SUMMARY

Motoneurons (MNs) are selectively damaged both in human amyotrophic lateral sclerosis (ALS) and corresponding mouse models of this neurodegenerative disease. A variety of studies indicate that mitochondrial dysfunction and disruption of the cellular Ca^{2+} homeostasis represent critical events during the disease process. Since little is known about the involvement of mitochondria in regulation of Ca^{2+} levels in MNs, the first aim of this work was to define the contribution of mitochondria to the clearance of physiological type Ca^{2+} loads. Second, the work aimed at characterizing the cellular consequences of mitochondrial dysfunction in MNs, with particular attention to changes in electrical properties and alterations in Ca^{2+} homeostasis, as this may give clues to the understanding of processes involved in MN degeneration and the selective vulnerability of MNs in ALS.

The contribution of mitochondria to buffering of Ca^{2+} loads was investigated employing acute mouse brainstem slices containing the hypoglossal motor nucleus and CCD camera based imaging techniques. It was demonstrated that in hypoglossal MNs, mitochondria constitute the dominant Ca^{2+} clearance mechanism accounting for buffering of ~50 % of voltage activated Ca^{2+} loads with amplitudes below 0.4 μM . The mitochondrial clearance rate constant (γ_{mito}) was approximated as 70 s^{-1} . By varying bath temperatures from 19 to 32 $^{\circ}\text{C}$, mitochondrial Ca^{2+} buffering was shown to be strongly temperature dependent ($Q_{10} = 2.1$). Complementary experiments indicated that the high efficiency of mitochondrial Ca^{2+} buffering even for low amplitude Ca^{2+} elevations is sponsored by a high level of mitochondrial activity and a significant interaction of mitochondria and areas of Ca^{2+} accumulation around influx sites.

To elucidate the consequences of mitochondrial dysfunction on MN membrane properties and intracellular Ca^{2+} homeostasis, hypoglossal MNs were patch-clamped within the brain slice and mitochondrial function was disturbed using the complex IV inhibitor sodium cyanide (CN). CN activated a TTX-insensitive Na^{+} conductance, which depolarised MNs by 10.2 ± 1.1 mV and consequently increased spontaneous action potential activity. Reactive oxygen species (ROS) originating at the respiratory chain were identified as potential mediators of the Na^{+} current. CN responses in

hypoglossal MNs were further characterized by a significant increase in the cytosolic Ca^{2+} load following four different mechanisms: i) an increased Ca^{2+} influx during elevated firing rates, ii) Ca^{2+} release from mitochondrial stores, iii) retardation of cytosolic Ca^{2+} clearance rates due to lacking mitochondrial Ca^{2+} buffering and (iv) a drop in cellular ATP levels. Taken together, the observations identify mitochondrial dysfunction as a critical stressor of motoneuron function, potentially contributing to MN degeneration in ALS. The findings further support a model, where the selective vulnerability of MNs results from a synergistic accumulation of risk factors, including low cytosolic Ca^{2+} buffering, strong mitochondrial control of $[\text{Ca}^{2+}]_i$, and a weak protection against increases in electrical excitability during metabolic disturbances.

ABBREVIATIONS

aCSF	artificial cerebrospinal fluid
ALS	amyotrophic lateral sclerosis
AP	action potential
AP-5	D(-)-2-amino-5-phosphonopentanoic acid
ATP	adenosin triphosphate

TEA	tetraethylammonium chloride
TTX	tetrodotoxin
VC	voltage clamp
$\Delta\psi$	mitochondrial membrane potential

1. INTRODUCTION

1.1 Amyotrophic Lateral Sclerosis (ALS)

Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease clinically characterized by progredient loss of muscle force and breathing capacity, swallowing difficulties as well as spasticity of upper and lower limbs. The incidence is 1-2 per 100.000 persons per year; the age of onset varies from mid 20 to mid 70 with most patients being affected between 53 and 57 years. About 90 % of ALS cases are sporadic, the remaining 10 % are of genetic origin, mainly with an autosomal dominant inheritance. Clinically there is no apparent difference in onset or progression between sporadic and familial forms, which has led researchers to hypothesize that both forms share at least some identical components in their pathogenesis and are very likely to share a common final pathway.

Fig. 1.1: Motoneurons that degenerate in ALS include primary motoneurons in the motor cortex, brainstem motoneurons in motor nuclei and motoneurons in the ventral horn of the spinal cord (taken from Rowland & Shneider, 2001).

1.2 Pathogenesis of ALS

Corresponding to the clinical picture, ALS is characterized by a proгредиant loss of cortical, spinal and brain stem motoneurons (Fig. 1). As for most neurodegenerative diseases, the mechanisms leading to selective degeneration of motoneurons in ALS are far from being understood. For sporadic forms of ALS, several pathogenic factors have been proposed, including glutamate excitotoxicity (Rothstein *et al.*, 1992; Heath & Shaw, 2002), neurofilament disruption (Julien *et al.*, 1998) and excess Ca^{2+} influx through neuronal Ca^{2+} channels (Appel *et al.*, 1994). As for the familial forms of ALS, 5-10 % are caused by mutations in the gene encoding Cu/Zn superoxide dismutase (SOD1).

SOD1-mediated injury

Mutations in the SOD1 gene underlying a familiar form of ALS were discovered in 1993 (Rosen *et al.*, 1993) and still are the only proven cause for ALS. Generation of transgenic mice expressing human mutant SOD1 (mtSOD1) as a model for ALS (Gurney *et al.*, 1994) has greatly helped researchers to investigate the mechanisms underlying ALS. So far, studies suggest that mtSOD1 affects motoneurons by a “toxic gain of function” rather than a loss of function. This assumption is based on the observations that i) knock-out mice, which completely lack the SOD1-gene, do not develop a phenotype of motoneuron degeneration (Reaume *et al.*, 1996) and ii) 6-times over-expression of wildtype SOD1 in mtSOD1-mice does not rescue these mice from motoneuron degeneration (Bruijn *et al.*, 1998). The idea of a “gain of function” is further supported by the fact that more than 90 different ALS-associated mutations in the SOD1 protein have been described with no correlation of enzyme activity and severity of disease (Bowling *et al.*, 1995). However, the exact mechanism by which mtSOD1 affects motoneurons still needs to be clarified.

1.3 Disruption of intracellular Ca^{2+} homeostasis in ALS

Independent of the cellular/molecular event initiating motoneuron degeneration in ALS, disruption of intracellular Ca^{2+} homeostasis is thought to play a key role in the disease process. Elevated Ca^{2+} levels have been found in motor nerve terminals from ALS patients (Siklos *et al.*, 1996), in motoneurons of mice after transferring antibodies from ALS patients (Engelhardt *et al.*, 1995) and in motoneurons from mtSOD1 transgenic mice (Siklos *et al.*, 1998). The crucial role of Ca^{2+} was

furthermore demonstrated in cell culture models of ALS, where motoneuron degeneration was either induced by AMPA/kainite exposure (Carriedo *et al.*, 1996) or by transfection of mtSOD1 (Roy *et al.*, 1998). Finally, a disruption of intracellular Ca^{2+} homeostasis as central event in the disease process is supported by experiments where an increase in cytosolic Ca^{2+} buffers such as parvalbumin protected motoneurons from degeneration both in cell culture and in the mtSOD1 mouse model of ALS (Ho *et al.*, 1996; Beers *et al.*, 2001; Van Den Bosch *et al.*, 2002).

1.4 Involvement of mitochondria in ALS

Increasing evidence indicates an involvement of mitochondria in ALS, both in sporadic and in mtSOD1-related forms (Menzies *et al.*, 2002b). First, structural alterations of mitochondria, such as swelling, were observed in motoneurons of ALS patients and transgenic SOD1 mice (Sasaki & Iwata, 1996; Kong & Xu, 1998; Fig. 1.2).

Fig. 1.2: Mitochondria in motoneurons of mutant SOD1 transgenic mice show abnormalities like dilated cristae (asterisk) and leaking outer membrane (arrow; taken from Kong & Xu, 1998).

More recently, dysfunction of mitochondria has been described in ALS. This dysfunction was partially associated with mutations in mitochondrial DNA and altered mitochondrial electron chain activity (Swerdlow *et al.*, 1998; Borthwick *et al.*, 1999; Wiedemann *et al.*, 2002). In mtSOD1 based ALS, mitochondrial dysfunction has been shown to be induced by the mutated protein itself, which inhibits complex II and IV of the respiratory chain (Menzies *et al.*, 2002a). That mitochondrial dysfunction is causally related to motoneuron degeneration rather than being a secondary event is suggested by the fact that it occurs during early disease stages (Jung *et al.*, 2002). Even more convincing is the observation that chronic mitochondrial inhibition may induce selective motoneuron degeneration *in vivo* and *in vitro* (Kaal *et al.*, 2000).

1.5 Factors underlying selective vulnerability of motoneurons in ALS

The fact that certain cell types such as spinal or brainstem motoneurons are primarily affected in ALS, whereas others are usually spared, is called “selective vulnerability”. Many studies have been undertaken to elucidate the features determining selective motoneuron vulnerability in ALS. One important factor that has been determined is a low cytosolic Ca^{2+} buffering capacity (κ_S) corresponding to a low expression of Ca^{2+} binding proteins (i.e. calbindin, parvalbumin, calretinin) in vulnerable cells (Lips & Keller, 1998; Palecek *et al.*, 1999; Vanselow & Keller, 2000; Fig. 1.3). Under physiological conditions, low κ_S enables fast and highly localized cytosolic Ca^{2+} signalling at low energy cost, but presumably enhances the vulnerability of motoneurons under pathophysiological conditions. Whereas vulnerable motoneurons show κ_S values in the range of 40, cells that are usually not affected in ALS such as oculomotor neurons, hippocampal CA1 or Purkinje neurons display several-fold higher κ_S values (~200, 250 and 800, respectively).

Fig. 1.3: Above, expression of Ca^{2+} -binding proteins (calretinin, calbindin and parvalbumin) in the hypoglossal nucleus (12) and surrounding brain stem nuclei. Scale bars: 100 μm (taken from Paxinos *et al.*, Chemoarchitectonic atlas of the rat brainstem, Academic Press, 1999). Below, comparison of κ_S values between different cell types. Vulnerable motoneurons are marked by arrows.

Support for the concept that low cytosolic Ca^{2+} buffering contributes to the selective motoneuron vulnerability is provided by experiments, in which a controlled increase in cytosolic Ca^{2+} buffers rescued motoneurons from ALS-associated degeneration in cell culture models but also in living mice expressing mtSOD1 (Roy *et al.*, 1998; Beers *et al.*, 2001; Van Den Bosch *et al.*, 2002).

Further factors that are proposed to support a selective motoneuron vulnerability in ALS are the presence of Ca^{2+} permeable α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors (Shaw & Eggett, 2000; Vandenberghe *et al.*, 2000) and a high neurofilament content (Julien *et al.*, 1998). Additionally, a high level of mitochondrial activity serving the high energy requirements of motoneurons is thought to contribute to it (Menzies *et al.*, 2002b). This assumption is supported by the observation that mitochondrial inhibition induces a selective motoneuron degeneration *in vitro* (Kaal *et al.*, 2000). Taken together, it seems that no single property, but rather an accumulation of a variety of factors is responsible for the vulnerability of motoneurons to ALS-associated damage.

1.6 Mitochondrial function in cell physiology

As this work will focus on the role of mitochondria in motoneurons and ALS, the physiological properties of mitochondria will be briefly summarized.

ATP generation

Mitochondria have long been known to be the primary energy source in mammalian cells. ATP is generated by the F_0F_1 ATP synthase located in the inner mitochondrial membrane, which utilizes the existence of a proton gradient over the inner mitochondrial membrane for ATP synthesis. This proton gradient, which also constitutes a potential gradient ($\Delta\psi$, mitochondrial matrix more negative than cytosol), is generated by an efflux of protons during electron transport at the respiratory chain (Fig. 1.4). The most important proton donor is nicotinamide adenine dinucleotide (NADH) constituting also the source of electrons for the respiratory chain. When spending proton and electron at the level of complex I, NADH is oxidized to NAD^+ . Regeneration to NADH takes place in the citrate cycle in the mitochondrial matrix.

Fig. 1.4: Illustration of the mitochondrial respiratory chain located in the inner mitochondrial membrane. The pathway of electron transport is indicated in black, proton pumping in red. The fluorescent substrate NADH is oxidized to the non-fluorescent NAD^+ on the level of complex I (after Voet & Voet, 1995).

Ca²⁺ cycling

Mitochondria are also known as important players in cellular Ca^{2+} handling (Duchen, 2000; Nicholls & Budd, 2000; Rizzuto *et al.*, 2000). This evidence is based on the discovery of active Ca^{2+} uptake and extrusion mechanisms in the inner membrane of mitochondria. It is generally believed that during a variety of physiological-type stimuli, mitochondria take up Ca^{2+} via a Ca^{2+} uniporter driven by the potential gradient $\Delta\psi$. The rate of mitochondrial Ca^{2+} uptake is believed to depend on the cytosolic Ca^{2+} concentration, with increasing operation of the uniporter at high cytosolic Ca^{2+} levels. Ca^{2+} is mainly brought out of mitochondria via the $\text{Na}^+/\text{Ca}^{2+}$ antiporter operating usually at maximum rate. If the rate of mitochondrial Ca^{2+} uptake exceeds Ca^{2+} extrusion, then Ca^{2+} can accumulate in mitochondria (Fig. 1.5). Studies on isolated mitochondria have shown that this occurs when cytosolic $[\text{Ca}^{2+}]$ reaches levels higher than 300 nM. As Ca^{2+} and phosphate residues can form insoluble complexes in the inner mitochondrial matrix, mitochondria are capable of storing Ca^{2+} and doing so to compensate for increasing Ca^{2+} influx.

Ca^{2+} cycling in mitochondria is tightly linked to oxidative phosphorylation and energy production (Nicholls & Budd, 2000). This is based on the fact that certain enzymes of the citrate cycle (i.e. pyruvate dehydrogenase, isocitrate dehydrogenase) are activated by increases in mitochondrial matrix $[\text{Ca}^{2+}]$. The increased activation of the citrate cycle is reflected in an elevated reduction state of NADH, which increases oxidative phosphorylation and ATP synthesis.

Fig. 1.5: Illustration of the activity of mitochondrial Ca^{2+} transport systems. Mitochondrial Ca^{2+} accumulation occurs when the activity of the uptake system (Ca^{2+} uniporter) exceeds those of the efflux system ($\text{Na}^+/\text{Ca}^{2+}$ exchanger; after Voet & Voet, 1995).

Under certain circumstances, mitochondria can release large amounts of Ca^{2+} in the cytosol. At least two different pathways for Ca^{2+} release have been proposed. First, release of Ca^{2+} by reverse mode action of the Ca^{2+} uniporter and second, release of Ca^{2+} via opening of an unspecific cation channel, the mitochondrial permeability transition pore (mPTP). The latter one is usually restricted to pathological conditions.

