of

the same SV sample determined by using a modified Lowry-Peterson method (page 35, subsection 2.2.2.3), the average protein mass per SV could be calculated. Figure 3.14 shows the plotted data of the vesicle concentration versus the protein concentration of the same sample. Besides the measurements for mouse SVs (Figure 3.14, black), two preparations of rat SVs purified by the same method were also measured (Figure 3.14, red) for a direct comparison with the literature [119]. The mass of proteins per vesicle was calculated as

$$m^{Pro} = \frac{c^{Pro}}{c^{SV} \cdot N_L}$$

in which c^{Pro} is the protein concentration, c^{SV} is the vesicle concentration, and N_L is Avogadro's number.

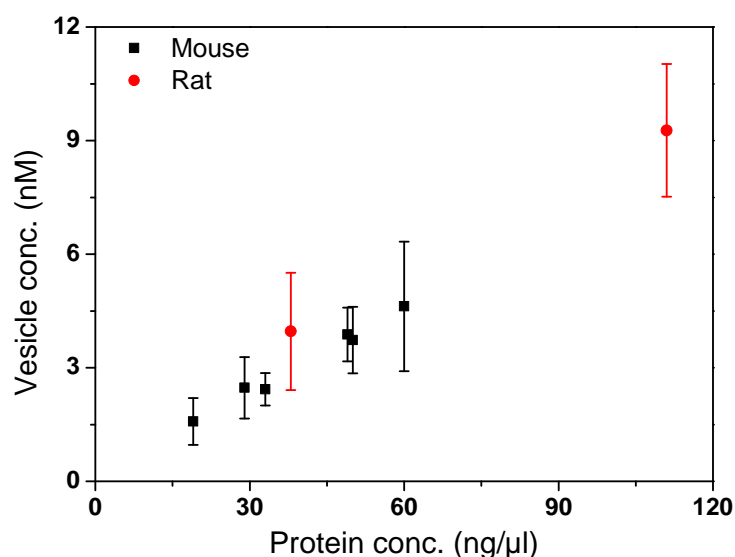

Figure 3.14: SV concentration plotted versus the protein concentration of the same sample.

Besides mouse SVs (black), two rat SV samples purified using the same method (red) were plotted as a direct comparison.

The average vesicular protein mass of mouse SVs was calculated as the weighted average of all the single purifications: $m^{Pro} = (21.4 \pm 2.1) \times 10^{-18}$ g/vesicle, corresponding to 12.9 ± 1.3 MDa. The average mass for rat SVs obtained from two purifications was $(18.8 \pm 3.2) \times 10^{-18}$ g/vesicle, corresponding to 11.3 ± 1.9 MDa (Figure 3.15)

which reflected the previous study measured with scanning transmission electron microscopy (STEM) [119].

Figure 3.15: Calculated protein mass per SV for mouse compared to rat. For one single SV, the average protein mass for mouse was $m^{Pro} = (21.4 \pm 2.1) \times 10^{-18}$ g/vesicle (black), whereas for rat it was $(18.8 \pm 3.2) \times 10^{-18}$ g/vesicle (red).

3.3 α -SNAP inhibits SNARE-mediated membrane fusion but not partial SNARE-zippering

Neuronal SNARE proteins synaptobrevin 2 (Sb), syntaxin 1A (Sx) and SNAP 25A (SNAP25) assemble from their N-termini toward their C-termini, pull the synaptic vesicle membrane and the presynaptic membrane together and provide free energy, which is essential to open the fusion pore [63, 79, 91, 116]. The disassembling of the SNAREs requires AAA+ ATPase NSF (*N*-ethylmaleimide-sensitive factor) [81, 115] and its co-factors SNAPs (soluble NSF attachment proteins), which attach NSF to the SNARE complex, and proceeds via an enzymatic activity of NSF [22].

α -SNAP is one of the most abundant isoforms of SNAP proteins [94]. It possesses an $\alpha 1$ region at its N-terminus which is essential for binding to the Q-SNARE complex, so that deletion of the N-terminus completely disrupts the SNARE association [52]. Furthermore, α -SNAP consists of a hydrophobic loop at the N-terminus which is responsible for membrane attachment [132] and shows SNARE-independent membrane lipid binding [110]. This membrane attachment also facilitates the disassembly of the

SNARE complex [132].

Besides its regulatory function during membrane priming and fusion in cooperation with NSF [18, 83, 120, 133], free α -SNAP inhibits vesicle fusion and thus the exocytosis in various biological systems [4, 9, 103, 120, 127]. However, the details of this effect are yet unclear.

