Tag der mündlichen Prüfung: 7.4.2015

Eidesstattliche Erklärung

Hiermit erkläre ich, dass ich die vorliegende Dissertation selbstständig verfasst und keine anderen als die angegebenen Hilfsmittel genutzt habe. Alle wörtlich oder inhaltlich übernommenen Stellen habe ich als solche gekennzeichnet. Ich versichere außerdem, dass ich die vorliegende Dissertation nur in diesem und keinem anderen Promotionsverfahren eingereicht habe und, dass diesem Promotionsverfahren keine endgültig gescheiterten Promotionsverfahren vorausgegangen sind.

Bu tezi sevgili hocama adanmıştır.
Bana en güzel ve en önemli seyler öğreten hocam.

Short Summary

Expiration of fossil fuels and climate irregularities directs the energy demands towards renewable energy sources for the energy supply in future. In this frame, geothermal energy gives a substantial contribution to the strategies of renewable-source based energy production. Efficiency of this component requires to develop new geothermal sites and to improve the performance of existing systems. The main contribution of geoscience is to optimize and characterize the potential of geothermal sites.

One of the essential steps of reservoir characterisation is the understanding of fluid flow in the reservoir. Fluid flow in tectonic active areas is mainly controlled by fault zones. In this study, structural mapping and hydrogeological analysis is used to provide insights into the regional reservoir setup. Here, geohydrochemical analysis is performed to characterize fluid- and rock-composition and the interaction between fluids and rocks. On the other hand, numerical simulations are used to explain the role of fault hydraulic conductivity and fluid properties on temperature and pressure distribution in the study area.

The study area is the high-enthalpy geothermal field Lahendong in Sulawesi-Indonesia. It hosts a producing geothermal power plant producing 80 MW of electricity. Geoscientific investigations in the Lahendong geothermal field have started early 1970s. However, the evolution and distribution of thermal fluids within the target area is still in debate. The present day conceptual model shows that the geothermal field consists of two sub-reservoirs separated by horizontally less permeable fault zones. Brine of low pH is predominantly seen in the north while moderate pH fluids exist in the south and east. Accordingly, production rates vary between the northern and southern parts by a factor of five. However, faults behave permeable sub-parallel to the strike. Therefore, hot springs arise mostly along or at junction of faults. Lahendong area is characterized by basaltic andesite, tuff and volcanic breccia.

Detailed investigations on hydraulic conductivity of fault zones show that faults either act as fault-normal flow barriers due to sealing of the fault core, or as conductive pathways in the damage zone sub-parallel to the fault strike. The damage zone, especially in case of extensional faults, is characterized by fractures. The impermeable fault core is a barrier between one reservoir section, which is characterized by acidic water, considerable gas discharge, high productivity and strongly altered and fractured rocks and another section, which hosts pH-neutral waters, high temperatures and less altered rocks. Those reservoir conditions observed on-site have been converged in numerical hydrochemical models. The fault-controlled vertical and horizontal fluid flow is used to simulate different reservoir sections. Recharge and discharge in the model occurs along the faults. However, fluid flow is also influenced by fluid phase transition. Steam propagation at top of faults stimulates vertical fluid rise, because steam propagates faster due to lower density. Therefore, in case of 2-phase

flow simulations, permeabilities have to be lower to satisfy same pressure and temperature conditions.

The main contribution of this study is to show that systematically performed structural analysis helps to understand the fluid flow in geothermal reservoirs. It has been confirmed that the hydrotectonic concept combining the tectonic and hydrogeological information essentially improves the understanding of subsurface flow of thermal fluids, which is the basic source of geothermal power plants. This is crucial for site selection and smart drilling strategies, which supports a sustainable exploitation of the geothermal field avoiding risks, such as low-productive wells or the production of highly corroding waters. Results also guide reservoir management in case of a potential for field extension, as performed in Lahendong.

Kurzfassung

Der weltweit steigende Energiebedarf stellt die Menschheit vor immer größere Herausforderungen. Im Angesicht des Klimawandels und der begrenzten Verfügbarkeit von fossilen Energieträgern liegt eine besondere Verantwortung bei der Entwicklung von erneuerbaren Energieressourcen. Dabei spielt die Geothermie eine besondere Rolle, da sie zur Deckung der Grundlast geeignet ist. Zu der Bewertung von geothermischen Potentialen leisten die Geowissenschaften einen großen Beitrag.

Das geothermische Potential eines Standorts hängt vor allem von der Art und Ausbreitung von Störungszonen ab, da sie wesentlich den Grundwasserfluss kontrollieren. In dieser Arbeit werden verschiedene geowissenschaftliche Methoden miteinander kombiniert, um die Wirksamkeit von Störungszonen zu bewerten. Strukturgeologische Kartierungen und hydrogeologische Felduntersuchungen erklären die Ausbreitung und hydraulische Funktion von Störungszonen im Untersuchungsgebiet. Geohydrochemische Untersuchungen geben Auskunft über Fluid- und Gesteinszusammensetzung und deren Wechselwirkungen. Numerische Simulationen des Gebietes zeigen, dass sowohl Störungszonen als auch Fluideigenschaften wichtig für die Verteilung von Druck und Temperatur im Reservoir sind.

Das Untersuchungsgebiet ist das Hochenthalpy-Geothermiefeld Lahendong in Sulawesi (Indonesien). Ein Kraftwerk produziert hier 80 MW Elektrizität. Die ersten Untersuchungen im Gebiet starteten in den 1970er Jahren. Jedoch sind Genese und Verteilung der thermalen Wässer noch nicht komplett verstanden. Das aktuelle konzeptionelle Modell zeigt eine Aufteilung in mehrere Reservoirbereiche. Die verschiedenen Bereiche sind durch horizontal impermeable Störungszonen voneinander getrennt. Den nördlichen Bereich kennzeichnen saure Wässer und den südlichen Teil pH-neutrale Wässer. Auch die Produktivität variiert stark zwischen den beiden Reservoirbereichen. In vertikaler Richtung sind Störungszonen jedoch durchlässig, was dazu führt, dass heiße Quellen entlang von Störungen oder deren Kreuzungspunkten auftreten. Die Reservoirgesteine in Lahendong sind basaltische Andesite, Tuffe und vulkanische Brekzien.