Free radical production

Besides important roles in energy production and calcium handling, mitochondria constitute the main source of free radicals in the cell, owing to inefficient transport of electrons in the respiratory chain (Lopez-Barneo *et al.*, 2001). Radicals are produced preferentially at the semiquinone site (level of complex III), where an electron can be transferred to O_2 to produce superoxide (O_2^-). Superoxide is easily converted to hydrogen peroxide (H_2O_2) and hydroxyl radicals (OH), altogether being referred to as reactive oxygen species (ROS).

1.7 Aim of this work

The present work aims at investigating physiological and pathophysiological aspects of mitochondrial function in motoneurons, considering that disruption of such processes may contribute to motoneuron degeneration in ALS. Of particular interest was the interplay between mitochondrial function and cellular Ca^{2+} homeostasis as previous studies have identified low endogenous Ca^{2+} buffering, high amplitude Ca^{2+} transients and localized Ca^{2+} profiles as typical features of motoneurons.

The first aim of this study was therefore to define the impact of mitochondrial function on $[Ca^{2+}]_i$, in particular to buffering of Ca^{2+} transients, which are a characteristic part of motoneuron physiology. The second aim was to evaluate the consequences of a disturbed mitochondrial metabolism, with respect to $[Ca^{2+}]_i$ and membrane properties, as this should give clues to understanding of processes involved in motoneuron degeneration and the selective vulnerability of motoneurons in ALS.

2. MATERIALS AND METHODS

2.1 Preparation of acute mouse brainstem slices

All electrophysiological and optical recordings described in this work were performed on acute mouse brainstem slices prepared from young (1-5 days old) NMR1 mice. Animal experiments were carried out in accordance with the guidelines of the Ethics Committee of the University of Göttingen. Animals were decapitated and the head was immediately placed into 4°C cold artificial cerebrospinal fluid (aCSF, in mM: 118 NaCl, 3 KCl, 1 MgCl₂, 25 NaHCO₃, 1 NaH₂PO₄, 1.5 CaCl₂, 20 glucose; 320 mosm; pH 7.4 achieved by continuous bubbling with carbogen (95% O₂, 5% CO₂)). Under visual control, skin and skull cap were removed, permitting free access to the brain. From anterior to posterior, the brain was carefully loosened from the cranial base, the cranial nerves being cut with fine scissors. The isolated brain was then placed in a petri dish filled with aCSF. Using a scalpel, the telencephalon was cut away from cerebellum and brainstem. Subsequently, cerebellum and brainstem were separated by an axial cut. The isolated brainstem was glued on an agar block with the dorsal side facing the agar. The agar block was glued on a 20° angled block with the rostral side of the brainstem directed upwards. The block was then placed in an aCSF-containing chamber so that the brainstem's ventral side faced the blade (Fig. 2.1).

Fig. 2.1: Position of the isolated mouse brainstem during slicing.

Transverse brainstem slices were cut using a vibratome (LeicaVT100S, Leica Instruments GmbH, Nussloch, Germany) from rostral to caudal reaching the region of interest when the IVth ventricle had passed its largest diameter. At this level, for recordings of rhythmic motor activity, a single transverse brainstem slice was prepared with a thickness of ~600 µm containing the pre-Bötzing complex and large parts of the hypoglossal nucleus. For all other experiments, transverse slices were cut with a thickness of ~200 µm. In this way, up to 4 slices could be obtained containing neurons of the hypoglossal nucleus.

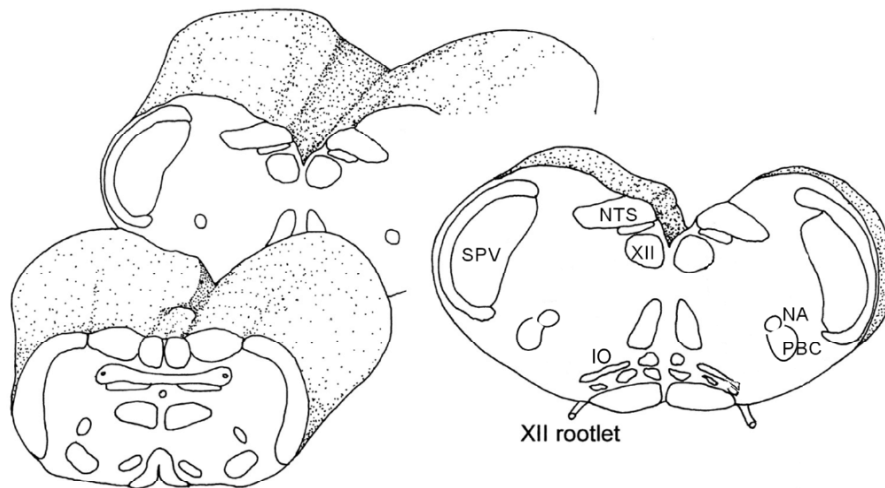

Fig. 2.2: Schematic drawing of the medulla oblongata, from which slices were taken containing the hypoglossal nucleus (XII), ambiguous nucleus (NA), pre-Bötzinger complex (PBC), solitary tract nucleus (NTS), the spinal part of the trigeminal nucleus (SPV) and the inferior olive (IO; modified after Ramirez *et al.*, 1997).

After preparation, 600 μm thick slices were directly transferred into the recording chamber and rinsed with 28°C warm aCSF. Thin slices (200 μm) were transferred to 33 °C warm aCSF, which then cooled down to room temperature (RT, 20-22°C). In the recording chamber, all slices were fixed with an U-shaped platinum wire, on which nylon strings were glued.

2.2 Experimental set-up

In Göttingen, most of the experiments were performed with a set-up allowing simultaneous electrophysiological recording and CCD camera imaging. The recording chamber containing the brain stem slice was fixed on a microscope table under a Zeiss microscope (Axioskope, Zeiss, Göttingen, Germany). The microscope table was movable in an XY direction under the microscope. Additionally, the microscope was placed on a sliding table (Spindler & Hoyer, Göttingen, Germany) allowing XY movements of the microscope over the preparation. The whole set-up was installed on a table providing air-suspension and surrounded by a Faraday cage in order to protect it from vibration and low frequent electric noise. The recording chamber allowed continuous perfusion with aCSF via Tygon[®] tube connection. For all optical measurements, a 63x water immersion objective (Achromplan, Zeiss) was employed.

2.3 Recording of rhythmic motor activity

Hypoglossal motoneurons (MNs) are part of the respiratory network which generates the rhythm of breathing in mammals. They receive input from the rhythm-generating centre, the pre-Bötzinger complex located in the ventro-lateral medulla, and respiratory-related activity is projected via the hypoglossal nerve (XII) to tongue and pharynx muscles. The function of tongue and pharynx innervation during breathing is to stabilize the upper airway system to prevent its collapsing during inspiration. In 1991, Smith et al. (1991) demonstrated that a ~600 μm thick preparation of the lower brainstem, which includes the pre-Bötzinger complex and large parts of the hypoglossal nucleus, can maintain rhythmic respiratory-related activity *in vitro*. This respiratory-related activity can be recorded as motor output from hypoglossal (XII) rootlets (Fig. 2.3), which was performed in some experiments described in this work.

Fig. 2.3: Left, schematic drawing of a brain stem slice containing the respiratory network, where rhythmic activity is generated in the pre-Bötzinger complex and projected to the hypoglossal nucleus. Motor output (XII activity) is recorded from the hypoglossal rootlets. An example of rhythmic motor activity is shown on the right (lower trace). The integrated activity is shown above (modified after Ramirez et al., 1997).

Rhythmic respiratory-related activity of hypoglossal rootlets was recorded using suction electrodes pulled from borosilicate glass tubes (Kimax 51, Kimble Products, Vineland, NY, U.S.A.) and standard electrophysiological equipment (Lips & Keller, 1998). To obtain regular rhythmic activity, the potassium concentration of the aCSF was raised to 8mM.

2.4 Identification of hypoglossal motoneurons in the slice

In brainstem slices, hypoglossal motoneurons (MNs) were identified by their localization in the hypoglossal nucleus paramedian ventral of the IVth ventricle or the central channel (Fig. 2.4). They could furthermore be distinguished from neighbouring neurons by their large size (somatic diameter usually > 15 μm) and their rounded shape. In patch-clamp experiments, suitable MNs were additionally selected by their ability to fire action potentials in a drug-free solution and the occurrence of spontaneous synaptic activity.

Fig. 2.4: Acute mouse brainstem slices (200 μm thick) seen in transmitted light in 10x (left) and 60x (right) magnification. The dashed line surrounds the hypoglossal nucleus paramedian, ventral of the central channel (left); the arrows point to single hypoglossal motoneurons (right).

2.5 Electrophysiological recordings

For patch-clamp experiments, patch pipettes were pulled from borosilicate glass tubes (Kimax 51, Kimble Products, Vineland, NY, U.S.A.). The intracellular pipette solution contained (mM) 140 KCl (alternatively 120 CsCl and 20 TEA), 10 HEPES, 2 MgCl_2 , 4 Na_2ATP , 0.4 NaGTP (adjusted to pH 7.3 with KOH or CsOH). When filled with intracellular solution, pipettes displayed resistances of 1.8-3.5 $\text{M}\Omega$. Under visual control, patch pipettes were approached to hypoglossal MNs using 3-dimensional piezo-electric control (Physik Instrumente, Waldbronn, Germany) and continuous application of positive pressure to avoid contamination of the pipette tip and to remove extracellular matrix surrounding hypoglossal MNs. Correct positioning of the pipette tip in close proximity of hypoglossal MNs was indicated by occurrence of a slight membrane cavity. Subsequently, positive pressure was removed and MN membrane was gently sucked into the pipette tip. Membrane seals developed with resistances >1 $\text{G}\Omega$ as indicated by continuous application of test pulses (-10 mV,

5 ms). The whole-cell configuration (Hamill *et al.*, 1981) was established by rupture of the membrane in the pipette tip. Whole cell recordings in voltage clamp (VC) and current clamp (CC) mode were performed using an EPC-9 patch clamp amplifier (HEKA Electronics, Lambrecht, Germany). After rupture of the seal, series resistance (R_s , 6-15 M Ω) was continuously monitored. VC recordings were performed only when R_s stabilized and cells displaying R_s higher than 20 M Ω were excluded from analysis. In part of the experiments, R_s was compensated up to 50 %. Voltage and current pulse generation and data acquisition were performed with a Macintosh computer running PULSE software 8.11 (HEKA). Whole-cell currents were recorded with sampling frequencies of 4-10 kHz and filtered (Bessel filter, 2.9 kHz) before analysis. For analysis, PulseFit (HEKA) and IgorPro (Wavemetrics Inc., Lake Oswego, OR, U.S.A.) software were employed.

2.6 CCD camera imaging

CCD camera imaging was applied to monitor dynamic changes in $[Ca^{2+}]_i$ and mitochondrial parameters of hypoglossal MNs in the slice. Fluorescence excitation was done by using a computer-controlled monochromator (Polychrome II, TILL Photonics, Gräfelfing, Germany), which was connected to an upright microscope via quartz fibre optics and a minimum number of optical components for maximum fluorescence excitation (objective Achromplan W 63x, 0.9W). By this system, wavelengths in the range of 300-700 nm could be generated with a bandwidth of 13 nm, making the use of excitation filters unnecessary. The emitted light was directed to a dichroic mirror with mid reflection depending on the fluorescent dye used (fura: 425 nm, rhod123: 510 nm; Zeiss, Germany). Fluorescence signals were detected with a peltier-cooled (-15°C) slow scan CCD camera (IMAGO, TILL Photonics) displaying 12-bit dynamics and an A/D converter with 12.5 MHz sampling rate. Fluorescence changes in defined "regions of interest" (ROIs) were monitored online using a PC running TILL Vision Software V4.0 (TILL Photonics). To maximize the speed of fluorescence recordings, camera binning was set to 4x4 (120x160 pixel) allowing sampling rates up to 15 Hz at reasonable spatial resolution. The analysis of fluorescence signals was performed off-line with IGOR (Wavemetrics, Lake Oswego, OR, U.S.A.) software.

2.7 Confocal laser scanning microscopy

A confocal laser scan system (model 510, Zeiss, Germany) was used for localisation studies of mitochondrial networks. In these experiments, acute slices were loaded with 1 μM mitotracker green/AM for 30 min followed by a 30 minutes wash. Slices were placed into a custom build recording chamber mounted on the microscope table and perfused with aCSF. Mitotracker green was excited using the 488 nm line of an argon laser and fluorescence was collected using a 505-530 nm band-pass filter. Data acquisition and analysis was done using the LSM software provided by Zeiss.

2.8 Microfluorometric calcium measurements

Changes in cytosolic $[\text{Ca}^{2+}]$ were monitored using fura-2 ($K_d \sim 0.2 \mu\text{M}$) or fura-FF ($K_d \sim 5.5 \mu\text{M}$). The fluorescent dyes were brought into the cells either by addition of their potassium salts to the patch pipette solution (100 μM , Fig. 2.5), or by loading the slice with their membrane-permeable AM-ester forms (10 μM for 60 min at 33°C, subsequent wash >30 min at RT). In the latter case, the ester conjugate diffuses into the cell, where the ester group is cleaved so that the dye is trapped in the cytosol.

Fig. 2.5: CCD camera image of a patch-clamped hypoglossal motoneuron loaded with 100 μM fura-2. Fluorescence excitation was done at 390 nm.

Fura-2 and related Ca^{2+} indicators are classical ratiometric dyes due to their shift in the excitation spectrum upon binding of Ca^{2+} (Fig. 2.6). During increase of $[\text{Ca}^{2+}]_i$, the fluorescence activity of fura decreases when excited at $\sim 385 \text{ nm}$, whereas the fluorescence activity increases when excited at $\sim 340 \text{ nm}$. At $\sim 360 \text{ nm}$, fura displays its isosbestic point, where the emission is not dependent on Ca^{2+} . In the experiments described here, fura was alternately excited at 360 and 385 nm, as the objectives used did not transmit light at wavelengths around 340 nm. Excitation at 360 nm is furthermore advantageous, because it allows estimation of the dye concentration in the cell (Neher, 1995).

Fig. 2.6: Fluorescence excitation (detected at 510 nm) and emission (excited at 340 nm) spectra of Ca^{2+} -saturated (A) and Ca^{2+} -free (B) fura-2 in pH 7.2 buffer (taken from Molecular Probes homepage).