In a previous study of Y. Park and coworkers (unpublished data), fusion between purified chromaffin granules (CGs) and reconstituted large liposomes in the presence of α -SNAP was investigated. CGs are one of the different kinds of secretory vesicles isolated from the chromaffin cells of bovine adrenal medullae and are also classified as large dense-core vesicles (LDCVs), since they have an average size of about 200 nm and consist of an electron-dense core [26]. For their fusion process, CGs contain the same synaptobrevin and synaptotagmin as synaptic vesicles and are used as a model to study SNARE-mediated exocytosis [86]. The large liposomes had an average diameter of about 100 nm and were reconstituted with either 2:1 complexes (2 Sx:1 SNAP25) [35] or Δ N complexes (Sx, SNAP25 and Sb^{49–96}; see page 24, Table 2.2). The Δ N complex is a stabilized Q-SNARE complex using a small Sb^{49–96} fragment which can be displaced during assembly with the Sb of the target membrane and thus promotes rapid membrane fusion *in vitro* [91]. Besides α -SNAP, two N-terminal mutants were also used to determine the functional requirements. The mutants were α -SNAP^{33–295} with deleted N-terminus and α -SNAP^{F27,28S}, which has two point mutations on hydrophobic loop between the α 1 and α 2 helices at the N-terminus.

The fluorescence dequenching spectroscopy and the fluorescence anisotropy data confirmed that 1 μ M α -SNAP clearly inhibited CG fusion by blocking the SNARE assembly. Surprisingly, deletion of the Q-SNARE binding N-terminus (α -SNAP^{33–295}) or the membrane binding loop (α -SNAP^{F27,28S}) both revoked the inhibition, suggesting that the fusion inhibition of α -SNAP requires Q-SNARE binding and membrane attachment. Furthermore, the inhibition function of the α -SNAP is dependent on membrane curvature, so that an inhibition of fusion was not observed with liposomes with a diameter below 100 nm. In addition, the SNARE assembly during the CG fusion

was checked using SDS-PAGE in the presence of α -SNAP and its mutants. Using the neurotoxin TeNT, which cleaves only the free membrane anchored Sb, the detectable Sb on the SDS gel indicated the SNARE assembly [51, 87]. The SNARE assembly was not fully interrupted by α -SNAP and was recovered in the presence of α -SNAP^{F27,28S} which is in agreement with the results of the fusion experiment.

To answer the question whether the α -SNAP blocks the CG fusion but not the SNARE assembly, a set of SNARE-dependent docking experiments using FCS was performed under the same conditions as the CG fusion experiment described above. A diffusion time change [5] of the liposomes upon binding with CGs indicated that α -SNAP did not interrupt the CG docking and thus the SNARE zippering. In conclusion, α -SNAP inhibits the CG fusion via binding to SNARE complexes with the N-terminus and attaching membranes using the hydrophobic loop, thereby clamping the full SNARE assembly (Figure 3.16).

Figure 3.16: Schematic of CG docking with 100 nm liposomes in the presence of α -SNAP. α -SNAP binds to the SNARE complex with its N-terminus and attaches to the membrane via its hydrophobic loop. α -SNAP inhibits CG fusion but not the partial SNARE assembly.

3.3.1 Determination of CG docking by observing variations in diffusion time

The docking experiments were performed between ΔN complex anchored 100 nm large liposomes (page 37, subsection 2.2.5.2) and purified CGs (page 39, subsection 2.2.7). Here, docking and fusion could not be distinguished, since only the liposome was labeled with both NBD and rhodamine dye, and only the red detection channel was used. Therefore, docking mentioned in this subsection means all the cases where liposome and CG are “gluing” together.

Docking is mediated by SNARE assembly. Using FCS measurements, the changes in liposome diffusion time caused by a size increase upon docking could be determined. The FCS setup was described in a previous section (page 59, subsection 3.2.2) using an HQ645/75 bandpass filter. The average liposome number in the effective volume was about 0.4, so that single particle docking events could be observed. For the measurement, both 50 μg CGs and 10 μl liposome were diluted in 1 ml CG buffer containing K-glutamate and MgCl_2 (page 25, Table 2.3). α -SNAP was added with a final concentration of 1 μM . The mixture was incubated for 5 min at 37°C. As a negative control, 2 μM soluble Sb_{1-96} was pre-incubated with liposomes at 37°C for 30 min, then mixed with CGs, and incubated for another 5 min. Sb_{1-96} blocks the full SNARE assembly of the ΔN complex with the full-length Sb.

Figure 3.17 shows the FCS data of selected docking experiments. Three background diffusion time measurements of each ΔN liposomes, protein-free empty liposomes, and empty liposomes in the presence of CG yielded similar diffusion times of about 10 ms in every case. The negative control experiment with soluble Sb_{1-96} in the mixture of liposome and CG did not show any changes in diffusion time, as expected (Figure 3.17 first legend session, bottom left). An increased liposome diffusion time of about 50 ms was observed in both docking experiments in the presence and absence of α -SNAP (Figure 3.17 second legend session, top right).