Die Permeabilitätsverteilung der Störungszonen wird durch die Ausbreitung von Rissen kontrolliert. Risse sind vor allem in der Bruchzone der Störung verbreitet, was zu einer hydraulischen Durchlässigkeit parallel zur Störung führt. Die Unterteilung des Reservoirs in Lahendong wird durch diese Rissverteilung bestimmt. Der nördliche saure Teil des Reservoirs ist durch höhere Produktivitätsraten, Gasaustritte an der Oberfläche und stark alterierte und geklüftete Gesteine im Untergrund charakterisiert. Der südliche Abschnitt ist heißer und hat weniger stark alterierte Gesteine. Die beobachteten Reservoirereigenschaften wurden von hydrochemischen und hydraulischen Modellierungen bestätigt. Der Grundwasserfluss mit Neubildung und Austritten aus dem Reservoir ist im Gelände und im Modell vor allem durch

Störungszonen kontrolliert. Jedoch ist der Grundwasserfluss auch durch den Aggregatzustand des Wassers beeinflusst. Für die Modellierung von 2-Phasen-Ausbreitung müssen die Permeabilitäten angepasst werden, um gleiche Temperatur- und Druckbedingungen zu modellieren.

Der Hauptbeitrag dieser Arbeit liegt in der Demonstration, dass eine systematische struktureologische Analyse für das Verständnis von Grundwasserfluss in geothermischen Reservoiren unentbehrlich ist. Es wurde bestätigt, dass die Kombination von tektonischen, hydrogeologischen und geohydrochemischen Informationen den wichtigsten Beitrag für das Verständnis von Grundwasserströmungen leistet. Die Grundwasserströmung ist der wichtigste Faktor für die Wahl des richtigen Standortes für Produktion und Injektion in geothermischen Feldern. Eine detaillierte Analyse gewährleistet eine nachhaltige Nutzung des Feldes und verringert Risiken, wie schwach produzierende Bohrungen oder die Produktion von stark korrosiven Wässern. Auf dieser Grundlage kann eine Felderweiterung geplant werden, wie es in Lahandong angedacht ist.

1 Introduction

1.1 Objective

Growing energy demands of human being requires an extension towards renewable energy sources to provide a healthy energy-nature loop. Furthermore, in the frame of expiration of fossil fuels and climate irregularities, renewable energy sources play a key role for the energy supply in future. In order to satisfy the entire demand, the performance of existing energy systems should be improved while new reserves should be explored. In this context, geothermal energy gives a substantial contribution to the strategies of renewable-source based energy production.

Currently, geothermal energy component is being developed in many countries worldwide. This development is locally accelerated establishing supportive rules developed by governments, e.g. in Germany (Renewable Energy Law) and Indonesia (Law Nr.23/2003). Total capacity of the geothermal power plants worldwide remains at 12.1 GW_e while the total potential is estimated to be between 200 and 240 GW_e (Bertani, 2015, 2010; Stefansson, 2005). The largest budget of this total amount (29 GW_e - 12%) is covered by the Republic of Indonesia, where the use of geothermal energy is planned to be broadened adding 9.5 GW_e more capacity until 2025 (Erbaş et al., 2011).

The main contribution of geoscience to this developing energy component is to quantify potential of geothermal sites. The geothermal potential is strongly depending on the geological characteristics e.g. hydrogeological regime, fluid properties, faults and lithology (Moeck, 2014). The primary focus, of the study presented here, is the role of fault zones/fracture networks on operation and potential of geothermal reservoirs. This requires combination of broad range of multidisciplinary approaches. The challenge is to find the optimum balance between effort and relevance of adopted methodology to characterize fault zones/fractures and their effect on reservoir potential.

In this context, potential methods are evaluated to suggest an optimized workflow. The test ground of this study is located in North-Sulawesi, Indonesia. Lahendong geothermal field is a magmatic, fault-controlled high-enthalpy geothermal system. The site hosts a producing geothermal system, which has potential for further development and optimization. In particular, this study aims at optimizing the use of geothermal potential of the Lahendong geothermal field. The workflow developed here is generalized for characterization of geothermal fields with fault-controlled fluid flow.

The primary objective of this thesis is to assess the best-available workflow to evaluate the effect of fault zones on behavior of geothermal reservoirs. In this frame, key questions to be addressed are:

General questions:

- What is the role of fault zones in geothermal fields?
- What is the best combination of methods to characterize the efficiency of fault zones at geothermal sites?

Specific questions:

- How do fault zones control the set-up of a geothermal system?
- What is the influence of fault zones on subsurface fluid flow?
- How do geohydrochemical features change along faulted areas?
- What is the best way to numerically simulate a fault-controlled geothermal field?

1.2 State of knowledge at the Lahendong geothermal site

The target area, Lahendong geothermal field, is located in North Sulawesi-Indonesia. It hosts a producing geothermal power plant producing 80 MW of electricity. The site is being monitored and investigated since early 1970s. Several studies focused on resource of the Lahendong geothermal field. Investigations basically employ structural-geology, geochemistry, geophysics, well-logs and reservoir simulation.

Fig. 1 Topographic map showing the location of the study area

Structural-geology

The structural development of Lahendong geothermal field is dominated by volcano-tectonic depression of Tondano. The region is surrounded by active volcanoes in the north and in the south (Surachman et al., 1987). The central area is the Linau hydrothermal eruption crater reflecting rather a hilly topography (Siahaan et al., 2005). The complex tectonic setting combined with rich volcanic activity resulted in lots of calderas and faults in the target area and its surrounding. The main faulting zone is located around the Lake Linau consisting of NE-SW, NW-SE, E-W and N-S striking normal or strike-slip faults (Koestono et al., 2010). Stratigraphic units in the area exemplify pre- and post-caldera formations. Predominant types of rocks are andesite, tuff, ignimbrite, sediment intercalations and volcanic breccia (Sumintadireja et al., 2001).

Geochemistry

In the Lahendong area, two basic types of water exist in hot springs, namely, pH neutral and acidic types. Neutral water covers the southern section of the geothermal field with relatively low salt content. The acidic water appears in and around the Lake Linau with high SO_4 concentration and relatively low temperatures (Koestono et al., 2010). Element concentrations of the different fluids give rise to specific minerals, which control the mineral composition of the penetrated rock (Utami, 2011). Sulfate minerals, i.e., arise in rocks penetrated by fluids with high SO_4 -concentrations. Furthermore, minerals exposed to high temperatures and aggressive fluids undergo the process of alteration. The Lahendong reservoir is characterized by three different alteration zones, e.g., kaolinite-anhydrite, epidote-chlorite and sericite-actinolite zone. The kaolinite-anhydrite zone represents the acidic alteration effect at temperatures of 100 – 250°C while the epidote-chlorite zone hosts medium-temperature minerals, i.e. epidote, chlorite, crystalline quartz, calcite, illite and kaolinite. The sericite-actinolite zone is associated with a micro-diorite intrusion and temperatures of 300 – 350°C (Ganda, 1987).