For most recordings, where fura was loaded via the patch-pipette, the fluorescence ratios were converted into Ca^{2+} concentrations after a background correction had been performed. The two main sources of background fluorescence resulted from (1) dye that had distributed in the slice prior to the seal formation and (2) tissue autofluorescence (i.e. NADH, FADH). The background fluorescence was recorded in a ROI drawn beside the patch-clamped cell and to correct for it, the average fluorescence of the background window was subtracted from each image before ratioing. The resulting “background-corrected” ratio trace was transformed into $[\text{Ca}^{2+}]_i$ using the equation:

$$[\text{Ca}^{2+}]_i = K_d * (R_{\max} / R_{\min}) * (R - R_{\min}) / (R_{\max} - R) \quad (\text{Grynkiewicz } et al., 1985)$$

R_{\max} and R_{\min} are the fluorescence ratios for infinite high and infinite low cytosolic $[\text{Ca}^{2+}]_i$; K_d is the dissociation constant of fura-2. R_{\max} and R_{\min} were determined *in vivo* by loading cells with either 10 mM Ca^{2+} (R_{\max}) or 0 mM Ca^{2+} and 10 mM EGTA (R_{\min}). K_d , fura-2 was assumed as 225 nM according to previous work (Lips & Keller, 1998; Ladewig & Keller, 2000).

In experiments where the fura dyes were loaded as AM-esters, the background fluorescence was not clearly determinable, therefore fluorescent changes in defined ROIs are given in relative values F/F_0 , where F_0 is the fluorescence before stimulus or drug application. However, the conversion of ratio values into Ca^{2+} concentrations was approached by the following protocol. R_{\max} and R_{\min} were determined by exposing the AM-ester stained slice to 15 μM ionomycin either in the presence of

aCSF containing 10 mM Ca^{2+} (R_{\max}) or 0 mM Ca^{2+} and 10 mM EGTA (R_{\min}). Ionomycin is a Ca^{2+} ionophore leading to equalization of intra- and extracellular $[\text{Ca}^{2+}]$. Then, the equation given above was applied.

2.9 Analysis of calcium dynamics – the linear compartment model

Somatic Ca^{2+} dynamics of hypoglossal motoneurons can be analysed according to a linear one-compartment model that has been described previously (Neher & Augustine, 1992; Neher, 1995; Lips & Keller, 1998, 1999). In this model, a single “effective” extrusion rate γ is assumed, which is justified if somatic Ca^{2+} transients are described by a single exponential function. A second important parameter of the model is the “endogenous” Ca^{2+} buffering of the cell, which is quantified by the binding capacity κ_S . Both parameters can be determined by loading cells with a buffer with known buffering properties, i.e. the indicator dye fura-2. For a given concentration of the indicator dye, the corresponding “exogenous” binding capacity κ_B can be calculated from the equation

$$\kappa_B = [\text{fura}] * K_d / \{([\text{Ca}^{2+}]_{i, \text{rest}} + K_d)([\text{Ca}^{2+}]_{i, \text{peak}} + K_d)\}$$

where $[\text{Ca}^{2+}]_{i, \text{rest}}$, $[\text{Ca}^{2+}]_{i, \text{peak}}$ and K_d denote resting, peak calcium concentration and the dissociation constant of the indicator dye, respectively. The decay time constant (τ) of a given Ca^{2+} transient is then described by the equation $\tau = (\kappa_S + \kappa_B + 1) / \gamma$.

Previous studies have established $\kappa_S = 41 \pm 12$ for hypoglossal motoneurons (Lips & Keller, 1998). γ was calculated in the range of 131 s^{-1} to 35 s^{-1} for amplitudes between 60 nM and 476 nM, respectively (Lips & Keller, 1999).

2.10 Estimation of Ca^{2+} clearance rates using polynomial fits

Analysing Ca^{2+} dynamics according to the one-compartment model neglects non-linearities in Ca^{2+} clearance mechanisms. Therefore, for estimation of total and mitochondrial Ca^{2+} clearance rates, decay kinetics of Ca^{2+} transients were fitted with polynomial functions and further analysed as follows. 1) The decay of depolarisation-evoked Ca^{2+} transients before and after FCCP incubation was fitted over 25-30 s from the first point of decay on with a polynomial function of 12th order, yielding the

most accurate fit. 2) The numerical derivative ($d[\text{Ca}^{2+}]_i/dt$) was calculated from the fit. 3) $-d[\text{Ca}^{2+}]_i/dt$ was plotted as a function of the $[\text{Ca}^{2+}]_i$ values obtained from the fit. 4) Plots from transients with similar amplitudes were pooled ($n=3$ for control and FCCP) and described by a polynomial function of seventh order. 5) The resulting polynomial fits -one for each condition- were then plotted as a function of the transient amplitude. 6) Finally, the fit calculated from the FCCP data was subtracted from the fit calculated for the control condition yielding the mitochondrial clearance rate ($\mu\text{M/s}$) as a function of $\Delta[\text{Ca}^{2+}]_i$.

2.11 Monitoring of mitochondrial parameters

Mitochondrial membrane potential ($\Delta\psi$) was monitored using rhodamine 123 (rhod123). Rhod123 is a positively charged molecule and therefore accumulates within the negatively charged mitochondrial matrix, where its fluorescence is quenched. Upon depolarisation of $\Delta\psi$, rhod123 is released into the cytosol and its fluorescence increases. Because rhod123 is a non-ratiometric dye, fluorescence intensities are given in relative values F/F_0 . In patch-clamp experiments, rhod123 was added to the pipette solution at $10 \mu\text{g/ml}$ according to a method described by Schuchmann et al. (2000). In other experiments, the slice was incubated with $10 \mu\text{g/ml}$ rhod123 for 10 minutes followed by an intensive wash.

Mitochondrial metabolism (respiratory chain activity) was monitored by the intrinsic NADH fluorescence of motoneurons. NADH is the substrate for complex I of the mitochondrial respiratory chain (compare Fig. 1.4), therefore an increase in respiratory chain activity is represented by a decrease in the NADH fluorescence intensity and vice versa. NADH was excited at 360 and emitted fluorescence was collected using a dichroic mirror with mid-reflection at 425 nm.

2.12 Multiphoton imaging of intrinsic NADH fluorescence

In experiments performed at the Dept. of Applied & Engineering Physics, Cornell University, U.S.A. (head Prof. Dr. W. W. Webb), the intrinsic NADH fluorescence of MNs in the slice preparation was monitored using two-photon microscopy. This approach allowed for a higher spatial resolution of cellular structures in the slice as compared to CCD camera imaging. Also advantageous was the fact that two-photon

microscopy restricts the excitation volume to the focus level ($<1\mu\text{m}$), so that no background fluorescence occurs. In the experimental set-up used, the laser beam was provided by a titanium-saphir-laser system (Spectra Physics, Mountain View, CA, U.S.A.), directed into a Bio-Rad MRC-600 scanning box with laboratory-built detection systems mounted on an Olympus BX50 upright microscope equipped with infra-red compatible dipping objectives (40x NA0.8 or 60x NA 0.9). The fluorescence emitted was filtered by a BGG22 filter set (Chroma, Rockingham, VT, U.S.A.) and detected by a photomultiplier tube (Hamamatsu, Bridgewater, NJ, U.S.A.). For excitation of NADH, wavelengths in the range of 740-760 nm were employed. In time-series, dynamic changes were evaluated in defined ROIs using ImageJ software (NIH, Bethesda, MD, U.S.A.).

2.13 Cytochrome-oxidase histochemistry

Cytochrome-oxidase histochemistry allows assessment of the respiratory chain activity in fixed tissue, i.e. brain slices (Wong-Riley, 1989). Deeply anaesthetized mice were perfusion-fixed with warm (37°C) phosphate buffered saline pH 7.4 (PBS: 0.1 M Na_2HPO_4 , 0.1 M NaH_2PO_4 , 0.9% NaCl) followed by cold (4°C) PBS containing 4% paraformaldehyde and 4% sucrose. Brains were dissected and postfixed in 4% paraformaldehyde/4% sucrose in PBS for 4 hours at 4°C . Brains were transferred to 20% sucrose in PBS for 1-2 days (until brains sank). Brains were embedded in OCT freezing compound and shock-frozen (30 seconds) in chilled 2-methylbutane (isopentane), which was cooled down in liquid nitrogen. Frozen blocks were wrapped with aluminium foil and stored in a freezer (-80°C) for >10 minutes. The tissue block was then equilibrated in a cold cryostat cabinet and tissue sections were cut at $12\mu\text{m}$. Sections were mounted on plus-slides and incubated with sterile filtered cytochrome-oxidase histochemistry buffer (0.1 M PBS containing 25 mg DAB (3,3'-diaminobenzidine), 10 mg cytochrome c and 2 g sucrose per 50 ml) for 3-4 h in the dark. Sections were washed three times with cold 0.1 M PBS, air-dried and cover slipped. The dark reaction product is a measure of cytochrome-oxidase activity.

2.14 Materials

All calcium indicator dyes, as well as mitotracker green, were purchased from Molecular Probes (Leiden, Netherlands). Tetrodotoxin citrate (TTX), 6-cyano-7-nitroquinoxaline-2,3-dione disodium salt (CNQX) and D(-)-2-amino-5-phosphonopentanoic acid (AP-5) were purchased from Tocris (Bristol, U.K.), all other chemicals were from Sigma (St. Louis, MO, U.S.A.) or Merck (Darmstadt, Germany). Stock solutions were prepared as follows: fura-2 pentapotassium salt was dissolved in aqua_{dest} at 1-2 mM, fura-2 AM and fura-FF AM were dissolved in DMSO at 1 mM, rhod123 was dissolved in ethanol (10 mg/ml). Carbonyl cyanide 4-trifluoromethoxyphenylhydrazone (FCCP) was dissolved in ethanol at 10 mM. Sodium cyanide (CN) and sodium azide were dissolved in aqua_{dest} (2 M) and diluted to the final concentration immediately before the experiment.

2.15 Statistical analysis

If not indicated otherwise, values in the text are given as mean \pm standard error (SEM), error bars in figures represent SEM too. The significance after pharmacological intervention was calculated using student t-test. The significance of linear correlation coefficients (r_0) was determined by calculation of the probability $p(|r| \geq r_0)$ according to Taylor (1982).

3. RESULTS

3.1 Mitochondrial Ca^{2+} buffering in mouse hypoglossal motoneurons

In this section, the contribution of mitochondria to regulation of intracellular Ca^{2+} homeostasis in hypoglossal motoneurons (MNs) will be investigated.

3.1.1 Stimulation of Ca^{2+} transients in motoneurons loaded with fura-2/AM

The first aim of the study was to test the role of mitochondria as Ca^{2+} buffer in MNs under physiological conditions. For this purpose, a protocol was established, which allowed monitoring of intracellular Ca^{2+} transients in MNs in brain slices without washing out intracellular structures, as might occur during patch-clamp recordings. This was important since cytosolic dialysis could disrupt cytoskeletal elements that establish mitochondrial localisation within a cell. Additionally, previous experiments indicated that the pattern of Ca^{2+} response following a defined activation protocol may differ between patch-clamped and ester-loaded cells (unpublished observation). Therefore an experimental protocol was developed, where motoneurons in brain slices were loaded with the membrane-permeable dye fura-2/AM. Fig. 3.1.1 shows such fura-2/AM loaded hypoglossal neurons, where differences in fluorescent intensity are largely explained by different depths of cells within the slice.

Fig. 3.1.1: Illustration of a mouse brain stem slice containing the nucleus (Ncl.) hypoglossus. On the right, a CCD camera image (4x4 binning) showing hypoglossal MNs loaded with fura-2 AM (excitation at 390 nm). Antidromic activation of hypoglossal MNs in the slice was achieved by delivering short repetitive depolarising current pulses (single pulse 0.4-2 ms, 50-150 μA) at 40 Hz via a glass pipette placed along the axonal pathway of the hypoglossal nucleus. Pulse protocol is shown at lower right.

Besides the advantage of preventing “wash-out” of the cytosol by patch pipette dialysis, the protocol of AM-loading allowed me to utilize the specific anatomy of the system by selecting a cutting plane for brain stem slices that preserved a substantial fraction of the hypoglossal nerve. This permitted the selective activation of hypoglossal MNs by applying antidromic stimulation to their axons forming the hypoglossal nerve (Fig. 3.1.1). Furthermore, by using the previously established quantitative model of Ca^{2+} homeostasis (see Methods), it was possible to estimate the cytosolic fura-2 concentration in AM-loaded hypoglossal motoneurons without whole-cell recording. This was done by evaluating the recovery time constant τ of cytosolic Ca^{2+} transients after fitting with a single exponential function, which indicated cytosolic fura-2 concentrations in the range of 100 to 200 μM .

Fig. 3.1.2: Monitoring of $[\text{Ca}^{2+}]_i$ (360/390 nm fluorescence ratio) within a region of interest drawn over the soma of a fura-2/AM loaded hypoglossal MN in the slice. **A** Increasing numbers of depolarising pulses evoke $[\text{Ca}^{2+}]_i$ transients with increasing amplitudes. 0.1 fura-2 ratio unit corresponds to ~ 100 nM elevation of $[\text{Ca}^{2+}]_i$. **B** 50 stimuli were delivered at different stimulation frequencies. Note that the amplitude of $[\text{Ca}^{2+}]_i$ elevation is dependent on the stimulation frequency with highest elevation around 50 Hz. The arrow indicates onset of stimulation.

To establish reproducible recording conditions, first, control stimulation experiments were performed. Fig. 3.1.2 demonstrates that stimulation-evoked $[\text{Ca}^{2+}]_i$ elevations were strongly correlated with the number of stimulation pulses applied. Ca^{2+} responses increased rapidly from a resting level of ~ 0.1 μM and displayed many similarities with transients observed during rhythmic respiratory-related activity in an intact neuronal network (Ladewig & Keller, 2000). Maximum $[\text{Ca}^{2+}]_i$ elevations for 128 stimuli were calculated as ~ 300 nM. The amplitude of stimulation-evoked Ca^{2+} transients was also strongly correlated with the strength of current (20-200 μA) applied (not shown). $[\text{Ca}^{2+}]_i$ elevations were largest when choosing stimulation

frequencies around 50 Hz (Fig. 3.1.2 B), which is close to the maximum steady state firing rate of hypoglossal MNs. Such data suggested that fura-2/AM loaded slices represent a reliable tool to study Ca^{2+} dynamics in hypoglossal MNs.

3.1.2 Contribution of mitochondria to Ca^{2+} clearance

To test the contribution of mitochondria to clearance of stimulation-induced Ca^{2+} transients in hypoglossal MNs, the protonophore p-trifluoromethoxy-phenylhydrazone (FCCP) was applied. This drug dissipates the proton gradient across the inner mitochondrial membrane leading to depolarisation of the mitochondria potential ($\Delta\psi$). As Ca^{2+} uptake into mitochondria is thought to critically depend upon the potential gradient over the inner membrane, protonophores are considered to critically impair mitochondrial Ca^{2+} accumulation.

To see how FCCP acted in the slice preparation, $\Delta\psi$ of hypoglossal MNs was monitored in rhod123 stained slices and FCCP (1 μM) was added (Fig. 3.1.3). The experiment showed that it took at least 3 minutes until robust mitochondrial depolarisation was achieved, thus, in following experiments slices were exposed to FCCP for at least 4 minutes.