Each docking experiment was measured in 30×10 s fragments, and the results

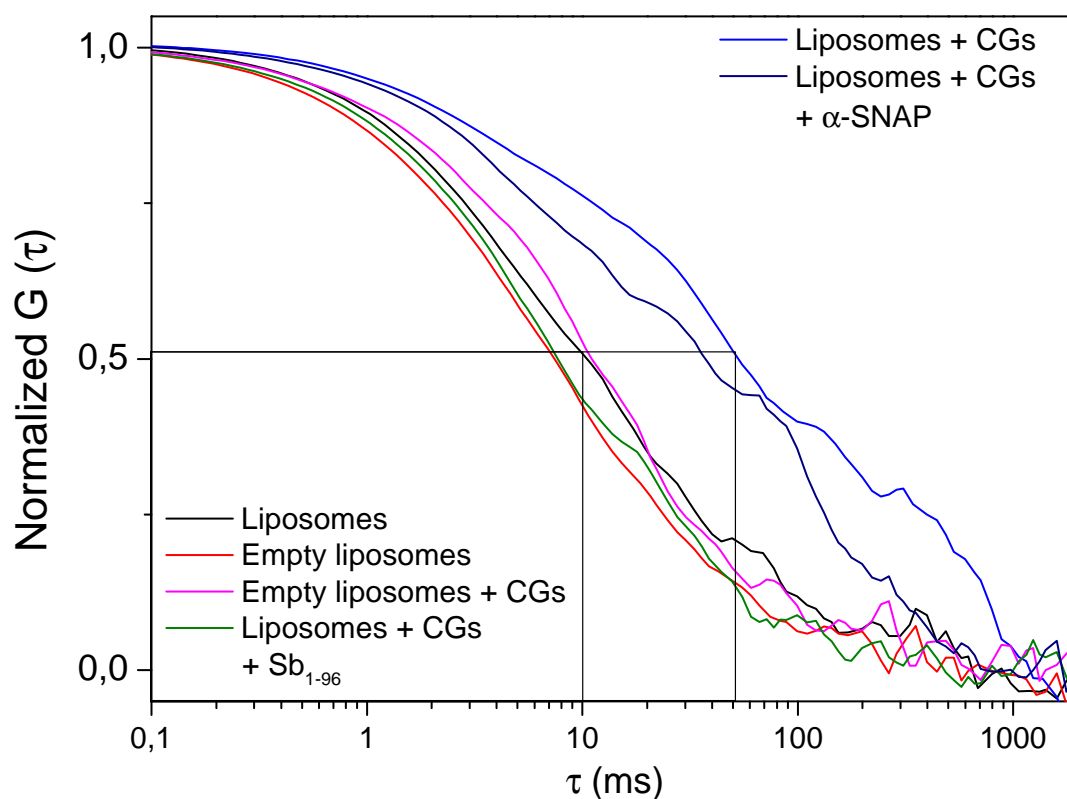

Figure 3.17: Diffusion time determination of the liposome docking experiments with CGs using FCS. Liposomes were reconstituted with ΔN complexes. Empty liposomes contained no proteins. The first data set with four FCS curves shows two liposome measurements (black and red), and two negative control measurements, in which either the empty liposomes were mixed with CGs (pink), or the liposomes were mixed with CGs in the presence of soluble Sb_{1-96} (green). All these no-docking measurements resulted in a diffusion time of about 10 ms. For the positive control measurement, in which ΔN liposomes were mixed with CGs (blue), a diffusion time of 50 ms was measured, indicating that liposomes were docked with CGs. Addition of α -SNAP nearly did not change the diffusion time of liposomes (dark blue), suggesting that α -SNAP cannot block CG-docking. Except for the two “liposome only” measurements, all the Liposome- CG mixtures were incubated at 37°C for 20 min. Sb_{1-96} was pre-incubated with liposomes at 37°C for 30 min.

are presented as a histogram of the diffusion time (Figure 3.18). In the cases of the empty liposomes and the negative control experiments, almost all of the 30 measurement fragments showed a diffusion time within 15 ms, which indicated that there was no docking. The docking experiment with ΔN liposomes and CGs showed a clearly broader distribution of the diffusion time (Figure 3.18).

Figure 3.18: Histogram of the docking experiment using liposome and CG. 30×10 s measurement fragments are plotted as a histogram of diffusion time. Protein-free empty liposomes showed a narrow distribution of the diffusion time within 15 ms (blue). Repeated fusion experiments with ΔN liposomes and CGs showed several occurrences of diffusion times of up to 50 ms indicating that a large fraction of the liposomes was docked/fused (black). The negative control experiment performed through pre-incubating with soluble Sb_{1-96} of the ΔN liposomes showed only little docking/fusion to CGs confirming that docking is mediated by SNARE assembly (red).