Well-log analysis

Well-logs collected at exploration holes show that the reservoir formation consists of Tertiary and Quaternary aged volcanic rocks (Sulasdi, 1986). Main rock types are andesite, basalt, tuff, volcanic breccia and pyroclasts. Lithological and pressure distribution from well-logs show that the reservoir is in 1100 – 2300 m depth. Pressure distribution is near to hydrostatic pressure, which indicates a fluid-dominated regime and an overall subsurface fluid flow direction from S to N (Sumintadireja et al., 2001). This fluid flow controls the temperature in the reservoir by convection regime. The highest temperature is measured south of Lake Linau as 300°C at 1000 m depth (Koestono et al., 2010).

Geophysics

The Lahendong area has been previously intensively studied using geophysical approaches. Investigations focus on the central study area hosting the main upflow zones. The center of the study area, the Linau Caldera, is projected in gravity data in the same shape as at surface. The reservoir extent in vertical axis is visible in magnetotelluric data. Resistive structures, which represent the reservoir, appear at 500 m depth in the north and at 1500 m depth in the south. The reservoir is overlain by a non-resistive cap rock. Location of this low resistivity cap rock correlates with the main upflow area. Outflow from the reservoir goes through geothermal manifestations, such as hot springs and fumaroles (Sumintadireja et al., 2001).

Numerical reservoir simulation

Available three-dimensional model for the Lahendong area shows the system in natural state before production start. It forecasts the performance of the system for the next 30 years. The fit of the model to the measured data depends on the data quality. Modeled scenario forecasts

that the production of 60 MW_e for a time period of 30 years leads to a pressure drop of 10 bar (Yani, 2006).

1.3 State of the art in characterizing fault-controlled geothermal systems

1.3.1 Physical set-up of faults

Internal structure of fault zones is in principle the same for all fault types. The central fault core is surrounded by two symmetrically arranged fracture zones (Fig. 2). Dimension of core and distribution of fractures are varying depending on fault history. The faults are classified in terms of degree of fracturing as thin/wide fracture zones with a distinct/small fault core (Caine et al., 1996).

The temporal evolution of a fault zone develops as follows: 1) The fractured damage zone initiates to evolve under the control of local stress conditions in the host rock. 2) Fractured areas are partially transferred into fault core merging and rotating the rock fragments (Billi et al., 2003). 3) Filling the fractures by those small rock particles builds the fault core and leads to less permeability, while the fractured zones remain permeable in direction of fracture opening, e.g. sub-parallel to the strike. This is why faults can be impermeable perpendicular to fault plane while being permeable parallel to the strike of the fault. Hydraulic conductivity of fault zones varies up to ten orders of magnitude independent from the fault type (Caine et al., 1996).

Fig. 2 Schematic set up of a strike slip fault zone with fractured damage zones (Gudmundsson et al., 2001)

However, understanding hydraulic conductivity of faults is still in debate due to their complex set-up and limited in-situ observations (Aydin, 2000; Fairley, 2009). The hydraulic conductivity of faults can be determined by permeability measurements of rock samples from the faulted area. Permeability is measured in-situ or in the laboratory or can be estimated by geohydrochemical or geophysical analysis or numerical reservoir modeling. Permeability dominates the behavior of fluid flow in the subsurface even in micro-scale. Therefore, detecting permeability variations requires high-resolution methods. Measurement points have to be in a proper set-up to detect even small varieties in permeability (Antonellini and Aydin, 1994; Barton et al., 1995; Evans et al., 1997; McDermott et al., 2006; Zimmermann et al., 2000).

1.3.2 Characterizing the efficiency of fault zones

Sustainable operation of a geothermal site requires a detailed understanding of subsurface fluid flow. In tectonic active areas fluid flow is mainly controlled by hydraulic conductivity of the fault zone. The faults control the flow rate, flow direction and hydrochemistry through a geothermal area. In particular, faults act as barriers, conductors or composite systems against the fluid flow depending on their state within the surrounding stress-field (Moeck and Dussel, 2007).

Investigation of a geothermal site starts with first exploration period where the main focus is to characterize faults, their stress field and the resulting hydraulic efficiency. This initial information is updated integrating the results from borehole measurements or numerical simulations. Final model for the fault network is developed based on location, geometry and the other properties of the surrounding faults compiling all available information obtained from structural geology, geochemistry, geophysics, well testing and reservoir modeling (Hatherton et al., 1965; Hochstein, 1990; Wanjie, 2012).

Geological and structural measurements are performed through the outcrops and eventually combined to generate structural-geological map of the target area. The structural data are further analyzed to understand regional stress field. The field studies are extended towards understanding the properties of surface water, such as hot springs, creeks and lakes as well as rocks. Those geochemical and hydrogeological investigations are performed analyzing physicochemical and physical parameters in the laboratory, e.g., major ions of gas and water samples, rock composition and permeability.

Geophysical approaches are implemented to cover deeper depth ranges. Approaches use the different responses of subsurface layers to addresses different issues at depth, such as bedrock basement, structural displacements, distribution of alteration and water saturation. The methods comprise gravity, magnetotelluric, seismic and electrical resistivity studies. Furthermore, well-logs provide directly measured subsurface data. Here, the most important

measurements are temperature, pressure, porosity and alteration patterns. Finally, a numerical model is designed based on all available data to reconstruct the initial state of the field and afterwards forecast spatiotemporal behavior of the reservoir.

The methods to be used are selected considering the scale of interest. Surface observations are flexible in spatial sampling frequency as long as the structural or geological features are available, e.g., hot springs or outcrops. Geophysical techniques are able to satisfy a resolved scale of meters depending on topography and field accessibility. Well-logging samples only one spot at surface but provides a high resolution in vertical axis. The amount of field observations as well as well-log measurements determines the resolution of numerical modeling, which is used to understand evolution of the geothermal field.

It is important to understand the fault set-up in detail in order to elaborate on production and injection sites and ultimately to place new wells, which will enhance the sustainability of the geothermal system. In this study, a proposed scheme of combined methods is used to better characterize geothermal potential of green fields as well as to optimize the performance of producing geothermal systems.