Fig 3.1.3: Monitoring of the mitochondrial potential ($\Delta\psi$) over the soma of a hypoglossal MN bath loaded with rhod123. Addition of FCCP (1 μM) increases rhod123 fluorescence (F/F_0) excited at 485 nm indicating depolarisation of $\Delta\psi$. Maximum depolarisation of $\Delta\psi$ is achieved ~4 minutes after onset of incubation with FCCP.

Then, $[\text{Ca}^{2+}]_i$ was monitored by the fura-2 360/390nm fluorescence ratio and a control stimulation was carried out to evoke a rise in $[\text{Ca}^{2+}]_i$ before FCCP were washed-in (Fig. 3.1.4 A). The strength of stimulation was always chosen to evoke $[\text{Ca}^{2+}]_i$ transients with amplitudes between 50 and 200 nM that resembled those observed in the rhythmic respiratory network (Lips & Keller, 1999; Ladewig & Keller, 2000). Oligomycin (5 $\mu\text{g/ml}$), a specific blocker of the mitochondrial F_1F_0 -ATP synthase, was added together with FCCP to prevent any accelerated consumption of cellular ATP by reverse mode operation of the ATP synthase (Budd & Nicholls, 1996; Babcock *et al.*, 1997; David *et al.*, 1998). Consistent with previous observations (Babcock *et al.*, 1997; Ladewig *et al.*, 2003), FCCP induced an increase in resting $[\text{Ca}^{2+}]_i$ of variable

size and duration apparently reflecting release of stored Ca^{2+} out of mitochondria. This effect was clearly attributable to FCCP, because oligomycin alone did not affect resting $[\text{Ca}^{2+}]_i$ levels within the first 10 minutes of application (Fig. 3.1.4 B).

Fig. 3.1.4: Imaging of cytosolic $[\text{Ca}^{2+}]_i$ (360/390 nm fluorescence ratio) in hypoglossal MNs loaded with fura-2/AM. Antidromic stimulation (\blacktriangle) induces cytosolic Ca^{2+} transients. **A** FCCP (1 μM) was added to depolarise mitochondria as indicated. Oligomycin (5 $\mu\text{g}/\text{ml}$) was added in addition to prevent accelerated ATP consumption. Note that FCCP reversibly increased resting $[\text{Ca}^{2+}]_i$ (**A**), as this was not seen when oligomycin (5 $\mu\text{g}/\text{ml}$) was added alone (**B**).

When voltage-dependent Ca^{2+} influx was then stimulated in the presence of FCCP and oligomycin, the decay time constant τ of stimulus-evoked $[\text{Ca}^{2+}]_i$ transients was prolonged to 1.92 ± 0.13 times the value obtained for control elevations with mean amplitudes of ~ 120 nM ($\tau = 2.38 \pm 0.26$ s before and 4.39 ± 0.42 s after addition of drugs; $p < 0.01$; $n = 17$; Fig. 3.1.5 A and C). Since application of oligomycin alone did not affect the recovery time ($\tau = 1.99 \pm 0.19$ s and 1.71 ± 0.09 s before and after addition of oligomycin alone; $p > 0.05$; $n = 8$; Fig 3.1.5 B and C), the effect of FCCP is clearly attributable to collapse of $\Delta\psi$, and not to inhibition of ATP-synthesis. The peak amplitude of Ca^{2+} transients was not significantly altered by FCCP (Fig. 3.1.5 D; relative change from 1 ± 0.11 to 1.16 ± 0.07 after addition of FCCP and oligomycin; $p > 0.05$) nor by oligomycin (relative change from 1 ± 0.12 to 1.15 ± 0.11 after addition of oligomycin alone; $p > 0.05$).

These results were almost undistinguishable from the data obtained on patch-clamped hypoglossal MNs in the same preparation using the same indicator dye,

where the protonophore FCCP prolonged the recovery time of Ca^{2+} transients 1.94 fold without significantly altering in the transient amplitude (Ladewig *et al.*, 2003).

Fig. 3.1.5: Stimulation-evoked $[\text{Ca}^{2+}]_i$ transients before and 10 min after addition of FCCP and oligomycin (**A**) and after addition of oligomycin alone (**B**). The black bars indicate duration of stimulation. Note the different acquisition rates of 10 Hz (**A**) and 3 Hz (**B**). **C**, **D** Graphical summary of the effect of FCCP and oligomycin on the decay time constant (τ) and amplitude ($\Delta[\text{Ca}^{2+}]_i$) of stimulation-induced Ca^{2+} transients. Note that neither the amplitude nor the decay of stimulation induced Ca^{2+} transients is significantly affected by oligomycin alone ($n=8$), whereas FCCP prolongs the recovery time of Ca^{2+} transients to 1.92 ± 0.13 fold the control value without altering the amplitude ($n=17$).

To better characterize mitochondrial Ca^{2+} handling, the time integral of stimulus-evoked $[\text{Ca}^{2+}]_i$ transients ($\Delta[\text{Ca}^{2+}]_i * \tau$) was also considered. Most important, increases in $[\text{Ca}^{2+}]_i$ integrals after FCCP application provide an estimate for the total amount of $[\text{Ca}^{2+}]_i$ that is buffered by mitochondria. In the experiments, these drugs led to a 2.27 ± 0.25 -fold increase in the $[\text{Ca}^{2+}]_i$ integral, indicating that ~50% of depolarisation-induced Ca^{2+} influx is taken up by mitochondria in the undisturbed cell, a value that can also be assumed for patch-clamped motoneurons.

3.1.3 Temperature dependence of mitochondrial Ca^{2+} buffering

In the next experiments, the temperature dependence of mitochondrial Ca^{2+} buffering was tested. So far, all studies investigating mitochondrial Ca^{2+} buffering in MN somata were performed at room temperature (Carriedo *et al.*, 2000; Ladewig *et al.*, 2003) thus neglecting the potential influence of temperature on mitochondrial mechanisms, which has i.e. been demonstrated by David & Barrett (David & Barrett, 2000).

Fig. 3.1.6: A Imaging of $[\text{Ca}^{2+}]_i$ by the 360/390 nm fluorescence ratio in a hypoglossal MN loaded with fura-2/AM. Ca^{2+} transients were elicited by antidromic stimulation (open bar) first at room temperature (19°C), then after increasing the bath temperature to 31°C. The temperature change reduced the decay time constant (τ) of stimulation-induced Ca^{2+} transients to 0.48 ± 0.07 control ($p < 0.01$, $n = 17$). **B** At near physiological temperatures (29-32°C), application of FCCP (1 μM) in the presence of oligomycin (5 $\mu\text{g}/\text{ml}$) prolonged the decay time constant (τ) of stimulation-induced Ca^{2+} transients to 1.81 ± 0.22 control ($p < 0.04$, $n = 11$). Thus, mitochondria buffer a similar fraction of Ca^{2+} load at near physiological temperatures compared to room temperature (compare to Fig. 3.1.5 A), but the rate of mitochondrial Ca^{2+} uptake was significantly speeded up at higher temperatures.

Stimulation-induced Ca^{2+} transients in fura-2/AM loaded hypoglossal MNs displayed significantly faster recovery times at 29-32°C compared to room temperature (19-21°C). This could be seen, when gradually increasing the temperature over a period of ~5 min and analysing stimulation-induced Ca^{2+} transients before and after

temperature change as demonstrated in Fig. 3.1.6 A (reduction of tau (τ) to 0.48 ± 0.07 control; $n=17$; $p<0.01$). At the same time, the amplitude of Ca^{2+} transients increased to 1.82 ± 0.19 fold control ($p<0.01$). Fig. 3.1.6 B illustrates the effect of mitochondrial depolarisation on stimulation-induced Ca^{2+} transients at 29-32°C. Comparable to the previous experiment at room temperature (Fig. 3.1.5 A), incubation with 1 μM FCCP together with oligomycin (5 $\mu\text{g}/\text{ml}$) for more than 4 minutes prolonged the recovery time of stimulation-induced Ca^{2+} transients to 1.81 ± 0.22 fold control ($p<0.04$; $n=11$), but had no significant effect on the transient amplitude. This indicated that the fraction of Ca^{2+} taken up by mitochondria near physiological temperatures does not significantly differ from the one at room temperature. However, as the recovery time of Ca^{2+} transients was more than doubled for a temperature increase of 10 °C, it was concluded that mitochondrial Ca^{2+} uptake must also have speeded up ~ 2 fold ($Q_{10}=2.1$) to yield the same relative contribution. Taken together, the results therefore support the assumption that mitochondrial Ca^{2+} uptake is highly temperature dependent in mouse hypoglossal MN somata.

3.1.4 Impact of mitochondrial Ca^{2+} buffering on voltage-activated Ca^{2+} currents

A surprising finding of this study and corresponding experiments on patch-clamped MNs (Ladewig *et al.*, 2003) was that inhibition of mitochondrial Ca^{2+} uptake prolonged the recovery time but did not significantly alter the amplitude of voltage-activated Ca^{2+} transients (Fig. 3.1.5). This was unexpected, because studies on cultured MNs and motor nerve terminals showed a large increase in the amplitude of Ca^{2+} transients as a result of mitochondrial inhibition (Carriedo *et al.*, 2000; David & Barrett, 2000). Therefore, the possibility was considered that FCCP by itself or the lack of mitochondrial Ca^{2+} buffering as a consequence of FCCP action might influence voltage-activated Ca^{2+} influx in a way similar to that described for chromaffin cells (Hernandez-Guijo *et al.*, 2001).

To test this issue, hypoglossal MNs were patch-clamped in the slice and Ca^{2+} currents were elicited by repetitive 200 ms depolarisations from -60 mV to 0 mV (every 20 s). Like it has been described in previous studies (Powers & Binder, 2003), different patterns of Ca^{2+} current activation – apparently with and without a contribution of dendritic channels – could be observed. Peak Ca^{2+} current amplitude

displayed a considerable run down over time (Fig. 3.1.7 A). Mitochondrial Ca^{2+} uptake was then inhibited by addition of 1 μM FCCP, but without significantly altering the course of current decline as compared to the control population (control population $n=7$; treated with FCCP $n=6$). FCCP did not significantly change the inactivation time constant (τ) of depolarisation-evoked Ca^{2+} currents either (Fig. 3.1.7 B). Ca^{2+} currents were recorded in the presence of FCCP over a period of 6-7 minutes, where robust mitochondrial depolarisation has to be expected (compare Fig. 3.1.3) and therefore any significant change in current amplitude or inactivation due to disturbed mitochondrial Ca^{2+} buffering would have been detected.

Fig. 3.1.7: A Whole cell Ca^{2+} currents were elicited in patch-clamped hypoglossal MNs by repetitive (every 20 s) step depolarisation from a holding potential of -60 mV. The inset shows a representative Ca^{2+} current and the pulse protocol. The graph plots relative peak currents (mean \pm standard deviation) of motoneurons under control conditions (open circles, $n=7$) or treated with FCCP (1 μM , filled circles, $n=6$). I_0 is the current at beginning of FCCP application. Note that FCCP does not significantly affect the decline of Ca^{2+} currents over time. **B** Inactivation time constants (τ) of Ca^{2+} currents (mean \pm standard deviation) of the same cell population analysed in A. FCCP was added at time point 0 (filled circles) with no significant effect on the course of Ca^{2+} current inactivation compared to control cells (open circles).

3.1.5 Impact of dye affinity

Next, the possibility was considered that the lacking effect of FCCP on the amplitude of Ca^{2+} transients was attributable to the low affinity indicator dye fura-2. This was conceivable since in those studies where FCCP dramatically increased the amplitude of Ca^{2+} transients, dyes with much lower affinity (fura-2FF and Oregon green BAPTA 5N) had been used.

To test this possibility slices were loaded with fura-FF ($K_d \sim 5.5 \mu\text{M}$), which displays a ~ 6 fold lower Ca^{2+} buffering capacity (κ_B) for $[\text{Ca}^{2+}]_i$ elevations below 500 nM compared to fura-2. AM-loading and stimulation of Ca^{2+} transients were performed as described for fura-2/AM. As expected, decay time constants (τ) of stimulation-induced Ca^{2+} transients were significantly faster when fura-FF was used ($\tau = 0.9 \pm 0.1$ s; $n=12$; mean amplitudes ~ 280 nM) compared to values for fura-2 ($\tau = 2.4 \pm 0.3$ s; $n=17$; $p<0.01$) and almost reached the value of 0.7 ± 0.2 s that was calculated for hypoglossal MNs under undisturbed conditions (Lips & Keller, 1998).

Fig. 3.1.8: Imaging of $[\text{Ca}^{2+}]_i$ (360/390 nm fluorescence ratio) in a hypoglossal MN loaded with fura-FF/AM. Ca^{2+} transients were elicited by antidromic stimulation (open bar). A change in the fura-FF ratio of 0.03 corresponds to a change in $[\text{Ca}^{2+}]_i$ of ~ 500 nM. Incubation with FCCP (1 μM) in the presence of oligomycin (5 $\mu\text{g}/\text{ml}$) for 4-8 min prolonged the recovery time of voltage-activated Ca^{2+} transients to 2 ± 0.36 fold control ($n=12$, $p=0.02$). The peak amplitude was increased to 1.33 ± 0.11 fold control ($p<0.05$). Note that this increase in amplitude was not seen when fura-2 was used as indicator dye (Fig. 3.1.5).

Fura-FF loaded MNs were then incubated with FCCP (1 μM) and oligomycin (5 $\mu\text{g/ml}$) for 6-8 min to depolarise mitochondria. As illustrated in Fig. 3.1.8, this prolonged the recovery time of voltage-activated Ca^{2+} transients to 1.9 ± 0.4 s, which corresponds to a 2.08 fold prolongation compared to the control value ($n=12$ cells, 7 slices, $p=0.02$). The magnitude of prolongation was comparable to the experiments using fura-2 (see Fig. 3.1.5). In contrast, the peak amplitudes of Ca^{2+} transients in fura-FF loaded cells were significantly increased to 1.33 ± 0.11 fold control after FCCP incubation ($p<0.05$), an effect that was not observed when fura-2 was employed. This indicated that the choice of the Ca^{2+} indicator dye and its affinity may influence evaluation of Ca^{2+} transient amplitudes and possible mechanisms for the observed phenomenon will be discussed below.

3.1.6 Quantification of mitochondrial Ca^{2+} clearance rate

To obtain more detailed information about mitochondrial Ca^{2+} handling in hypoglossal MNs, the attempt was made to quantify the rate of mitochondrial Ca^{2+} clearance in a way similar to previous studies (Herrington *et al.*, 1996; Fierro *et al.*, 1998). For maximal control of intracellular parameters, in particular the concentration of indicator dye, it was decided to evaluate clearance rates on patch clamped MNs, where Ca^{2+} transients were elicited by depolarisation to 0 mV from a holding potential of -60 mV. A CsCl based intracellular solution was chosen and 0.5 μM TTX, 10 mM TEA and 10 nM apamin were added to the CSF for simultaneous monitoring of Ca^{2+} currents. Although decay kinetics of voltage-activated Ca^{2+} transients up to 0.5 μM were appropriately described by single exponential functions, a more exact fitting was achieved using polynomial functions, indicating that clearance mechanisms are not entirely linear in the tested $[\text{Ca}^{2+}]_i$ range. Polynomial fitting was therefore applied for estimation of total and mitochondrial clearance rates.