3.3.2 α -SNAP does not fully block CG docking

Following the FCS measurement, 15 ms were set as the criterion for discriminating docked and free liposomes (Figure 3.18, dash line). The docked liposome (> 15 ms) were calculated as percentage of the total of 30 measured events. Each measurement was repeated at least five times using new preparations and the docking rate was obtained as the average and SEM (standard error of mean) of all the measurements (Figure 3.19).

About 65% of the liposomes were docked (fused) with CGs (Figure 3.19, no addition), and the deletion in the hydrophobic loop α -SNAP^{F27,28S} did not affect the docking (fusion) which confirmed the previous fusion experiment with CGs (Figure 3.19, F27,28S). The negative control experiment with soluble Sb¹⁻⁹⁶ showed that docking is mediated by SNARE assembly (Figure 3.19, Sb₁₋₉₆). Surprisingly, α -SNAP did not block the docking (about 50%, Figure 3.19, α -SNAP), whereas in the fluorescence dequenching assay α -SNAP prevented the CG fusion completely. Docking was reduced to background level using Sb₁₋₉₆, indicating that docking in the presence of α -SNAP is SNARE mediated.

In conclusion, α -SNAP is able to inhibit CG fusion via its SNARE binding N-terminus and the membrane attaching loop, but α -SNAP does not inhibit partial SNARE assembly and thus liposome docking.

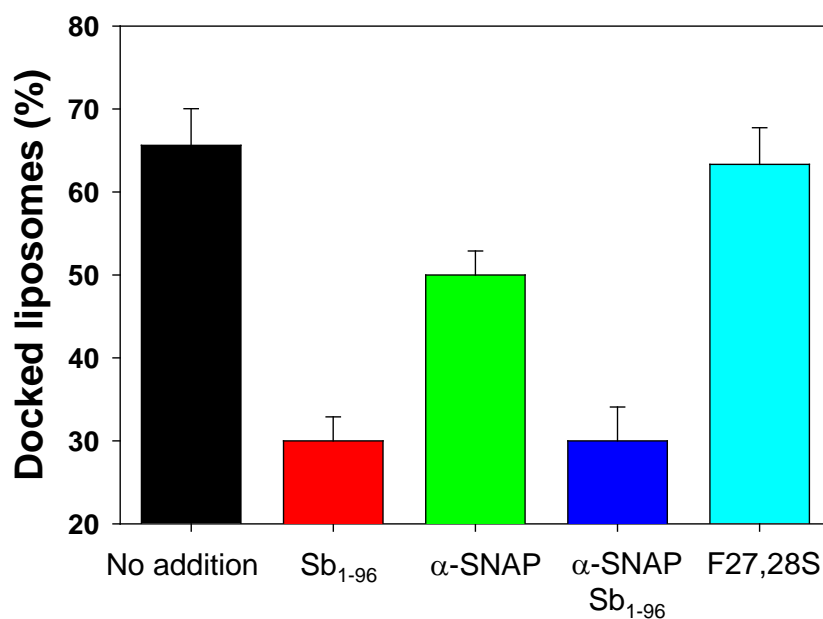

Figure 3.19: α -SNAP does not block the SNARE-mediated CG docking. Docking was measured between ΔN liposomes and CGs with 5 min incubation at 37°C. The docking rate was calculated as percentage of all the 30 measurement fragments. The error is given by SEM of more than five independent measurements. The normal docking/fusion rate was about 65% without adding α -SNAP (black). Docking was found to be reversible using soluble Sb₁₋₉₆. This indicates that docking is mediated by SNARE assembly (red). Docking was not fully disrupted by α -SNAP (green) and was still reduced to the background level using soluble Sb₁₋₉₆ (blue). Deletion of the hydrophobic loop of α -SNAP had no effect on CG docking (light blue), confirming the dequenching fusion experiment.

Chapter 4

Discussion

4.1 The conflict of *cis*- and *trans*-membrane interaction of synaptotagmin-1

Focusing on the two calcium dependent binding domains C2A and C2B of synaptotagmin-1, as well as its calcium independent binding site (polybasic lysine stretch) of C2B, the contribution of each of these independent binding regions to the Syt1 mediated membrane tethering was investigated using a sensitive tethering assay based on FCCS.