1.3.3 Geometry of and subsurface fluid flow in fault-controlled geothermal fields

Since the early 1970's, hydrothermal systems have been investigated using structural and geological approaches (Nukman, 2014). These investigations show that the most prominent geothermal sites have been found in the vicinity of active fault systems (Nukman and Moeck, 2013). Especially, fault intersections host appropriate physical settings for geothermal sites as the permeability and therefore the fluid flow is substantially enhanced at such spots (Curewitz and Karson, 1997). The influence of faults/fractures on fluid flow is obviously seen at hot springs located along the fault zones (Fig. 3). In that frame, the structural variation as well as the hot spring locations along the fault zones should be investigated to understand subsurface permeability and its control on fluid flow (Moeck, 2014).

At the Taupo Volcanic Zone the permeability and therefore the fluid flow is enhanced at highly fractured regions, resulting in upward movement of water towards the hot springs at surface (Rowland and Sibson, 2004). Another example is located at the Ohaki geothermal site, where conjugate active fault zones provide the highest hydraulic conductivity and therefore the location for the most productive boreholes (Grindley, 1961). The upward movement of water is not the only reason controlling the fluid flow patterns. Fluid infiltration into the faults/fractures is also important to consider for characterizing the fluid flow. In addition, absence of recharge must be avoided to keep up the lifetime of a geothermal system (Portugal et al., 2000).

Similar characteristics have been observed in the Lahendong geothermal area. There is a systematic relation between hot spring location and fault intersections in the Lahendong field. Hydraulic conductivity of faults enhances fluid rise towards the surface (Brehme et al., 2014). Therefore, alignment of hot springs allows locating permeable and highly fractured zones in case the outcrops are rare due to dense tropical vegetation.

Fig. 3 Fluid flow along fault zones with fluid rise and infiltration in permeable fault damage zones

Combining hydrogeological knowledge obtained from hot springs as well as outcrops displays an integrated picture of permeability in a geothermal field. However, hydrochemical properties of rising water provide additional insight into the directional dependence of permeability within faults. Variations in water types are in general interpreted to represent different sources in geothermal fields due to large separation distances (Simsek, 2003).

1.3.4 Geohydrochemistry in fault-controlled geothermal systems

Geohydrochemical investigations focus on fluid composition and rock formation through the geothermal area. This combined information allows understanding the water-rock interaction. Geohydrochemical measurements, in particular, allow to investigate fluid flow, temperature-patterns, the ratio between steam and water and scaling/corrosion potential of fluids along the reservoir field (Arnorrsson, 2000). Conclusions are integrated to generate a conceptual model, which gives a first order idea about the production capabilities as well as the sustainability of the reservoir.

Productivity of geothermal reservoirs is strongly dependent on subsurface fluid flow that is enhanced in highly fractured areas leading to enhancement in water-rock-interaction. During chemical reaction between water and rocks, both change their composition to get into

equilibrium stage. This change results in alteration of rocks by dissolution, precipitation or replacement of minerals. Change in water characteristics are measured by salinity, pH and temperature. Those measurements are finally used to trace fractured zones since fluid and rock properties change as a result of high fluid movement. Therefore, geohydrochemical measurements provide an alternative approach to resolve subsurface structures.

Fig. 4 Two different reservoir sections separated by an impermeable fault zone

Fractured zones cause leakage from the geothermal reservoir, which results in upward movement of fluids towards hot springs at surface (Fig. 4). The geohydrochemical investigation of hot springs allows understanding the upward movement because every substance in water composition acts differently during this process. Boron concentrations, i.e., accumulates in a narrow area of the Lardarello geothermal field and resolves the subsurface temperature, lithology and fluid flow patterns of the field because boron concentration increase while condensation and precipitates under certain lithological circumstances (Tonami, 1970). In addition, the extent and the type of alteration patterns give another constraint to subsurface fluid flow. Quartz-adularia and kaolinite alteration, i.e., is used to trace main upflow spots in Ohakuri geothermal field (Henneberger and Browne, 1988).

In the Lahendong geothermal field, two different types of water rise at the surface. The fluid composition controls alteration of subsurface host rocks (Utami, 2011). The higher chemical activity results in more distinctive alteration patterns. Therefore, performing geohydrochemical measurements is essential to understand subsurface fluid content and rock properties in order to verify the processes and the structures controlling the fluid flow.

1.3.5 Numerical Simulation of subsurface fluid flow controlled by faults and fluid properties

Examples from different geological settings show that the geothermal potential increases at highly fractured areas (Moeck, 2014). Fault-controlled geothermal resources and energy recovery are nowadays routinely investigated by reservoir modeling (Pruess and Narasimhan, 1982; Sanyal et al., 2000). The models are developed in 2D sections or 3D volumes through the reservoir depending on the complexity of the reservoir addressed. A starting conceptual model is defined using a priori information about flow of groundwater, major permeable zones, recharge and discharge areas and heat flow (O'Sullivan et al., 2001).

A numerical model developed for the Rhine Graben reveals that graben-parallel fluid convection is controlled by highly permeable faults. It has been understood that major geothermal systems there evolve as superposition of such permeable faults (Bächler et al., 2003). In a second model, developed for Basin and Range geothermal site, vertical fluid rise has been observed along active fault systems. Hydraulic conductivity of fault zones is therefore the main parameter controlling fluid flow and temperature distribution (Wisian and Blackwell, 2004). Here, vertical flow paths play an important role for performance of geothermal fields.

Basically, numerical models are used to represent the natural state of a geothermal system before start of production. The models are calibrated with real measured data, which are collected in the field. Modeling results fit the temperature measurements easily while simulated enthalpy and pressure values give high residuals. This is due to phase change of water, which substantially changes the pressure and enthalpy in principle. At the Momotombo geothermal site in Nicaragua flow rates and enthalpies have not been sufficiently converged by modeling results, especially for the wells producing steam (Porrás et al., 2007). This is caused by complex fluid flow due to changing fluid properties during phase transition. In consequence, besides the hydraulic conductivity, phase transition controls subsurface fluid flow in fault-controlled geothermal fields.

Subsurface fluid flow in the Lahendong geothermal field has been simulated using two numerical models, namely: a thermal-hydraulic model and a 2-phase model. Proposed pathways for major fluid flow have been confirmed by the numerical models assuming that most of the fluid flow and heat transport occurs through faults and fractures. However, 2-phase propagation gives constrain on reconstructing natural temperature, pressure and 2-phase patterns in the Lahendong reservoir.