Experiments were performed, where 3-4 depolarising voltage steps of increasing duration (50 – 950 ms) were applied every 40 s to obtain Ca^{2+} transients with increasing amplitudes. Mean resting $[\text{Ca}^{2+}]_i$ was measured as ~ 90 nM ($n=6$). Then, 1 μM FCCP was added to depolarise mitochondria and 4 minutes later, the voltage step protocol was repeated. At that time, resting $[\text{Ca}^{2+}]_i$ was slightly elevated by 39 ± 10 nM ($n=6$) compared to the control condition. For calculation of total and mitochondrial Ca^{2+} clearance rates, Ca^{2+} transients with amplitudes of 0.3-0.4 μM

before and after addition of FCCP were selected and the decay was fitted with a polynomial function of 12th order (Fig. 3.1.9 A). The polynomial fits were then used to calculate clearance rates as a function of $\Delta[\text{Ca}^{2+}]_i$ as described in the methods section. Finally, the rates of Ca^{2+} clearance were corrected for Ca^{2+} buffering by cytosol and added indicator dye (100 μM fura-2). This was done by multiplying with the binding ratio of the cytosol, $\kappa_S = 41$ (Lips & Keller, 1998), and the binding constant of fura-2, κ_B . The latter one was given by the equation

$$\kappa_B = [\text{fura}] * K_d / \{([\text{Ca}^{2+}]_{i, \text{rest}} + K_d)([\text{Ca}^{2+}]_{i, \text{peak}} + K_d)\}$$

assuming $K_{d, \text{fura-2}} = 0.22 \mu\text{M}$, $[\text{Ca}^{2+}]_{i, \text{rest}} = 0.1 \mu\text{M}$ and $[\text{Ca}^{2+}]_{i, \text{peak}} = (0.1 \mu\text{M} + \Delta[\text{Ca}^{2+}]_i)$. In Fig. 3.1.9 B, the buffer-corrected clearance rates as a function of $\Delta[\text{Ca}^{2+}]_i$ are displayed. The average clearance rate constant under undisturbed conditions (γ_{total}), which is represented by the slope of the control trace, is 152 s^{-1} ; the average mitochondrial clearance rate constant (γ_{mito}) is 70 s^{-1} .

Fig. 3.1.9: Quantification of total and mitochondrial Ca^{2+} clearance rates using polynomial fitting. **A** Ratiometric recording of $[\text{Ca}^{2+}]_i$ from a patch-clamped hypoglossal MN (indicator dye 100 μM fura-2) before and after addition of 1 μM FCCP. Ca^{2+} transients were evoked by depolarisation to 0 mV. The decay of Ca^{2+} transients is fitted with a polynomial function of 12th order. **B** The clearance rates obtained from the polynomial fit (average of 3 different cells) were corrected for Ca^{2+} buffering by cytosol and indicator dye and plotted as a function of the Ca^{2+} transient amplitude. The rate obtained from control depolarisations is a measure of the total Ca^{2+} clearance. The mitochondrial clearance rate was obtained by subtraction of the rate for the FCCP condition. Resting $[\text{Ca}^{2+}]_i$ was $\sim 100 \text{ nM}$.

3.1.7 Evaluation of mitochondrial activity and distribution

The high fraction of mitochondrial Ca^{2+} uptake during Ca^{2+} transients with amplitudes below 400 nM seemed surprising in light of the assumption that mitochondria are considered a low affinity Ca^{2+} uptake system (Xu *et al.*, 1997; Rizzuto *et al.*, 2000). Several arguments might help to overcome this apparent contradiction, including i) a high density of mitochondria in the cytosol correlating to a high level of mitochondrial activity and ii) a close proximity of mitochondria and Ca^{2+} influx sites. The first option was already indicated by a recent study, which evaluated the respiratory chain activity by cytochrome oxidase histochemistry in fixed rat brainstem slices (Liu & Wong-Riley, 2003). To confirm a high level of mitochondrial activity in hypoglossal MNs in our preparation, cytochrome oxidase histochemistry was performed using young NMRI mice (11-13 days old). 12 μm sections were incubated with cytochrome c reaction buffer for 3-4 hours and the dark reaction product was imaged using a digital camera. Fig. 3.1.10 shows a brainstem slice, where a variety of brainstem nuclei appear dark due to deposition of the reaction product. The hypoglossal nucleus is clearly one of the darker nuclei indicating a comparably high level of mitochondrial activity. The higher magnification reveals that the reaction product is found in the soma of hypoglossal MNs as well as in surrounding dendrites suggesting that mitochondria are present in both compartments. These findings were in good agreement with the study from Liu & Wong-Riley.

Fig. 3.1.10: Cytochrome oxidase histochemistry of fixed mouse brainstem slices. Deposition of the dark reaction product correlates with the level of mitochondrial activity. **Left**, 4x magnification, reconstruction of two single images. Brainstem nuclei are marked as follows: hypoglossal nucleus (XII), dorsal vagal nucleus (X), solitary tract nucleus (STN), spinal trigeminal nucleus (SpV), ambiguous nucleus (NA), inferior olive (IO). **Right**, the hypoglossal nucleus in 40x magnification. The arrows mark motoneuron somata. The dark reaction product is found in somata and dendrites.

To demonstrate a high level of mitochondrial activity also in the preparation that had been employed for physiological measurements, acute slices from neonatal mice were stained with 10 $\mu\text{g/ml}$ rhodamine 123 (rhod123), which accumulates in respiring mitochondria, where its fluorescence is quenched (Fig. 3.1.11 *A*). After a wash-out period, mitochondria were depolarised with 1 μM carbonyl cyanide 3-chlorophenylhydrazone (CCCP) releasing rhod123 into the cytosol (Fig. 3.1.11 *B*). The intensity of rhod123 fluorescence after mitochondrial depolarisation should give an estimate of the amount of rhod123 that had been taken up previously. As shown in Fig. 3.1.11 *C*, the hypoglossal nucleus was characterized by a bright rhod123 fluorescence after CCCP incubation as compared to the surrounding areas. This indicated a high level of mitochondrial activity of hypoglossal MNs also in the acute slice preparation.

Fig. 3.1.11: CCD camera images of rhodamine 123 (rhod123) stained acute mouse brainstem slices. **A** Rhod123 stained cells in the hypoglossal nucleus, where the dye is mainly trapped within the mitochondria. **B** After incubation with 1 μM CCCP, rhod123 is released into the cytosol. **C** The hypoglossal nucleus (paramedian below the IVth ventricle) is characterized by a bright rhod123 fluorescence indicating that mitochondria had taken up a considerable amount of rhod123 before depolarisation. Scale bar: 100 μm .

Finally, to obtain more information about the distribution of mitochondria within MNs, acute slices were stained with the mitochondrial-specific dye mitotracker green and the fluorescence pattern was imaged using confocal laser scanning microscopy. As shown in Fig. 3.1.12, the mitochondrial network extends from the soma into the

dendrites. Although the spatial resolution limits statements about the localisation of mitochondrial clusters to the μm range, it appears that part of the mitochondria are found in close proximity to the cell membrane.

Fig. 3.1.12: Confocal laser scan images of hypoglossal MNs within acute mouse brain slices. Mitochondria are labelled with mitotracker green (green). On the right, cytosol and nucleus are additionally stained with fura-red (red). Scale bars: 10 μm .

3.2 Impact of mitochondrial dysfunction (CN) on motoneuron membrane properties

In the following sections (3.2 and 3.3), the functional impact of an impaired mitochondrial metabolism on electrical properties and intracellular Ca^{2+} homeostasis of hypoglossal motoneurons is described. Mitochondrial function was disturbed by bath application of 1-2 mM sodium cyanide (CN), which inhibits complex IV of the mitochondrial electron transport chain. This protocol was chosen for several reasons, i) in ALS, a notable decrease in complex IV activity has been observed (Menzies *et al.*, 2002a; Wiedemann *et al.*, 2002), ii) it is considered to be a valid model for hypoxia (“chemical hypoxia”). Additionally, CN action has been described as quick and reversible (Nowicky & Duchon, 1998; Kawai *et al.*, 1999; Müller *et al.*, 2002).

3.2.1 Impact of CN on rhythmic motor activity

First, the impact of CN on hypoglossal motoneurons integrated in a functionally intact network was investigated. For this purpose, rhythmic motor activity was recorded from hypoglossal rootlets in the thick slice preparation (see Methods section 2.3) and CN was added.

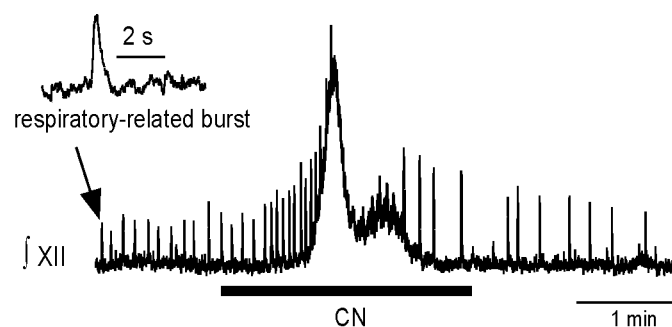

Fig. 3.2.1: Integrated recording of rhythmic respiratory-related activity from hypoglossal (XII) rootlets. Bath application of cyanide (CN, 1 mM) increases frequency and amplitude of rhythmic bursts and enhances tonic activity, indicating increased activity of hypoglossal motoneurons during CN treatment.

Fig. 3.2.1 shows integrated rhythmic activity recorded from hypoglossal (XII) rootlets. Within 1 min, bath application of 1 mM CN increased the frequency of rhythmic bursts and increased the burst amplitude to 2.3 ± 0.3 control ($n=5$). In the majority of cases (4 out of 5), this was followed by a transient tonic activation of the XII nerve seen as an upward shift in the baseline of the integrated XII trace, which lasted for 1-2 min. Whereas rhythmic activity characteristically turned into a frequency depression during CN application, burst amplitudes remained elevated during CN action. Wash-out of

CN resulted in normalization of burst amplitudes and slow (5-10 min) recovery of burst frequency. Because it is generally agreed that the amplitude of rhythmic bursts reflects the activity of hypoglossal MNs, these findings suggest that hypoglossal MNs respond to CN with a substantial increase in activity. It is interesting to note that the respiratory network response described here shares the same characteristics as described for deprivation of oxygen (Ramirez *et al.*, 1997).

3.2.2 Impact of CN on electrical properties of hypoglossal MNs

After having defined the impact of impaired mitochondrial metabolism on MN network activity, CN-induced changes were investigated on the cellular level. For this purpose, whole cell patch-clamp recordings on hypoglossal MNs in the brain slice were performed. In current clamp mode, hypoglossal MNs displayed a resting membrane potential (V_m) of -62.1 ± 1 mV ($n=12$). Approximately 30% of the cells showed spontaneous spike discharge with a mean discharge frequency assessed within 1 minute before drug application of 0.27 ± 0.19 Hz. Upon addition of 2 mM CN, hypoglossal MNs depolarised by 10.2 ± 1.1 mV ($n=9$) within 15 s (Fig. 3.2.2 A) and mean discharge frequencies increased to 0.46 ± 0.2 Hz ($p<0.01$). CN also increased synaptic activity as exemplified i.e. in Fig. 3.3.1 A. After washout of CN, potential changes reversed within 1 minute, whereas synaptic and action potential activity returned to baseline levels within 3 minutes.

To investigate the relative contribution of synaptic activity and firing rates, CN applications were performed in the presence of synaptic blockers (10 μ M CNQX, 100 μ M APV, 10 μ M bicuculline and 10 μ M strychnine) and/or TTX (Fig. 3.2.2 B, C). When postsynaptic receptors were blocked, hypoglossal MNs displayed a mean resting V_m of -63.3 ± 1.6 mV ($n=12$) and a CN-induced depolarisation of 13.8 ± 3 mV ($n=11$), which was comparable to control responses ($p>0.05$). When 0.5 μ M TTX was added alone or in addition to synaptic blockers, CN-induced depolarisations were again comparable to control (11.3 ± 1.7 mV, $n=7$; 13.3 ± 2 mV, $n=6$; $p>0.05$), indicating that they primarily resulted from intrinsic membrane conductances.

Fig. 3.2.2: **A** Membrane potential (V_m) recorded from a patch-clamped hypoglossal MN in acute mouse brainstem slice. Bath application of CN (2 mM) quickly induces MN depolarisation and enhances synaptic activity, leading to spontaneous action potential generation. Wash out of CN repolarises membrane potential and reduces synaptic activity over 1-2 minutes, finally action potential activity stops. **B**, **C** The depolarising response of hypoglossal MNs to CN persists in the presence of TTX (0.5 μ M) and/or during blockade of postsynaptic receptors with (in μ M) 10 CNQX, 100 APV, 10 bicuculline and 10 strychnine, indicating that membrane depolarisation was mediated by changes in MN membrane properties and not by changes in synaptic transmission or glutamate release.

3.2.3 Differential response of vulnerable and resistant neurons to CN

In order to test whether the increased neuronal excitability of hypoglossal MNs during CN action was a feature attributable to MNs or if this might represent a general cellular response in our preparation, we performed complementary recordings from vulnerable facial (VII) MNs and neurons of the nucleus dorsalis vagus (X), which is located directly dorsal of the hypoglossal nucleus and which is typically tolerant to hypoxia and resistant to damage in ALS.

Fig. 3.2.3: **A** Membrane potential (V_m) recorded from a patch-clamped MN in the facial nucleus (VII). Bath application of CN (2 mM) depolarises facial MNs by 7 ± 1 mV ($n=7$) with repolarisation after wash-out of CN. **B** V_m recorded from a patch-clamped neuron in the nucleus dorsalis vagus (X). Addition of CN (2 mM) reversibly hyperpolarizes the vagal neuron by 7.5 ± 0.9 mV ($n=4$) and reduces spontaneous spike discharge. **C** Comparison of the CN-induced V_m change in vulnerable MNs (hypoglossal and facial) and resistant vagal neurons. (Intracellular solution contained 100 μ M fura-2.)

In current clamp mode, facial MNs displayed a resting V_m of -61.7 ± 1.7 mV ($n=7$). Similar to hypoglossal MNs, addition of CN reversibly depolarised facial MNs by 7 ± 1 mV ($n=7$; Fig. 3.2.3 A). In contrast, vagal neurons showed a resting membrane potential around -41 mV and displayed tonic spike discharge at frequencies of 3-4 Hz (Fig. 3.2.3 B). CN hyperpolarized vagal neurons by 7.5 ± 0.9 mV ($n=4$) and reduced action potential firing, which was consistent with previous studies showing that CN activates hyperpolarizing ATP-sensitive K^+ channels (Kulik *et al.*, 2002; Müller *et al.*, 2002). Taken together, these experiments indicated that the CN-induced increase in electrical excitability was specific for vulnerable MNs.