In this study, all the three binding sites engage in the tethering process of the membrane anchored Syt1 to the target membrane containing 20% PS or both 20% PS and 1% PiP2. Less than 50% tethering caused by the polybasic stretch occurs in the absence of calcium whereas 100 μ M CaCl₂ can almost double the tethering rate with at least one active C2 domain. This result confirms figures from the previous studies using isolated C2 domains [3,6,95]. Membrane anchorage does not affect the *trans* interaction of the C2 domains (Figure 4.1a). Similarly, Syt1 also tethers the membrane anchored SNARE complexes. However, the binding is mainly based on the polybasic stretch of C2B and does not show a significant dependency on calcium (Figure 4.1b). Particularly, binding to the membrane anchored single Sx1A is slightly enhanced by calcium, in agreement

with previous reports [7, 19, 21, 125].

Figure 4.1: Model of the *trans*-tethering of the membrane anchored Syt1 to the target membrane containing either acidic phospholipids or SNAREs. a. Membrane anchored Syt1 tethers the target liposome in both calcium dependent and independent manners. Target membrane contains either 20% PS or both 20% PS and 1% PiP2. b. Syt1 binds the membrane anchored SNAREs without any calcium enhancement except the binding with the isolated Sx1A.

Surprisingly, 20% PS in the host membrane of Syt1 completely inhibits the *trans*-tethering to the target membrane in all the cases, indicating that Syt1 interacts in *cis* to its host membrane (Figure 4.2). In contrast to this finding, both soluble C2AB fragment and single C2B domain were reported to be able to cluster the vesicles in several studies [3, 111, 141].

It is conceivable that clustering requires at least two independent binding sites. The experimental finding in this study using soluble C2AB fragments confirms this finding. However, clustering is only observable if C2AB fragments are saturated on the liposome surface (Figure 4.3), which reflects the case investigated in previous studies. Below the concentration at which binding is saturated, C2AB binds only to one liposome.

There is no direct explanation from the experimental results, why C2AB only clusters liposomes under saturating conditions, since all the liposomes in the solution are similarly occupied. Nevertheless, the space and orientation requirements for placing

Figure 4.2: All *trans*-tethering is inhibited if the host liposome of Syt1 contains 20% PS. Target liposome contains either acidic phospholipids (a) or SNAREs (b). No tethering is observable even in the presence of 100 μM CaCl_2 .

Figure 4.3: C2AB fragment is able to cluster the liposome under a saturating concentration on the liposome surface. Clustering is reversible by adding 2 mM EGTA.

both C2 domains of one C2AB fragment on the membrane surface may still leave a smaller area which is barely sufficient to bind one C2 domain, and furthermore to cross-link a second liposome. Alternatively, cross-linking is only observable when the liposome surface is fully covered by C2AB fragments, so that a maximum number of C2AB bridges are achieved to stabilize the membrane tethering. With these findings, many seemingly contradictory reports in the literature could be harmonized [3,60].

In conclusion, the *cis*-binding model confirms the previous studies, in which membrane anchored Syt1 reduces the fusion efficiency in the *in vitro* experiments [71,111], and exhibits a declaration for this observation, that the C2 domains of Syt1 bind in *cis* orientation to its host membrane containing acidic phospholipids and become inactive for cross-linking the plasma membrane. Some of the conflicting reports about Syt1 in artificial systems may be thus explained [67,71,111].

Along with this study, similar results have been reported [65] based on a related experimental design [23], which are largely in agreement with this study. Complementing data has also shown that SNAREs and Syt1 involved in membrane fusion is only calcium stimulated, if excess PS is present in the target membrane of Syt1 [70]; which is in accord with the tethering experiments using low percentage PS (5%) in the host liposome of Syt1.

Most importantly, the results have emphasized the conflict of *cis*- vs. *trans*-membrane interaction of Syt1. *Cis* binding of the membrane anchored Syt1 is still observable even if the PS composition is lowered to 12% in the host membrane, which is comparable to the natural synaptic vesicles containing more than 15% anionic phospholipids, suggesting that *cis*-interaction may occur under physiological conditions. This has been confirmed by several preliminary data using SVs and CGs (unpublished data and [58]). It is conceivable that in a docked intermediate, the vesicle membrane and the plasma membrane get close enough to compensate for the *cis*-binding, and one of the C2 domains can *trans* bind the plasma membrane – probably C2B due to its special ability to PiP2 [6,73,104,134,141] – and thus mediate the cross-linking [67,141]. Alternatively, *cis*-binding may be prevented by some other factors, such as molecular