Fig. 5 Different hydraulic conditions at each side of the fault lead to 2-phase propagation and different reservoir pressures

However, modeling the Lahendong geothermal field brought certain difficulties during pressure- and 2-phase-simulation, especially due to simplified representation of reservoir geometry and therefore imprecise 2-phase distribution in TOUGH2 modeling approach. Inaccuracy in modeling of pressure distribution is therefore due to 2-phase flow in the reservoir. Flow velocity and pressure patterns in geothermal reservoir strongly depend on phase change of hydrothermal fluids. Hydraulic conductivity of faults as well as the fluid properties are the main parameters controlling the temperature and pressure patterns in a geothermal field and therefore must be adjusted carefully in order to simulate realistic reservoir behavior (Fig. 5).

1.4 Thesis outline

The primary objective of this thesis is to develop a workflow investigating the effect of fault zones on behavior of geothermal reservoirs. The fault zones are characterized using various methods designed for hydraulic conductivity determination. The most feasible methods are combined to ensure fast and reliable results. This is reasonable in terms of temporal and financial investment for the assessment of geothermal resources. Furthermore, this study shows the importance of continuous data update for the performance of producing geothermal fields. Extension of energy producing fields should be planned based on the knowledge gained through the combined methods.

The first chapter presents a hydro-/geological approach. Methods used here are structural mapping, water sampling, tracer experiments and well-log analysis. Results have been combined to generate a comprehensive conceptual model, which is presented in 2D view. It explains the local fault network, fluid properties, fluid flow as well as pressure and temperature distribution. This chapter has been published in ISI Journal - Geothermics as “A hydrotectonic model of a geothermal reservoir – A study in Lahendong, Indonesia”.

<http://dx.doi.org/10.1016/j.geothermics.2014.01.010>

The second chapter covers geohydrochemical investigations on water and rock samples collected in the Lahendong area. The samples are investigated using fluid analysis, geochemical analysis of rocks, recognition of alteration patterns and numerical simulation of geohydrochemical and thermal patterns. Results are considered to elaborate on the composition of water and mineral phases of rocks. Rock-water interaction leads to an increase in alteration at highly fractured areas. Results show that the fluid flow in faults has a strong influence on water and rock characteristics. This chapter is ready for submission to an ISI Journal.

The third chapter presents numerical models, which are developed based on all data gathered during the geological and geohydrochemical investigations. Additional data are obtained from thermal as well as hydraulic laboratory measurements. Simulations show the thermal and hydraulic behavior of the Lahendong geothermal field at natural state. Fault permeability controls fluid flow in the reservoir. Phase transition of fluids has been observed in fractured areas at shallow depths. Outcomes are ready for submission to an ISI Journal.

2 Results

2.1 A hydrotectonic model of a geothermal reservoir – A study in Lahendong, Indonesia

2.1.1 Introduction

High temperature geothermal systems are observed along active plate margins that accommodate different geological settings, e.g. active volcanism at subduction zones or crustal spreading in extensional regimes. Hochstein (1990) points out that elevated temperature and a degree of convection are the main controlling factors in the classification of geothermal systems. High temperature geothermal systems can be further subdivided into brine-, two-phase- and vapour-dominated systems.

Various exploration methods are employed to investigate undeveloped geothermal resources. Hochstein (1988) suggests to study surface thermal springs and the geochemistry of surface and groundwater as a first step in reservoir characterisation. Further, Cumming (2009) proposes to combine geological observations, analysis of geophysical investigations especially magnetotelluric resistivity, hydrogeological models, and chemical composition of fluids in thermal springs to provide insight into the internal functioning of a reservoir system.

One of the essential elements in reservoir characterisation is the assessment of the role of fault zones and fractures because they control fluid flow in the reservoir as shown by Marques et al. (2011) and Goyal and Kassoy (1980). The ability of fractures to channel fluids is related to the present-day stress field which need to be in a favourable orientation for the fractures to display some aperture to transmit fluids (e.g. Banks et al., 1996; Ferrill and Morris, 2003; Larsson, 1972).

Caine et al. (1996) suggest a detailed visualisation of the internal fault structure with a fault core permeability primarily controlled by the lithology and its degree of alteration and the adjacent fractured damage zone dominating permeability. The damage zone permeability can be up to 10,000 times larger than the permeability in the fault core (Evans et al., 1997).

Fig. 6 Location of the study area and wells at Lahendong, North Sulawesi. Deviated wells are shown as lines, vertical wells as dots

This overall interaction between state of stress, fault structure, and fluid flow can be described as *hydrotectonics* (Moeck, 2005). The author describes the spectrum of fracture permeabilities by changes in fault orientations resulting in significant variations in fault-normal stresses despite a homogeneous stress field at a larger scale.

The area of investigation is located in North Sulawesi, East Indonesia and is the location of an operating geothermal power plant with a production capacity of 80 MWe. North Sulawesi is dominated by calc alkali potassic volcanism, which is detached from its source due to migration of the north branch of Sulawesi (Walpersdorf et al., 1998a). Furthermore, North Sulawesi is influenced by subduction from north and from east. The northern subduction does not display volcanic activity as is still relatively young (Walpersdorf et al., 1998a). However, subduction of the Molucca Sea from the east causes arc volcanism (Silver and Moore, 1978). Such evolved magmas result in ash-flow tuffs consisting of rhyodacites and rhyolites. Lake Linau located in an explosion crater is the most recent demonstration of this activity (Lécuyer et al., 1997).

In our study, we use field-based methods (e.g. detailed geological mapping and fault structure analyses) to provide insight into the regional geology, structural geology, hydrochemistry, and the hydrogeological regime. Here we combine tectonic as well as

hydrogeological approaches to better constrain the effect of faults on reservoir fluid flow in a frame of a hydrotectonic model for a magmatic, structurally controlled geothermal system.

Detailed investigations of the hydro- and geochemistry of fluids and rocks in Lahendong are the focus of another publication (section 2.2). Isotopic studies on fluid and rock samples as well as a thermal-hydraulic model from before and after production start of the Lahendong site are under progress and will be published in forthcoming papers.