3.2.4 CN-induced inward currents (I_{CN})

Membrane conductances in hypoglossal MNs were further investigated in voltage clamp mode, where bath application of 2 mM CN activated an inward current $I_{CN} = -51 \pm 9$ pA ($n=8$, holding potential -60 mV). Its magnitude was relatively constant in a voltage range of -80 to -40 mV as revealed by voltage ramp protocols (20 mV/100 ms, not shown). To identify the underlying charge carrier, I_{CN} was investigated under different ionic and pharmacological conditions (Fig. 3.2.4). At first, the potential contribution of persistent, TTX-sensitive Na^+ channels was studied, which have recently been described in hypoglossal MNs (Powers & Binder, 2003). In agreement with the current clamp data (compare Fig. 3.2.2), TTX did not significantly alter I_{CN} (-56 ± 13 pA, $n=7$, $p>0.05$). A contribution of K^+ conductances was probed by blocking K^+ currents with tetraethylammonium chloride (TEA, 20 mM internal and 10 mM external) and replacing K^+ by caesium in the pipette, without any significant effect ($I_{CN} = -62 \pm 15$ pA, $n=10$, $p>0.05$). Blockade of Ca^{2+} currents by the non-selective Ca^{2+} channel blocker $CdCl_2$ (200 μ M) also did not significantly change I_{CN} (-46 ± 8 pA, $n=4$, $p>0.05$). The observation that Ca^{2+} was not the main charge carrier was additionally confirmed by experiments in current clamp mode, where removal of Ca^{2+} from the extracellular solution (Ca^{2+} free aCSF containing 1 mM EGTA; $n=3$) did not influence CN-induced depolarisations (Fig. 3.2.4 B).

Fig. 3.2.4: The magnitude of inward current (I_{CN} , voltage clamp, HP -60 or -70 mV) or membrane depolarisation (current clamp) induced by 2 mM CN is compared under different experimental conditions. **A** No significant difference in the amplitude of I_{CN} is found when TTX is present in the aCSF compared to the control condition (control: -51 ± 9 pA, $n=8$; TTX: -56 ± 13 pA, $n=7$). Also blockade of potassium currents with TEA and replacement of intracellular potassium by caesium does not significantly alter I_{CN} as compared to the control condition (TTX, TEA, CsCl: -62 ± 15 pA, $n=10$), nor did additional wash-in of cadmium to block Ca²⁺ conductances (TTX, TEA, CsCl, CdCl₂: -46 ± 8 pA, $n=4$). **B** CN depolarises V_m even when Ca²⁺ is completely removed from the extracellular solution (containing 1 mM EGTA), further indicating that Ca²⁺ is not the charge carrier of I_{CN} . **C** Reducing the extracellular Na⁺ concentration from 144 to 26 mM decreases I_{CN} to 40 ± 13 % of the control value (I_{CN} control: 45 ± 9 pA, low Na⁺: 18 ± 9 , $p < 0.05$, $n=4$), re-addition of Na⁺ increased I_{CN} back to 76 ± 10 %, indicating that Na⁺ is the main charge carrier of I_{CN} at the given membrane potential. (A-B, intracellular solution contained 100 μ M fura-2)

Interestingly, I_{CN} reversed around 50 mV after blockade of K⁺, Ca²⁺ and TTX-sensitive Na⁺ channels. Since the reversal potential for chloride (Cl⁻) was chosen ~ 0 mV, TTX-insensitive Na⁺ conductances were identified as a potential charge carrier. To evaluate this, we changed the extracellular Na⁺ concentration from 144 mM to 26 mM (replacement of NaCl by choline chloride), which reduced I_{CN} to 40 ± 13 % of control (I_{CN} control: 45 ± 9 pA, low Na⁺: 18 ± 9 pA, $p < 0.05$, $n=4$; Fig. 3.2.4 C). Re-addition of Na⁺ to the perfusion solution substantially increased I_{CN} (76 ± 10 % of control). Taken together, these experiments identify TTX-insensitive Na⁺ conductances as prominent charge carriers of I_{CN} in hypoglossal motoneurons.

Coming back to the CN-induced change in membrane conductance in vagal neurons, it was possible that the pronounced activation of K^+ conductances in these cells covered an activation of smaller inward currents. Therefore, in vagal neurons, a potential activation of inward currents by CN was tested, when K^+ was replaced by caesium in the pipette solution and K^+ channels were additionally blocked with 10 mM TEA in the bath solution. Cells were held between -40 and -50 mV and 2 mM CN was applied for 1-3 minutes. This hardly affected membrane currents (maximum observed inward current: 6 pA, not shown) indicating that vagal neurons do not possess CN-sensitive inward currents.

3.2.5 Activation profile of I_{CN}

An interesting question was related to the cellular mechanisms that mediated the fast onset of I_{CN} . As the primary cellular target of CN is the mitochondrial respiratory chain, CN application is expected to block complex IV and collapse the potential gradient ($\Delta\psi$) across the inner mitochondrial membrane. Inhibition of complex IV is further thought to increase the concentrations of physiological electron donors NADH and $FADH_2$.

I_{CN} in relation to NADH and mitochondrial potential ($\Delta\psi$)

The intrinsic fluorescence of NADH allows mitochondrial metabolism to be indirectly monitored in the slice without addition of fluorescent dyes. In experiments performed at the Dept. of Applied & Engineering Physics at Cornell University, two-photon excitation was used to characterize the NADH fluorescence in the hypoglossal nucleus. The hypoglossal nucleus was easily recognized by a high level of intrinsic fluorescence in both motoneurons and astrocytes (Fig. 3.2.5 A). To prove NADH fluorescence as an indicator of mitochondrial metabolism, control experiments were performed, in which respiratory chain activity was inhibited by hypoxia (Fig. 3.2.5 B) or CN (1 mM; Fig. 3.2.5 C). Both protocols reversibly enhanced the intrinsic NADH fluorescence in both neurons and astrocytes. This observation confirmed the use of NADH imaging for assessment of mitochondrial metabolism.

Fig. 3.2.5: Two-photon imaging of intrinsic NADH fluorescence in acute mouse brainstem slices. **A** The hypoglossal nucleus is characterized by a bright NADH fluorescence both in motoneurons (MNs) and astrocytes (arrows). **B** Inhibition of the respiratory chain by hypoxia reversibly increases NADH fluorescence both in motoneurons (n=12) and astrocytes (n=3). **C** A similar effect is observed during mitochondrial inhibition with 1 mM CN (8 MNs, 5 astrocytes).

In further experiments performed in Göttingen, the CN-induced changes in NADH were monitored in parallel to changes in $\Delta\psi$ and V_m in patch-clamped hypoglossal MNs by using CCD camera imaging (rhod123 as indicator of $\Delta\psi$; Fig. 3.2.6 A). Addition of 2 mM CN to the bathing solution increased rhod123 fluorescence as well as NADH autofluorescence with a delay after onset of depolarisation of 3 ± 2.2 s (rhod123, $n=6$) and 6.3 ± 1.5 s (NADH, $n=8$). To test whether the onset of I_{CN} was dependent on depolarisation of $\Delta\psi$, the mitochondrial uncoupler p-trifluoromethoxy-phenylhydrazone (FCCP; 1 μ M) was added. FCCP shunts the proton gradient over the inner mitochondrial membrane, thus depolarising mitochondria while respiratory chain activity continues. As expected, FCCP increased rhod123 fluorescence, but left NADH-autofluorescence essentially unaffected. FCCP also failed to induce changes in V_m (V_m change during FCCP: 1 ± 2 mV, $n=6$, $p<0.01$, Fig. 3.2.6 B) and did not induce inward currents in voltage clamp mode (-60 mV; $n=3$), indicating that activation of I_{CN} was independent of $\Delta\psi$ depolarisation.

Fig. 3.2.6: **A** CCD camera imaging of intrinsic NADH fluorescence and mitochondrial potential ($\Delta\psi$) using rhod123 in a patch-clamped hypoglossal MN. Both CN (2 mM) and FCCP (1 μ M) depolarise mitochondria, but FCCP does not increase NADH. FCCP also fails to increase V_m indicating that CN-induced MN depolarisation is independent of mitochondrial depolarisation. **B** Comparison of CN and FCCP induced changes in V_m .

I_{CN} mimicked by azide

It was then tested whether activation of I_{CN} could be reproduced by other substances that interfere with the mitochondrial respiratory chain. Whereas the complex I inhibitor rotenone (25-50 μ M, $n=3$) failed to alter V_m within 5 minutes (Fig. 3.2.7 A), the complex IV inhibitor, sodium azide (2 mM) depolarised the plasma membrane by 7.1 ± 1 mV and increased AP discharge similarly to CN ($n=9$; Fig. 3.2.7 B). These

findings suggested that the mechanism that mediated activation of I_{CN} was located downstream of complex IV.

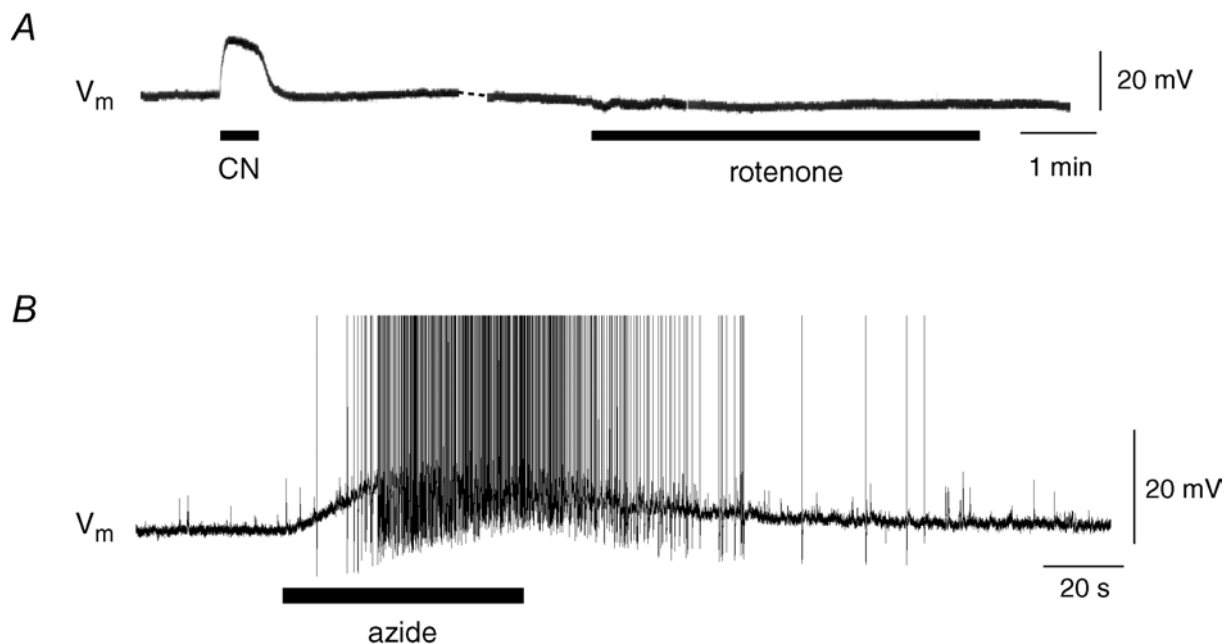

Fig. 3.2.7: Whole-cell current clamp recordings from hypoglossal MNs. **A**, The complex I inhibitor rotenone fails to alter V_m , whereas **(B)** the complex IV inhibitor sodium azide (2 mM) mimics the CN-induced depolarisation and increases action potential discharge (APs were truncated). In **A**, blockers of postsynaptic receptors (CNQX, AP-5, bicuculline, strychnine) were present in the aCSF.

Effect of antioxidants on I_{CN}

The next possibility considered was that inhibition of complex IV may increase the formation of superoxide (O_2^-) by transfer of electrons to oxygen at the semiubiquinone site of the respiratory chain. Superoxide and related reactive oxygen species (ROS) may act as signaling molecules by shifting redox pairs to the oxidized state (Lopez-Barneo *et al.*, 2001). The potential involvement of ROS in mediating I_{CN} was tested by the ability of the antioxidants and ROS scavengers ascorbic acid and trolox[®] to interfere with the induction of I_{CN} . Brain slices were pre-incubated with 1 mM ascorbic acid and 750 μ M trolox[®], a derivative of α -tocopherol (vitamin E), for 30-50 min, and the drugs were also present during the following CN exposure (2 mM for 50-60 s). The drug concentrations used were shown to be effective in previous studies *in vitro* (Vergun *et al.*, 2001; MacGregor *et al.*, 2003). Pre-incubation with ascorbic acid and trolox[®] reduced the mean amplitude of I_{CN} to 40 % (-22 ± 6 pA,

n=8) of the value that had been found under control conditions ($p < 0.01$; Fig 3.2.8). In two of the eight cells tested, I_{CN} was totally abolished.

Taken together, the experiments suggested that an increase in the formation of ROS following complex IV inhibition was involved in the activation of I_{CN} .

Fig. 3.2.8: **A** Whole-cell voltage clamp recording from a hypoglossal MN. The antioxidants ascorbic acid (1 mM) and trolox (750 μ M) prevent induction of the inward current by CN. **B** In summary, ascorbic acid and trolox reduce I_{CN} to 40 % (-22 ± 6 pA) of the value that was found under control conditions ($p < 0.01$, $n=8$), indicating that a redox mechanisms was involved in activation of I_{CN} , possibly due to an increased production of reactive oxygen species (ROS).

3.3 Impact of mitochondrial dysfunction (CN) on motoneuron Ca^{2+} levels

3.3.1 Impact of CN on resting $[\text{Ca}^{2+}]_i$

To investigate the impact of impaired mitochondrial metabolism on motoneuron $[\text{Ca}^{2+}]_i$, electrophysiological recordings were combined with calcium imaging measurements. The patch-clamp attempt was justified as there was no apparent difference in mitochondrial Ca^{2+} handling between patch-clamped and AM-ester loaded cells, but it provided additional information about the electrical properties of hypoglossal MNs.

Fig 3.3.1: **A** Simultaneous recording of membrane potential (V_m) and $[\text{Ca}^{2+}]_i$ in a patch-clamped hypoglossal MN. Action potential activity was blocked with $0.5 \mu\text{M}$ TTX. Bath application of CN (2 mM) first depolarised V_m and then increased resting $[\text{Ca}^{2+}]_i$ with a delay of $\sim 18 \text{ s}$ both in the soma and primary dendrites (**B**, **C**). After wash-out of CN, $[\text{Ca}^{2+}]_i$ slowly returned to baseline.