crowding or charge screening. The latter has recently been observed [89], i.e. that 5 mM polyvalent anions ATP can shield the *cis*-membrane interaction, since the calcium dependent membrane affinity of Syt1 is similar to the calcium affinity of ATP, and ATP competes with the lipid membrane for binding Syt1 in a calcium dependent manner. However ATP can only prevent the membrane binding of Syt1 if the PS concentration is not higher than 15% and no PiP2 is present. Again, 15% PS is comparable to the natural lipid composition in SVs and CGs. On the other hand, 1% PiP2 enhances the calcium binding between Syt1 and the membrane by more than a factor of four, possibly due to the direct binding of the polybasic stretch of the C2B domain to PiP2 [89]. In conclusion, Syt1 binds the vesicular membrane in *cis* in the absence of ATP and becomes inactive for cross-linking the plasma membrane, whereas ATP interrupts the *cis*-binding of Syt1 and activates the C2 domains to bind the plasma membrane containing PiP2 [89]. This finding is important, because the shielding model of ATP may balance the *cis*- and *trans*-membrane interaction of Syt1 and thus modulate the membrane fusion. Cross-linking could be thought of as an “intermediate” of both *cis*- and *trans*-binding, so that the C2B domain interacts with PiP2 in the plasma membrane and C2A backbinds to the vesicular membrane [141]. If this is the case, it is still not clear whether the cross-linking proceeds in a single step or in a sequence of steps.

Moreover, the *trans*-binding of Syt1 already tethers the vesicle to the plasma membrane, since Syt1 is anchored in the vesicular membrane by the transmembrane domain, raising the question whether a calcium dependent cross-linking is still required for its function in membrane fusion.

The advantage of a cross-linking model is to lower the distance between the membranes and promote the SNARE assembly [141]. Finally, it cannot be ruled out that calcium dependent *cis*-binding is sufficient for triggering the membrane fusion, in such fashion as to induce change in the vesicular membrane curvature.

4.2 α -SNAP inhibits SNARE-mediated CG fusion, but does not fully block CG docking

Neuronal exocytosis is mediated by SNAREs assembly, termed “zippering” of the vesicular protein synaptobrevin and the Q-SNARE proteins syntaxin and SNAP-25 located in the target membrane [63]. The zippering proceeds from the N-terminus to the C-terminus [91]. α -SNAP has been reported to inhibit vesicle fusion [4, 9, 103, 120, 127]. The preliminary fusion experiments between CGs and reconstituted liposome performed in the neurobiology department have shown that α -SNAP completely prevents CG fusion and that the inhibition requires binding of the α 1 region of the N-terminus to the C-terminus of the Q-SNARE complex near the membrane and the membrane attachment of the hydrophobic loop of the N-terminus (unpublished data). As an extension of these results, docking between the purified CGs and the 100 nm liposome was investigated in the presence of α -SNAP or its N-terminus mutants (α -SNAP^{del} and α -SNAP^{F27,28S}). Liposomes contained stabilized Q-SNARE complex. Docking was monitored via diffusion time changing using FCS. Surprisingly, docking was still observable under the same conditions, by which fusion is prevented. The negative control using soluble Sb¹⁻⁹⁶ restored the docking, indicating that docking is SNARE dependent. In conclusion, α -SNAP blocks the CG fusion at the C-terminal side of the SNARE complex (unpublished data of the neurobiology department), but does not prevent the partial SNARE assembly starting from the SNARE N-terminal end, and preserves the vesicle in a docked intermediate.

This unexpected result has never been observed before and sheds light to the regulatory role of the α -SNAP in membrane fusion. However it is necessary to question whether a partial assembly of SNARE proteins at the C-terminal side is conceivable. The ternary SNARE complex structures has highly conserved layers, in which the side chains of the amino acid interact in the “tube” of the four SNARE motives [36]. Furthermore, the X-ray study suggested that the SNARE helical bundle is extended from the SNARE motives to the linker region by the further side chain interaction and the

linker region directly contributes to membrane fusion [112]. It has also been reported, that the transition region between the SNARE motives and the linker region plays an important role in membrane fusion [106, 109, 126]. Due to these, a single deletion mutant of synaptobrevin was introduced at position 84 (Sb Δ 84), which consists the +8 layer of the SNARE helical bundle and is directly followed by the linker region [55]. Sb Δ 84 bearing liposomes cannot fuse if the liposome contains stabilized Q-SNARE complex (Δ N complex) as long as at least one of the liposome populations is comprised of large liposomes (radius from 40 to 100 nm), since the +8 layer is disrupted by deletion. However, the FCCS results combined with FRET lifetime analysis [23] have shown that Sb Δ 84 still docks the large liposome, indicating that partial SNARE assembly still proceeds under these conditions [55]. Although this result cannot be directly compared with the α -SNAP mediated partial SNARE assembly, it suggests a scenario in which SNARE assembly can be halted at the C-terminus end, if the layer structure of the SNARE complex is disrupted. Thereby, it is conceivable that the interaction between the α 1 region of α -SNAP and the SNARE's C-terminal side near the membrane may be strong enough to deform one of the layers and dock the liposomes by partial SNARE assembly. Finally, it has to be pointed out, that the increased membrane curvature of the small liposome (diameter 45 nm) overcomes the inhibition of α -SNAP and promotes the membrane fusion (unpublished data from Dr. Yongsoo Park).