2.1.2 Setting of the geothermal system Lahendong

Lahendong is located in North Sulawesi, approximately 30 km south of Manado (Fig. 6). The topography of the area is basically formed by volcanoes and two lakes. Lake Tondano at ca. 680 m above sea level (asl) east of the study area is the largest lake in North Sulawesi. The smaller Lake Linau is located 780 m asl west of Lake Tondano. The lake water is of light green colour, but the most significant property is the acidity with a pH of 2.7. Between the lakes volcano summits rise up to 1,150 m asl. The area is surrounded by Mount Soputan, Mount Mahawu and Mount Empung. Mount Lengkoan and Mount Tampusu are located inside the study area. Currently, Mount Empung, which is located 10 km Northwest of Lahendong, is one of the most active volcanoes in Indonesia. Abundant vegetation and small rivers cover the rolling hill landscape. Lake Linau is fed and drained by a creek.

North Sulawesi located in the wet tropical climate zone has a constant temperature of 25.9°C throughout the year (DWD, 2012). Regional rainfall is controlled by the Intertropical Convergence Zone that accommodates heavy rainfall from November to May (Dam et al. 2001). The average annual rainfall is 2,662 mm (DWD, 2012). This large precipitation depth either discharges as surface runoff via creeks or infiltrates as recharge into the subsurface. Infiltration is basically determined by the topographic relief and infiltration capacity contributing to fluid flow within the reservoir system (Hochstein, 1988). The overall hydraulic gradient is oriented in a SW to NE direction.

Fig. 7 Tectonic setting in East Indonesia and North Sulawesi

The Lahendong geothermal field is owned and operated by P.T. Pertamina Geothermal Energy. It has an installed capacity of 80 MWe fed by 8,300 tonnes of steam per day produced by 10 production wells for the last 12 years. Since the estimated potential is still significantly beyond the present-day production (ca. 120 MWe) it is planned to enlarge the system by drilling new wells (Koestono, 2010). Therefore, it is necessary to characterise the reservoir and to identify the major controls for fluid flow in order to optimise injection and production rates and ultimately to site new wells.

Four production clusters, each including several wells, provide steam directly used for electricity generation (Fig. 7). The borehole clusters comprise both vertical and deviated wells. Deviated wells in the Northern clusters have their landing zone below Lake Linau. In the South, production wells are deviated towards the flank of Mount Lengkoan and also towards Northeast (Fig. 6). True vertical depth reached by the production wells span the range between 1,118 and 1,975 m below ground level (bgl), which corresponds to ca. 308 m and 1,120 m below sea level (bsl). Injection is performed at the Northern boundary of the area.

Generally, the reservoir is a two-phase-system (Koestono, 2010). However, the Northern part has a lower steam proportion compared to the Southern part. Temperatures in the reservoir range from 200°C to 340°C, which is therefore classified as a high-enthalpy-reservoir following Hochstein (1990).

Available geophysical information from previous exploration campaigns are for example composed of magnetotelluric data. The results from the three-dimensional analysis of magnetotelluric data show a higher resistivity (propylitic zone) as a dome overlain by a shallow conductor that is interpreted to present a hydrothermal alteration zone under Lake Linau (Raharjo et al., 2010). Alteration was verified also by surface observations, e.g. thermal springs (Raharjo et al., 2010).

Siahaan et al. (2005) described the geological evolution of the Minahasa area: Minahasa, the Northeastern part of North Sulawesi, is an active volcanic arc, along a subduction zone of oceanic plates from N and SE. During the Miocene, volcanic rocks and marine sediments such as carbonates were deposited during a concurrent marine transgression and volcanic activity. The interbedded sediments form the basement rocks of the area. A regression and accelerated volcanic activity in Northern Sulawesi caused the explosion of Tondano, later followed by the Pangalombian eruption during the Pliocene / Pleistocene. The two calderas still dominate the present day topography and were transformed by Lake Linau and Lake Tondano (Fig. 2 and Lécuyer et al., 1997). Other eruptions like Kasuratan, Tampusu, Kasuan, Linau, and Masarang occurred during the Holocene (Yani, 2006). Around the crater rims basaltic andesitic lava, breccia, rhyolite, tuff, and lapilli-tuff were deposited (Siahaan et al., 2005). Geological units in the Lahendong area are divided into Pre-Tondano (basement from Miocene), Tondano, and Post-Tondano rocks and further subdivided into Pre-Pangolombian and Pangolombian units from Plio- to Pleistocene (Koestono et al., 2010; Siahaan et al., 2005; Yani, 2006).

North Sulawesi is located at a triple junction between the Eurasian, Australian, and Philippine plates, accommodating a relative plate motion of 7.5 – 9 mm/year (Fig. 2 and Walpersdorf et al., 1998b). The junction is explained by subduction of the Australian (AUS) and Philippines (PHI) plates under the Eurasian (EUR) and sinistral movement along the Australian-Philippine boundary (Fig. 7). However, Walpersdorf et al. (1998a) interpret the double subduction zone in the Molucca Sea to be a result of the Eurasian-Philippine collision. Whereas the Sangihe subduction started 25 Ma ago, the Halmahera subduction (start: 7 Ma ago) and the North Sulawesi Trench, for which the subduction started 5-8 Ma ago, is much younger (Fig. 2 and Di Leo et al., 2012).

The four diverging branches of Sulawesi indicate different origins and have developed within a complex subduction and faulting process. The Palu fault represents a boundary between North and West Sulawesi. South and East Sulawesi merges along the Matano fault.

Paleomagnetic (Otofuji et al., 1981; Surmont et al., 1994) and geophysical investigations (Hamilton, 1979; Silver et al., 1983) show a clockwise rotation of the Northern Arm of Sulawesi. A 20° rotation is dated back to early Pliocene (Silver et al., 1983). The pole of rotation is located in the Northeast of North Sulawesi (Otofuji et al., 1981; Socquet et al., 2006; Walpersdorf et al., 1998a). However, according to Otofuji et al. (1981), the rotation was already completed before the volcanic activity started during the Plio- to Pleistocene period.