In current clamp, short (45-60 s) applications of CN increased basal $[\text{Ca}^{2+}]_i$ by two different mechanisms. First, a small increase in $[\text{Ca}^{2+}]_i$ independent of action potential (AP) generation or synaptic activity was observed (Fig. 3.3.1 A-C). This augmentation, most likely mediated by mitochondria-controlled Ca^{2+} release from intracellular stores (see below), started $19 \pm 3 \text{ s}$ ($n=7$) after wash-in of CN and

displayed amplitudes ranging from 10 to 50 nM, which decreased upon repetitive CN exposure.

Fig. 3.3.2: **A** Monitoring of membrane potential (V_m) and $[Ca^{2+}]_i$ without TTX. The CN-evoked depolarisation enhances action potential (AP) discharge, which elevates $[Ca^{2+}]_i$; independently of the slow elevation described in the previous figure (arrow; APs were truncated). **B** The potential impact of CN-induced depolarisations on $[Ca^{2+}]_i$ was investigated in experiments, where AP firing was elicited by increasing current injection over a defined time interval (5 s) and corresponding $[Ca^{2+}]_i$ changes were assessed ($n=9$). The AP frequency / V_m relation (left) could be approximated by a sigmoid; $[Ca^{2+}]_i$ changes in response to AP firing were well described by a linear function (right, correlation coefficient 0.86). The plots indicate that i) the MN resting membrane potential is a critical determinant for I_{CN} -induced increases in AP firing rates and subsequent Ca^{2+} influx, and ii) I_{CN} -induced depolarisations can account for basal Ca^{2+} elevations of ~100 nM, provided that resting membrane potential of cells is in the appropriate voltage range. (Intracellular solutions contained 100 μM fura-2)

A second source of CN-dependent Ca^{2+} elevation was apparent when I_{CN} -mediated depolarisations evoked a series of action potentials (APs) as exemplified in Fig. 3.2.2 A. In this case, activation of voltage-dependent Ca^{2+} channels elevated cytosolic Ca^{2+} levels as previously investigated in great detail (Lips & Keller, 1999). To evaluate the impact of I_{CN} in a more systematic way, a series of depolarisations in

current clamp mode (5 s) was performed and AP firing rates and corresponding changes in somatic $[Ca^{2+}]_i$ were recorded ($n=9$). As indicated in Fig. 3.3.2 *B* (left), AP firing was strongly dependent on V_m and characteristic depolarisations of 10.2 ± 1.1 mV mediated by I_{CN} corresponded to increases in AP firing rates from 4 Hz to 16 Hz in the voltage interval -50 mV to -40 mV (dashed lines). Correspondingly, these firing rates were associated with $[Ca^{2+}]_i$ elevations of ~ 100 nM as illustrated in Fig. 3.3.2 *B* (right). In summary, these observations illustrate that i) the MN resting membrane potential is a critical determinant for I_{CN} -induced increases in AP firing rates and subsequent Ca^{2+} influx, and ii) I_{CN} -induced depolarisations can account for basal Ca^{2+} elevations of 100 nM, provided that resting membrane potential of cells is in the appropriate voltage range.

3.3.2 CN releases Ca^{2+} from mitochondria-controlled store

In subsequent experiments, we investigated the action potential-independent increase in $[Ca^{2+}]_i$ in more detail. When HMs were held in voltage clamp (-60 or -70 mV) in the presence of $0.5 \mu\text{M}$ TTX, CN (2 mM for 45 - 70 s) produced a delayed rise in $[Ca^{2+}]_i$ of 36 ± 8 nM ($n=10$) that was comparable to the $[Ca^{2+}]_i$ elevation observed under current clamp. Removal of Ca^{2+} from the extracellular solution did not prevent the increase in $[Ca^{2+}]_i$ ($n=6$, Fig. 3.3.3 *A*), indicating that Ca^{2+} was released from intracellular stores.

Fig. 3.3.3: **A** Monitoring of $[Ca^{2+}]_i$ using fura-2 ($100 \mu\text{M}$) in voltage-clamped hypoglossal MNs (HP -60 or -70 mV). The asterisks marks a somatic Ca^{2+} transient produced by depolarisation to $+10$ mV (500 ms). During incubation with nominally Ca^{2+} free CSF (open bar), CN application (2 mM) increases resting $[Ca^{2+}]_i$, indicating that Ca^{2+} is released from intracellular stores. **B** The magnitude of CN-induced Ca^{2+} release reflects the previous history of intracellular Ca^{2+} activity, which was determined by the average $[Ca^{2+}]_i$ ($\langle [Ca^{2+}]_i \rangle$) within 5 minutes before CN addition ($n=5$, correlation coefficient 0.96 ; $p < 0.05$, see Methods). Variations in $\langle [Ca^{2+}]_i \rangle$ were given by differential resting Ca^{2+} levels in the whole-cell configuration and a variable number (0 to 3) of depolarisations to 0 mV (500 ms) within the indicated time interval.

As shown in Fig. 3.3.3 *B*, the amount of releasable Ca^{2+} depended on the average $[\text{Ca}^{2+}]_i$ before CN addition with a statistically significant correlation coefficient $r_0 = 0.96$ (probability $p(|r| \geq r_0) < 0.05$, see also Methods). The average $[\text{Ca}^{2+}]_i$ before CN addition was assessed within a time interval of 5 minutes from 5 different cells, where variations in $\langle [\text{Ca}^{2+}]_i \rangle$ were given by differential resting Ca^{2+} levels in the whole-cell configuration and a variable number (0 to 3) of depolarisations to 0 mV (500 ms) within the indicated time interval. Taken together, these experiments suggested that the CN-sensitive store takes up Ca^{2+} during $[\text{Ca}^{2+}]_i$ elevations and releases it during subsequent CN action.

Then, I_m and $[\text{Ca}^{2+}]_i$ of the patch-clamped cell were monitored together with NADH autofluorescence of neighbouring MNs. A series of experiments indicated that changes in NADH autofluorescence during CN exposure are extremely synchronous among MNs in the same area so that neighbouring MNs can be considered representative for the patch-clamped cell regarding this particular parameter. Recording of $[\text{Ca}^{2+}]_i$ and NADH fluorescence in the same cell was not possible due to the overlapping spectra of fura-2 and NADH. This experiment revealed that the CN-induced release of Ca^{2+} followed the dynamics of mitochondrial metabolism very closely (Fig 3.3.4 *A*); the rise in $[\text{Ca}^{2+}]_i$ followed the rise in NADH fluorescence with a constant temporal interval of 4 ± 1 s ($n=12$). As the CN-induced accumulation of NADH is paralleled by depolarisation of $\Delta\psi$ (Fig. 3.2.6 *A*), the experiment suggested that CN released Ca^{2+} dependent on mitochondrial metabolism and $\Delta\psi$. This assumption was further confirmed by experiments where pre-incubation with the mitochondrial uncoupler carbonyl cyanide 4-trifluoro-methoxyphenylhydrazone (FCCP, 2 μM), which destroys $\Delta\psi$ and depletes the mitochondrial Ca^{2+} content, prevented the $[\text{Ca}^{2+}]_i$ elevation during subsequent CN action ($n=2$, Fig. 3.3.4 *B*).

Fig. 3.3.4 **A** Simultaneous monitoring of membrane current (I_m), $[Ca^{2+}]_i$ and mitochondrial metabolism (NADH autofluorescence). Application of CN (2 mM) raises $[Ca^{2+}]_i$ with kinetics that closely follow the changes in mitochondrial metabolism, suggesting that the Ca^{2+} was released from mitochondria-controlled stores. **B** FCCP (2 μ M) was applied to destroy $\Delta\psi$ and to deplete mitochondrial Ca^{2+} content. Subsequent addition of CN does not change $[Ca^{2+}]_i$, confirming that the CN-induced Ca^{2+} release was dependent on $\Delta\psi$. **C** Slices were incubated with CPA to inhibit the ER Ca^{2+} -ATPase and to deplete ER Ca^{2+} content (CPA incubation started \sim 25 s before onset of imaging). Voltage-induced Ca^{2+} transients were applied to fill mitochondrial stores (asterisks). Subsequent CN application raises $[Ca^{2+}]_i$, similar to the situation without CPA, indicating that the CN-sensitive Ca^{2+} store was most likely represented by the mitochondria and not the ER.

However, in previous work it has been shown that both mitochondria and endoplasmic reticulum (ER) act as important Ca^{2+} buffers in hypoglossal MNs and that release from both stores is closely linked to $\Delta\psi$ (Ladewig *et al.*, 2003). The observed CN-induced Ca^{2+} release could therefore originate from both stores. To test a contribution of the ER, the ER Ca^{2+} -ATPase was inhibited with 50 μ M cyclopiazonic acid (CPA) for at least 5 minutes, which released Ca^{2+} from the ER due to leakage of the ER membrane (Fig. 3.3.4 C). Control experiments showed that caffeine, which usually produces large Ca^{2+} elevations in hypoglossal MNs (Ladewig *et al.*, 2003), did not invoke a rise in Ca^{2+} , when CPA incubation preceded its action, indicating that CPA largely depleted the ER Ca^{2+} content (not shown). When CN was then added after CPA pre-incubation, it still produced an increase in $[Ca^{2+}]_i$ of 26 ± 5 nM ($n=6$). Since the amount of Ca^{2+} release strongly depended on preceding cytosolic Ca^{2+} activity, it was difficult to compare this value with the control condition. However, these observations strongly suggest that the CN-sensitive store, from which Ca^{2+} may be eventually released, is represented by the mitochondria.

3.3.3 Impact of CN on activity-dependent Ca^{2+} elevations

As has been shown previously, hypoglossal MNs display repetitive elevations in $[\text{Ca}^{2+}]_i$, which are linked to rhythmic respiratory activity and mainly result from the opening of voltage-activated Ca^{2+} channels (Lips & Keller, 1999; Ladewig & Keller, 2000). A fast clearance of these repetitive elevations in $[\text{Ca}^{2+}]_i$ is essential to maintain a low resting $[\text{Ca}^{2+}]_i$, particularly considering the low Ca^{2+} buffering capacity of hypoglossal MNs. As it is described in the first section of this work, mitochondrial Ca^{2+} uptake importantly contributes to a rapid clearance of cytosolic Ca^{2+} transients. Because mitochondrial Ca^{2+} uptake is dependent on the potential gradient over the inner mitochondrial membrane, depolarisation of $\Delta\psi$ as observed during CN action (Fig. 3.2.6) would predict disturbance in cytosolic Ca^{2+} clearance. To mimic the physiological situation, Ca^{2+} transients were repetitively elicited by short (200-500 ms) depolarisations to +10 mV from a holding potential of -60 mV elevating $[\text{Ca}^{2+}]_i$ to 200-500 nM from a resting level of ~80 nM. Clearance of Ca^{2+} transients was assessed by determining the recovery time constant tau (τ) after fitting with a single-exponential function. As expected, incubation with 1-2 mM CN for 1 to 4 minutes markedly prolonged the recovery of somatic Ca^{2+} transients to 1.96 ± 0.35 fold control ($n=6$, $p<0.03$; Fig. 3.3.5 A). After wash-out of CN, fast clearance of Ca^{2+} transients was largely restored.

In these experiments, ATP-deficiency as a causative factor for prolongation of recovery times was ruled out, since millimolar ATP concentrations were continuously supplied via the patch pipette. However, a decrease in cellular ATP levels is certainly expected during persistent inhibition of mitochondrial electron transport during *in vivo* conditions of hypoxia and may affect $[\text{Ca}^{2+}]_i$ in addition. To test the impact of ATP-depletion on regulation of $[\text{Ca}^{2+}]_i$ and recovery of activity-dependent Ca^{2+} transients, $[\text{Ca}^{2+}]_i$ was monitored in cells dialysed with ATP-free intracellular solution and Ca^{2+} transients were elicited every 60 s. Oligomycin (10 $\mu\text{g}/\text{ml}$) was then added to block mitochondrial ATP-production. In contrast to CN, oligomycin does not depolarise $\Delta\psi$, which was consistent with a lacking effect on the NADH autofluorescence (not shown). As illustrated in Fig. 3.3.5 B, wash-in of oligomycin left basal Ca^{2+} levels, as well as recovery times of Ca^{2+} transients, unaffected for several minutes, before recovery times progressively prolonged and, after a mean incubation time of 6.4 ± 1.2 min, resting $[\text{Ca}^{2+}]_i$ steadily increased ($n=6$).

Fig. 3.3.5: Monitoring of $[Ca^{2+}]_i$ in patch-clamped hypoglossal MNs using fura-2 (100 μ M), where elevations in $[Ca^{2+}]_i$ (100-400 nM above baseline) were elicited by short depolarisations to +10 mV from a holding potential of -60 or -70 mV. **A** Somatic Ca^{2+} -transients normalized to the same amplitude before and during 1-4 minutes of CN incubation (1 mM) are superimposed. Note that CN prolongs the recovery time constant τ of Ca^{2+} -transients to 1.96 ± 0.35 fold control ($n=6$; $p<0.03$). Wash-out of CN largely restores fast Ca^{2+} clearance. Because cells were dialysed with 4 mM ATP, the effect is attributable to disturbed mitochondrial Ca^{2+} uptake and not to ATP-depletion. **B** Hypoglossal MNs were dialysed with ATP-free intracellular solution and 10 μ g/ml oligomycin was added as indicated to block mitochondrial ATP production. While usually no change in recovery time constants of Ca^{2+} transients (τ) or resting $[Ca^{2+}]_i$ was noticed within the first 5 minutes, longer incubation times progressively prolonged τ . After a mean incubation time of 6.4 ± 1.2 min, resting $[Ca^{2+}]_i$ steadily increased.

4. DISCUSSION

4.1 Dominant role of mitochondria in clearance of physiological Ca^{2+} loads in hypoglossal motoneurons

The first part of this work has characterized the contribution of mitochondria to buffering of voltage-activated Ca^{2+} loads in hypoglossal motoneurons. The experiments indicated that mitochondria contribute importantly to a fast clearance of Ca^{2+} transients by taking up around 50 % of motoneuron Ca^{2+} loads even for $[\text{Ca}^{2+}]_i$ elevations with amplitudes as small as 50-200 nM (physiological range). By taking up Ca^{2+} , mitochondria also contribute to limiting the amplitude of voltage-activated Ca^{2+} elevations, which was revealed in experiments using dyes with lower affinity. These results are in good agreement with data obtained from motor nerve terminals (David & Barrett, 2000), with experiments on cultured motoneurons (Carriedo *et al.*, 2000) and with a previous study on patch-clamped hypoglossal motoneurons (Ladewig *et al.*, 2003), where significant mitochondrial Ca^{2+} uptake following voltage-activated Ca^{2+} influx has also been demonstrated. The fact that the study by Ladewig *et al.* yielded very similar results indicates that whole-cell patch-clamping is unlikely to disturb mitochondrial Ca^{2+} buffering in motoneurons.