4.3 Quantitative characterization of synaptic vesicles

Using a sensitive vesicle counting assay based on TP-FCS, freshly isolated homogeneous mouse synaptic vesicles with low density were characterized in terms of the particle number. The membrane labeling dye FM 1-43 was used to visualize the vesicles. Cooperating with the neurobiology department, the total protein mass of the same vesicle sample was determined using a modified Lowry-Peterson method. Combining both results, an averaged protein mass per single synaptic vesicle was obtained.

The result is very well related to the previous report of rat synaptic vesicle [119], indicating that the two different species have a similar property of the synaptic vesicles despite of their morphological differences in terms of body - and brain size. In particular, mouse synaptic vesicles have a larger protein mass than those of obtained from rats ($\sim 20\%$). With the known vesicle number as a starting point, many biological parameters can be identified at a single vesicle level, for instance protein composition and lipid composition.

Chapter 5

Conclusions

Neurotransmission requires rapid fusion of synaptic vesicles with the presynaptic membrane. This fusion is triggered by calcium influx and promoted by SNARE assembly. The vesicular protein synaptotagmin-1 acts as a calcium sensor and its *trans*-tethering to the plasma membrane is an essential step in the membrane fusion process. In this study, several details in membrane fusion have been investigated and discussed.

First, the molecular requirements of the *trans*- and *cis*-membrane interaction of synaptotagmin-1 have been analyzed. All of the three binding sites of synaptotagmin-1 (the C2A domain, the C2B domain and the polylysine patch) are involved in both of these processes. *Cis*-binding to the host membrane containing 20% phosphatidylserine seems to be a stable state and can be overcome by neither *trans*-binding between synaptotagmin-1 and the target membrane containing acidic phospholipids, nor by the interaction between synaptotagmin-1 and SNAREs inserted into the acceptor membrane. Similarly, with 12% phosphatidylserine in the host membrane—a situation comparable to that in wild-type vesicles [119]—*cis*-binding is found nearly exclusively. With 5% phosphatidylserine, however, the presence of either phosphatidylinositol-4,5-bisphosphate in the target membrane or calcium in the solution can invoke conversion to *trans*-binding with great efficiency.

Second, liposome cross-linking can be mediated by soluble C2AB fragments, when

all the binding sites for C2AB are saturated on the liposome surface. To rationalize this result, it is assumed that binding with only the C2A- or the C2B domain might occur under these conditions. The other-unbound-domain of the same synaptotagmin molecule will eventually lead to cross-linking, if it attaches to a different liposome. This finding confirms the observation of *cis*-binding and explains some of the conflicts in the existing literature. Apparently, a subtle balance between *cis*- and *trans*-binding of synaptotagmin-1 may play an important role in the regulation of neuronal membrane fusion.

Moreover, first data for the characterization of mouse synaptic vesicles, in terms of average protein mass per vesicle, was measured in this study. The results obtained for mouse synaptic vesicles are similar to those of rat synaptic vesicles and offer a single vesicle basis for further investigating mouse synaptic vesicles as well as membrane fusion in a quantitative fashion.

Finally, details of the inhibiting effect of α -SNAP on the fusion of chromaffin granules with larger liposomes were also investigated in the present study. The experimental findings suggest that α -SNAP inhibits fusion of chromaffin granules and stops the SNARE assembly at the C-terminal site, so that partial SNARE zippering can still mediate docking of chromaffin granules.

LIST OF TABLES

Abbreviations and Symbols

α -SNAP	N-Ethylmaleimide-sensitive factor attachment protein, α
<i>Abs</i>	Absorption
aa	Amino acids
AAA	ATPases associated with a variety of cellular activities
APS	Ammonium persulfate
BSA	Bovine serum albumin
CG	Chromaffin granules
CHAPS	3-[(3-Cholamidopropyl)dimethylammonio]-1-propanesulfonate
Cys	Cysteine
ddH ₂ O	Double distilled water
DNase I	Deoxyribonuclease I
DOC	Deoxycholic acid
DTT	Dithiothreitol
EDTA	Ethylenediaminetetraacetic acid
f.c.	Final concentration
fl	Femtoliter