Fig. 8 Cross-sections in the northern and southern well clusters as shown in Figs. 1 and 4 with geological layering, fault location, temperature distribution, casing of wells and reservoir location according to hydrochemical and borehole data

Structural investigations conducted in the Lahendong area are being carried out by P.T. Pertamina Geothermal Energy since 1982. This resulted in many scientific contributions, e.g. Koestono et al. (2010), Lécuyer et al. (1997), Siahaan et al. (2005), Sumintadireja et al. (2001), Surachman et al. (1987), Utami et al. (2004) and Yani (2006). Observed structures are basically strike-slip faults, normal faults, and caldera rims. Lécuyer et al. (1997) and Siahaan et al. (2005) describe a major strike-slip fault oriented in NE-SW direction, presently located between Lake Linau and Lake Tondano, affecting the development of Tondano and Pangalombian caldera (Fig. 7B). Some major faults are also striking NW-SE in the north and south of Lake Linau (Fig. 7B). The Lahendong geothermal system is strongly related to the Linau caldera but also influenced by local fault systems. As indicated by the location of thermal springs that are close to fault exposures at the surface, all faults are considered to have a hydraulic conductivity (Koestono et al., 2010; Siahaan et al., 2005; Surachman et al., 1987). Fault locations within the reservoir are well correlated with the zones of circulation

loss in the boreholes (Fig. 8). Thus, fluid pathways are expected to be mostly characterised by fracture dominated permeability (Yani, 2006).

2.1.3 Methods

The area surrounding the Lahendong site was tectonically mapped with particular emphasis on relevant features and subsurface circulation. These are fault orientations, discontinuities and joints, location of thermal springs, and the hydrogeochemical composition of groundwater from wells and hot springs. We measured orientation (strike and dip) of faults and joint planes as well as the slip direction (indicated by slickensides) (section 2.1.4, Fig. 9, Fig. 10).

Fault plane analysis includes measurements of striations and fault planes, and for better statistics, each fault plane/striation pair was measured at least four times. A total of 50 sites (outcrops and manifestations) have been visited. In average 10 measurements at faults and fractures have been performed. Fault planes are plotted in a lower hemisphere convention including stress inversion after Angelier (1979). The plots were prepared using TectonicsFP software (Ortner et al., 2002).

Hydrochemical properties are measured on-site by hand-held instruments at wellhead, in hot springs, rivers and lakes (e.g. pH, temperature, and electrical conductivity). Samples were obtained using a Mini-Separator to separate brine from steam. Logging was conducted by the operator providing downhole temperature, slotted liner zones, permeable zone and hydraulic heads. Permeable zones represent the area of total circulation loss during drilling. The perforated areas of casing are in the depth of main permeable zones. Temperature logs in wells were measured before the start of production and after having obtained a stable temperature and potential field following drilling and completion. They, therefore, represent initial conditions. Equipotentials were constructed using the Delaunay-Triangulation-Method based on data from permeable zones (Henderson, 2007).

Discharge measurements in rivers were performed using tracer dilution method with instantaneous injection. A fixed amount of tracer substance (NaCl) is injected instantaneously upstream. The tracer concentration breakthrough is recorded and integrated over time after having subtracted a natural background (Benischke and Harum, 1990).

2.1.4 Results

Borehole log data

The geological cross-sections shown in Fig. 3 are based on lithological information (mud-logs) of the boreholes. According to Sumintadireja et al. (2001), the wells in Lahendong intersect the Post-Tondano unit at the top (0 – 850 m bgl), the Tondano unit at 350 - 1,100 m bgl and the Pre-Tondano unit at the bottom (1,100 - 1,600 m bgl). Three main rock types were identified i.e. andesite, volcanic breccias, and tuff.

The lithological units vary between the northern and southern part of the reservoir (Fig. 8). Bedding layers below Lake Linau is nearly horizontal. Geological layers host breccia and andesite; slim layers of tuff occur in the NE. Here, the wells reach a true vertical depth of 1,897 m. Permeable zones in the acid reservoir are located in the depth range between 1,481 m bgl and 1,918 m bgl. The average pressure at this depth is 117 bar and the average temperature 237°C. Two faults border the reservoir. Both are normal faults, striking NW-SE and dip below Lake Linau. Highest temperature of 300°C was measured at a depth of 1,500 m, which corresponds to a thermal gradient of 200°C/km. Nevertheless, a significant

temperature decrease was observed in the NE in the direct vicinity of an inferred fault zone. This decrease is probably due to the circulation of cooling groundwater within the NE-SW striking and SE dipping fault zone.

Geological layers in the southern cross-section are also horizontally bedded. Thick layers of tuff extend across the whole area. Also the neutral reservoir is situated in a thick layer of breccia. Pressure and temperature are 121 bar and 319°C on average, respectively. The thermal gradient in this area is 145°C/km. A sinistral NE-SW oriented strike slip fault borders the reservoir to the NW. Compared to the north, temperatures in general are higher in the same depth range (i.e. 300°C is measured at 1,000 m depth). Isotherms suggest an upward flow in the SE and a temperature drop in the NW.

Structural geology in the field

Faults

The main faults strike in a NE-SW orientation in the Lahendong geothermal field. The azimuth is roughly 40° and the dip between 72° and 81° towards SE. Riedel shears and slickensides indicate left-lateral movement along the NE-SW faults. Stress inversion of the fault slip data results in a strike-slip regime where the maximum horizontal stress S_H is the maximum principal stress $S_H=S_1$ striking N-S, the minimum horizontal stress is the minimum principal stress $S_h=S_3$ striking E-W, and the vertical stress is the intermediate principal stress $S_V=S_2$. In this stress field, NE-SW striking faults are sinistral.

At least four different sinistral strike-slip faults develop in the region of interest. Between the faults step-over regions can be clearly recognised (Fig. 9). Segmentation of strike-slip faults is typically observed in the shallow crust and the direction of fault step-over controls the development of extension or push-up structures (Miller, 1994). While a left step-over of sinistral faults is characterised by extensive strain between the faults, right step-over show compressive strain due to the relative movement of fault-blocks (Fig. 10). Dilational zones are dominated by normal faults bordering an extensional basin. Thrust faults, however, connect sinistral faults with right step-over (Fig. 9). The secondary faults were attributed to the same development phase as that of the strike-slip faults. Both phenomena, extension and compression, were observed in the study area. Thrust faults representing a compression zone were observed in outcrops in the North and South. The northern fault plane strikes 129 - 162° and dips 30 - 66° towards SW, the southern one strikes 142 - 149° with a dip of 33 - 45° towards NE. The presence of normal faults surrounding Lake Linau confirms extensional movement. They dip towards the lake with an inclination ranging between 70° and 82° (Fig. 9). The extensional basin coincides with the Linau crater.