Further experiments demonstrated that mitochondrial Ca^{2+} uptake is highly temperature-dependent in motoneuron somata with ~2 fold higher uptake rate at 29-32°C compared to room temperature. This finding is consistent with a study from David & Barret (2000) showing that mitochondrial Ca^{2+} buffering on mouse motor nerve terminals is more efficient at near physiological temperatures than at room temperature. However, in contrast to their results, the relative contribution of mitochondria to clearance of cytosolic Ca^{2+} loads remained essentially constant in the tested temperature range. This indicated that experiments performed at room temperature still yield representative results regarding mitochondrial Ca^{2+} clearance in this preparation.

Quantitative information about total motoneuron Ca^{2+} clearance and mitochondrial Ca^{2+} uptake was obtained by calculation of clearance rates after polynomial fitting of the decay of Ca^{2+} transients (amplitudes up to 350 nM). The resulting clearance rates

for the undisturbed condition (average γ_{total} 152 s⁻¹) were found to be slightly higher than those calculated previously (Lips & Keller, 1999; see also Methods section 2.9), a fact that may result from differential composition of intracellular solutions or variable preservation of MNs in the slice. Mitochondrial Ca²⁺ clearance was characterized by a clearance rate constant of ~70 s⁻¹. This value (room temperature) and the characteristic ~2 fold increase in time integral of [Ca²⁺]_i transients after FCCP could be used to compare mitochondrial Ca²⁺ buffering between different cellular systems. This revealed that mitochondrial Ca²⁺ buffering of small amplitude elevations is much more prominent in motoneurons than other neuronal systems, such as sympathetic neurons (Friel & Tsien, 1994), dorsal root ganglion neurons (Werth & Thayer, 1994), hippocampal neurons (Mironov, 1995) or chromaffin cells (Herrington *et al.*, 1996; Xu *et al.*, 1997).

4.2 Mechanisms underlying efficient mitochondrial Ca²⁺ uptake

An interesting question was therefore, how such efficient mitochondrial Ca²⁺ uptake at low [Ca²⁺]_i can be reached in hypoglossal motoneurons and several explanations were considered. One possibility was that motoneuron mitochondria – in contrast to other neurons - take up Ca²⁺ preferentially via the “rapid uptake mode” (RaM). This mode has been described to account for efficient Ca²⁺ uptake during trains of Ca²⁺ pulses of physiological concentration (~400 nM) in isolated mitochondria (Gunter *et al.*, 1998). It was suggested that RaM is mediated by a specific transport mechanism that might be responsible for mitochondrial Ca²⁺ uptake from [Ca²⁺]_i transients *in vivo*. However, there is little evidence for existence of RaM in intact neurons and no statement about contribution of RaM in motoneurons can be made.

In contrast, mechanisms potentially contributing to mitochondrial Ca²⁺ uptake at low [Ca²⁺]_i that are supported by experimental evidence include i) a high density of mitochondria in the cytosol correlating to a high level of mitochondrial activity, and ii) a significant interaction of mitochondria and areas of Ca²⁺ accumulation around Ca²⁺ influx pathways. Previous studies already indicated a high level of mitochondrial activity in motoneurons (Wong-Riley, 1989; Shaw & Eggett, 2000) and this was now confirmed by rhod123 staining, cytochrome oxidase histochemistry and two-photon NADH imaging for the hypoglossal nucleus. The possibility (ii) that mitochondrial Ca²⁺ uptake was facilitated by a close proximity of mitochondria and Ca²⁺ influx sites was

supported by confocal laser scanning using mitotracker green, although the spatial resolution reached in these experiments restricted statements to the μm range. However, additional support is provided by experiments, in which the low affinity dye fura-FF was employed. This demonstrated an increase in Ca^{2+} transient amplitudes after mitochondrial depolarisation, which was not seen when fura-2 was used. The most likely explanation for the observed phenomenon was that fura-2 saturated at high $[\text{Ca}^{2+}]$ and therefore failed to detect an increase in transient amplitudes after FCCP. As the bulk cytosolic $[\text{Ca}^{2+}]$ did not exceed 500 nM during stimulation, saturation of fura-2 occurred most likely locally, in areas of Ca^{2+} accumulation around Ca^{2+} influx sites (voltage-dependent Ca^{2+} channels). This was even more likely as the low cytosolic Ca^{2+} buffering capacity of hypoglossal motoneurons significantly enhances formation of spatial gradients. Therefore, a model seems reasonable where a fraction of motoneuron mitochondria interacts with areas of high $[\text{Ca}^{2+}]$ around influx sites (Fig. 4.1).

Fig. 4.1: Model of interaction between mitochondria and areas of high $[\text{Ca}^{2+}]$ around voltage-dependent Ca^{2+} channels (VDCC).

The proposed model seems even more convincing considering that the picture of mitochondria as “biosensors of calcium microdomains” has emerged from a variety of studies (Lawrie *et al.*, 1996; Rizzuto *et al.*, 1999). This model also nicely fits with previous observations on hypoglossal motoneurons, where highly localized regulation of store-dependent Ca^{2+} profiles was revealed by two-photon microscopy (Ladewig *et al.*, 2003). The model is also consistent with the finding that a rise in mitochondrial $[\text{Ca}^{2+}]$ following voltage-activated Ca^{2+} influx is not delayed to the

increase in cytosolic $[Ca^{2+}]$ (Ladewig *et al.*, 2003). Although more studies are necessary to confirm interaction of mitochondria and local Ca^{2+} domains, the results support the assumption that Ca^{2+} accumulation around influx sites facilitates mitochondrial Ca^{2+} uptake in hypoglossal motoneurons and this, in addition to other mechanisms, may contribute to efficient mitochondrial Ca^{2+} uptake even when the bulk cytosolic $[Ca^{2+}]$ does not exceed 500 nM.

4.3 Consequences of disturbed mitochondrial metabolism

The aim of the second part of the study was to define the impact of mitochondrial dysfunction – as observed in forms of ALS - on motoneuron physiology. For this purpose, complex IV of the respiratory chain was inhibited with cyanide (CN) and the consequences were investigated with particular attention to membrane currents and $[Ca^{2+}]_i$. A summary of the mechanisms identified is given in Fig. 4.2.

The effect of CN on motoneuron membrane properties was characterized by opening of TTX-insensitive Na^+ conductances (I_{CN}), which depolarised the resting membrane potential (V_m) of motoneurons by ~10 mV and increased action potential activity. This response very much resembled the depolarisation of motoneurons during hypoxia (Haddad & Jiang, 1993), a fact that is not surprising considering that oxygen deprivation also inhibits the respiratory chain on the level of complex IV. Further experiments indicated that a redox mechanism was involved in activation of I_{CN} , because the antioxidants and free radical scavengers ascorbic acid and trolox[®] largely prevented it. The change in the redox state was possibly induced by increased levels of reactive oxygen species (ROS), which originate at the respiratory chain when complex IV activity is inhibited (Lopez-Barneo *et al.*, 2001). However, the involvement of ROS is challenged by the fact that the activation of I_{CN} significantly preceded the increase in NADH fluorescence, which indirectly monitored the build up of electrons at the respiratory chain. Although a very localized production of ROS that was not represented by the global NADH signal could account for the observed discrepancy, alternate models for I_{CN} activation should be considered. For example, a molecule other than complex IV could serve as sensor capable of responding to hypoxia, CN and azide, another complex IV inhibitor that mimicked the CN response. In this case, the redox state of a thiol-rich molecule as part of the channel itself or of a regulatory protein could constitute the sensor similar as it was suggested by

Hammerström and Gage (1998; 2000) for oxygen and CN sensing Na^+ channels in hippocampal neurons. Taken together, despite the plausible involvement of ROS in activation of I_{CN} , more experiments are necessary to determine the exact signalling pathway by which I_{CN} is mediated in MNs.

Fig. 4.2: Events following mitochondrial inhibition in vulnerable hypoglossal MNs: CN (similar to hypoxia and mtSOD1) inhibits complex IV (cytochrome c oxidase) of the respiratory chain. This increases the formation of reactive oxygen species (ROS), which potentially activate a depolarising Na^+ current (I_{CN}). Alternatively, the Na^+ current is activated by a direct redox mechanism. The Na^+ influx enhances the neuronal excitability and promotes Ca^{2+} influx during elevated firing rates (action potentials, AP). Inhibition of the respiratory chain furthermore decreases the mitochondrial potential gradient ($\Delta\psi$) leading to reduced Ca^{2+} uptake into the mitochondrial matrix and release of Ca^{2+} that was taken up during preceding activity. Mitochondrial inhibition additionally decreases cellular ATP levels, and this further enhances accumulation of intracellular Ca^{2+} .

In addition to the changes in electrical properties, several mechanisms were identified, by which mitochondrial inhibition increased the cytosolic Ca^{2+} load of hypoglossal motoneurons. Attributable to dissipation of the proton gradient ($\Delta\psi$), we observed release of Ca^{2+} from mitochondria-controlled stores and a notable retardation of cytosolic Ca^{2+} clearance rates. Additionally, voltage-dependent Ca^{2+} influx increased $[\text{Ca}^{2+}]_i$ during elevated firing rates. Since millimolar ATP concentrations were continuously supplied via the patch pipette, these effects were clearly independent of a drop in cytosolic ATP levels. On the other hand, a decrease in cellular ATP concentration, which was induced by oligomycin application while respiratory chain activity continued in another set of experiments, prolonged the recovery times of Ca^{2+} transients and progressively built up basal $[\text{Ca}^{2+}]_i$ with a delay of 5-6 minutes. These observations clearly indicated that early cytosolic Ca^{2+} disturbances during mitochondrial inhibition do not arise from energy depletion but rather from insufficient mitochondrial Ca^{2+} buffering and changes in the neuronal

excitability. Nevertheless, when cytosolic ATP levels drop below a certain critical value, $[Ca^{2+}]_i$ regulation is even more severely impaired.

4.4 Selective vulnerability of motoneurons

The reason why motoneuron populations are preferentially injured in ALS is still incompletely understood, and a variety of explanations have been proposed. Motoneurons are large, highly active cells with exceptional energy requirements, a fact that exposes them to elevated risks during metabolic demands. They also possess a high level of Ca^{2+} permeable AMPA receptors and a remarkably low cytosolic Ca^{2+} buffering capacity (K_S) (Alexianu *et al.*, 1994; Lips & Keller, 1998; Palecek *et al.*, 1999), which renders them particularly sensitive to excitatory glutamatergic transmission. This work now establishes that motoneurons are further characterized by a strong impact of mitochondria on $[Ca^{2+}]_i$ transients. This fact might enhance their vulnerability for several reasons. First, large Ca^{2+} fluxes into mitochondria enhance the risk for generation of reactive oxygen species, molecules that promote oxidative damage to the cell (Nicholls & Budd, 2000). Additionally, the strong mitochondrial control of $[Ca^{2+}]_i$ increases the risk for disturbance of Ca^{2+} homeostasis, once mitochondrial function is impaired.

The study furthermore indicates that vulnerable MNs are characterized by membrane properties, which promote a profound depolarisation during mitochondrial inhibition. In contrast, neurons in the nucleus dorsalis vagus, which are tolerant to hypoxia and also resistant to degeneration in ALS, hyperpolarise under the same conditions. Hyperpolarisation in vagal but also in hippocampal neurons in response to mitochondrial inhibition has been attributed to activation of ATP-sensitive and Ca^{2+} dependent K^+ channels (Koyama *et al.*, 1999; Englund *et al.*, 2001; Müller *et al.*, 2002). Although activation of ATP-dependent K^+ channels during mitochondrial inhibition has also been observed in hypoglossal MNs (Jiang & Haddad, 1991), its activation is apparently not sufficient to counteract the depolarisation induced by Na^+ influx. Taken together, these observations therefore suggest that selective MN vulnerability most likely results from a synergistic accumulation of risk factors, including low Ca^{2+} buffering, strong mitochondrial control of $[Ca^{2+}]_i$ and a weak protection against hypoxia-related changes in neuronal excitability.

4.5 Implications for the pathogenesis of ALS

Inhibition of the respiratory chain and mitochondrial dysfunction have been closely linked to the pathogenesis of ALS. This study has defined some of the pathophysiological changes resulting from mitochondrial inhibition such as an increase in excitability and cytosolic Ca^{2+} load in vulnerable motoneurons. Although very young animals were used in this study and the cellular changes were investigated over a time range of minutes whereas ALS damages motoneurons over months, the findings may have implications for motoneuron degeneration in ALS. Several observations support this assumption. For example, increased cytosolic Ca^{2+} loads resulting from mitochondrial inhibition are paralleled by observations on cell lines expressing mutant SOD1, which also show increased basal Ca^{2+} loads (Carri *et al.*, 1997; Kruman *et al.*, 1999). Moreover, the findings of depolarising Na^+ currents during complex IV inhibition resemble increased Na^+ currents and enhanced neuronal excitability in mutant SOD1 mouse spinal motoneurons (Kuo *et al.*, 2002; Kuo *et al.*, 2003). Although a causal link cannot be drawn, it seems plausible that increased excitability and increased Ca^{2+} loads are critical determinants of motoneuron degeneration. For example, a mitochondrial-dependent increase in motoneuron excitability may well explain the observed sensitisation to excitatory glutamatergic transmission that has been implicated in mutant SOD1-based ALS (Roy *et al.*, 1998). Substantial rises in cytosolic $[\text{Ca}^{2+}]$ may trigger secondary Ca^{2+} dependent phenomena, which promote neurotoxicity and eventually result in cell death. This includes activation of the Ca^{2+} dependent protease calpain and endonucleases, which promote cytoskeletal breakdown and DNA degradation. Accordingly, the potential link between motoneuron responses to mitochondrial inhibition and their selective vulnerability during ALS-related motoneuron disease will be an interesting area for future investigation.

6. Curriculum Vitae

Friederike Bergmann

born: 28 January 1974 in Wuppertal, Germany

Education

- 1993 High school degree (Abitur), Wilhelm-Dörpfeld-Gymnasium Wuppertal
- 1993-2000 Medical school, Albert-Ludwigs-Universität Freiburg, Germany, and Leopold-Franzens-Universität Innsbruck, Austria
- 2000 Dr. med., University of Freiburg, Germany

Clinical experience

- 2000-2001 Internship, Dept. of Clinical Neurophysiology, University of Göttingen, Germany

Research activity

- 1996-1998 MD student, Dept. of Physiology, University of Innsbruck, Austria
(*supervisor: Prof. Markus Paulmichl*)
- 2000-2003 PhD student (International Neuroscience Study Program), Dept. of Neurophysiology, University of Göttingen, Germany (*supervisor: Prof. Bernhard U. Keller*),
Member of the European Graduiertenkolleg "Neuroplasticity: from molecules to systems"
- 11/2001 Visiting scientist at the Dept. of Physiology, University College London, U.K.
- 08/2003 Scientific fellow at the Dept. of Applied & Engineering Physics, Cornell University, Ithaca, NY, U.S.A. (*head: Prof. Watt W. Webb*)

Teaching activity

- 2001-2003 Neurophysiology courses for MD students in Göttingen
(Praktikum, Seminar, Einführung)
- 2001-2002 Membrane- and Neurophysiology courses for Master students of the International Neuroscience Study program in Göttingen

Publications