ABBREVIATIONS AND SYMBOLS

FRET	Förster Resonance Energy Transfer
h	Hours
HEPES	4-(2-Hydroxyethyl)piperazine-1-ethanesulfonic acid
IEXC	Ion Exchange Chromatography
IMAC	Immobilized Metal ion Affinity Chromatography
IPTG	Isopropyl- β -D-thiogalactopyranosid
KCl	Potassium chloride
LUVs	Large unilamellar vesicles
Milli-Q	Ultrapure water
min	Minutes
NA	Numerical aperture
NBD-DOPE	1,2-Dioleoyl- <i>sn</i> -glycero-3-phosphoethanolamine- <i>N</i> -(7-nitrobenz-2-oxa-1,3-diazol-4-yl)
Ni-NTA	Ni ²⁺ -nitrilotriacetic acid beads
NSF	<i>N</i> -Ethylmaleimide-sensitive factor
OD	Optical density
OGPE	Oregon Green-PE
OPE	One-photon excitation
P:L	Molar protein to lipid ratio
PC	L- α -Phosphatidylcholine
PE	L- α -Phosphatidylethanolamine

PI	L- α -Phosphatidylinositol
PiP2	Phosphatidylinositol-4,5-bisphosphate
PMSF	Phenylmethanesulfonylfluoride
PS	L- α -Phosphatidylserine
RG	Rhodamine Green
Rhodamine-DOPE	1,2-dioleoyl- <i>sn</i> -glycero-3-phosphoethanolamine- <i>N</i> -lissamine rhodamine B sulfonyl ammonium salt
RPM	Revolutions per minute
RT	Room temperature
SDS	Sodium dodecyl sulfate
SDS-PAGE	Sodium dodecyl sulfate polyacrylamide gel electrophoresis
SEM	Standard error of the mean
SNAP25A	Synaptosomal-associated protein 25A
SNAPs	Soluble NSF attachment proteins
SNARE	Soluble <i>N</i> -ethylmaleimide-sensitive-factor attachment receptor
Sx1A	Syntaxin 1A
Syt1	Synaptotagmin-1
TCA	Trichloroacetic acid
TEMED	<i>N,N,N',N'</i> -Tetramethylethylenediamine
TPE	Two-photon excitation
Tricine	<i>N</i> -(Tri(hydroxymethyl)methyl)glycine

ABBREVIATIONS AND SYMBOLS

Trp	Tryptophan
TRPE	Texas Red-PE
Tyr	Tyrosine
v/v	volume/volume
w/v	weight/volume

Publication

Vennekate W, Schröder S, Lin CC, van den Bogaart G, Grunwald M, Jahn R, Walla PJ. "Cis- and trans-membrane interactions of synaptotagmin-1." *Proc. Natl. Acad. Sci. USA* 109, 11037–11042 (2012).

Another manuscript is in preparation.

Acknowledgement

I would like to thank both of my supervisors Professor Peter Jomo Walla and Professor Reinhard Jahn, for supporting me to complete my PhD thesis with many pleasant discussions and many important suggestions. Also I would like to thank Professor Claudia Steinem for joining my thesis committee and giving me lots of useful suggestions.

My collaboration partners, Dr. Geert van den Bogaart, Dr. Yongsoo Park, Dr. Saheeb Ahmed and Dr. Matthew Holt, have to be named not only for offering an active working atmosphere, but also for the growing friendships with them during the past four years.

I would like to give special thanks to Dr. Anna Cypionka and Dr. Wiebke Hanna Pohl for getting me start in the work group and sharing a great time with me.

I would like to thank all my friends of the Walla group and the Jahn department for having an enjoyable time with them. I thank for the great help from Dr. Javier Matias Hernandez, Jianhua Chen, Matthias Grunwald, Sabrina Schröder, Chao-Chen Lin and Mrs. Ursel Ries during my pregnancy leave, which enabled me to continue my project during an important period.

Finally, I would like to thank Inge Dreger and Hendrik Vennekate for revising the manuscript.

Curriculum Vitae

Personal information

Name: Wensi Vennekate, née Gao

Date of birth: December 23rd, 1982

City of birth: Tongliaoshi, China

Nationality: German

Education

- 2009/01-present Ph.D. student in Chemistry in the workgroup Biomolecular Spectroscopy and Single-Molecule Detection, Max-Planck-Institute for Biophysical Chemistry, Göttingen, Germany.
- 2008/11-2008/12 Practical training in the workgroup Biomolecular Spectroscopy and Single-Molecule Detection, Max-Planck-Institute for Biophysical Chemistry, Göttingen, Germany.
- 2003/10-2008/10 Diploma in Chemistry. Georg-August-University, Göttingen, Germany.
Thesis Title: *Wechselwirkung neuer Cholinkinase-Inhibitoren mit den Enzymen von Malaria-Plasmodium* (Interaction of Novel Cholinkinase Inhibitors with Malaria Plasmodium).
- 2002/12-2003/09 German language course (DSH), Goethe-Institute, Göttingen, Germany.
- 2001/09-2002/08 Student of industrial design, Beijing University of Technology, China.
- 1998/09-2001/08 Beijing No. 4 High School, China.