Fig. 10 (Top) Focal mechanisms and lower hemisphere plot of two stress phases acting in Lahendong with maximum and minimum stress direction and the induced faults in top view. (Below) Secondary structures in Phase I induce dilational and compressional step-over regions. Picture: Example for temporal evolution: N-S striking normal fault cuts a NE-SW striking strike-slip fault

A second dominating fault pattern is identified in a set of N-S and E-W striking faults. These faults are normal faults and are apparent from topographic traces at Mount Tampusu and visible in outcrops near Lake Tondano and Lake Linau (Fig. 9). The strike of the N-S faults ranges between 0° and 15°, the dip between 78° and 88° ESE, SSW, respectively. Stress field inversion indicates that the maximum principal stress is vertical, the maximum horizontal stress $S_H=S_2$ is in N-S direction and the minimum principal stress $S_h=S_3$ is in E-W direction (Fig. 10). Previously mapped faults are presented in Fig. 2B and where mapped among others by Koestono (2010), Koestono et al. (2010) and Utami et al. (2004). Here, we added the type of faults and dip directions in this study.

Joints

At geothermal hot springs, joints observed within well-consolidated or cemented rocks and sinter units provide an additional constrain for the present-state of the stress. In particular, sinter-hosted joints can be assumed to be recently generated and they therefore provide a measure of currently active movements and stresses. In the target area, our observations indicate that the joints mostly develop in a direction of NE-SW, N-S and E-W, and to some extent NW-SE (Fig. 9). E-W and N-S sets or corresponding NE-SW and NW-SE striking joints presumably indicate a fault-related stress-regime. In hydrothermal discharge areas, E-W and N-S sinter joints are of a dilative nature. Mineral precipitations from supersaturated geothermal fluids in the joints are evidence of extensional processes. The joints and the surrounding rocks (up to 2 cm) are highly altered by Fe-mineralization suggesting circulation of hot fluids.

Temporal evolution of the two stress regimes

The present geometric constellation of the fault zones in the study area is explained by fault kinematics and their geodynamic cycle. Furthermore, the stress analysis is used to elaborate on the correlation between the fault kinematics and the major geodynamic events in the area. Fault evolution is split into two phases based on stress inversion of slip data.

A stress tensor with maximum principal stress in N-S direction generated NE-SW striking sinistral strike-slip faults. This phase of faulting possibly occurred during the rotation of North Sulawesi and relevant compressional stress from northern directions. Today's clockwise rotation started ca. 5 Ma ago (Walpersdorf et al., 1998a). This movement increased the N-S oriented horizontal stress and generated NE-SW striking sinistral strike-slip faults.

The pattern of N-S and E-W striking faults might have developed because of a regional uplift in this area. The NW-subducting Molucca Sea plate might represent a driving force for an extensive melting process of the subducted slab in the mantle. A local to regional uplift could have been induced by individual magma chambers out of extensive melting processes of the subducted slab below Lahendong. This uplift in turn caused a break-up of the shallow crust into orthogonal fault patterns. The orthogonal pattern is most likely caused by radial extension with a vertical maximum principal stress axis typical for uplifting regions.

The relative temporal evolution of the two fault phases is supported by outcrop observations (Fig. 10). Measurements showed N-S striking normal faults cutting across NE-SW striking lateral faults. N-S and E-W striking faults are younger than the NE-SW oriented strike-slip faults and their accompanying secondary structures.

Since these dilative orthogonal fractures are found to be the youngest structures, the present day stress field is interpreted as a normal faulting regime with similar horizontal stresses resulting in $S_V > S_H > S_h$. Normal faults developed in that stage are supposed to be younger than 5 Ma. The thermal uplift might even have reactivated older strike-slip faults, which currently act as oblique normal faults.

The fault kinematics of older sinistral NE-SW striking faults and reactivated oblique sinistral normal faults with the accompanying orthogonal fracture pattern indicate an overall change in stress regime with rotation of stress axes. In the former stress field the maximum principal stress S_1 is oriented in N-S and S_h in E-W (black labelled faults in Fig. 9). However, in the current stage the maximum principal stress axis rotates from horizontal to vertical confirming a change in the stress regime from strike-slip towards normal faulting (Fig. 9). The rotation pole is the minimum principal stress axis $S_3 = S_h$. S_1 has also rotated from horizontal to vertical.

Fluid properties

Hydrochemical patterns

Physicochemical properties of groundwater and surface water have been extensively sampled during several field campaigns. Electrical conductivity (EC), pH and temperature have been measured on-site in hot springs, lakes, rivers and wells (Table 1, Table 2). Well-temperature measurements have been performed downhole before the start of production.

The Lahendong geothermal field is subdivided into two hydrochemical regimes based on temperature, electrical conductivity, and pH of the fluids. High electrical conductivities in the range of 4,620 – 9,700 $\mu\text{S}/\text{cm}$, pH in the range of 2.7 – 3.2, and temperatures in the range of 200 – 274°C characterise the acidic type of the well waters. On the other hand low electrical conductivities of ca. 400 to 1,729 $\mu\text{S}/\text{cm}$, moderate pH (4.2 – 6.5), and temperatures of 232 – 341°C define a neutral type of water. The acidic type of water is found in the north-western wells (beneath Lake Linau), the neutral type of water is observed in the south and northeast of Lake Linau. The different water types were also measured at depth. Acid highly saline water originated from deeper permeable zones, which can be assumed to be located below Lake Linau (Fig. 8). The average reservoir depth is ca. 2,000 m bgl compared to ca. 1,500 m bgl average depth for the neutral reservoir.

Table 2 Hydrochemical properties, reservoir temperature, water table, true vertical depth and permeable zone depth of reservoir water (TVD: true vertical depth, bgl: below ground level, asl: above sea level, colours from wells refer to the different types and the compartments: see Fig. 14)

	Well number	Wellhead elevation [m] asl	EC [$\mu\text{S}/\text{cm}$]	pH	SO ₄ [mg/L]	Cl [mg/L]	Si [mg/L]	RES-T [°C]	Water table [m] asl	TVD [m] bgl	Permeable zone from to [m] bgl

Spring water can be also subdivided into two types (Table 1). Hot springs with temperatures of 40 - 82°C, low pH-values of ca. 2 and EC of 1,291 to 7,835 $\mu\text{S}/\text{cm}$ are acid springs. However, neutral springs show lower EC (385 - 1,228 $\mu\text{S}/\text{cm}$), lower temperatures of 41 - 58°C, and higher pH values (~6.5). Acidic hot springs are located mostly in the NW of the study area, where also the acid reservoir water is situated while the neutral springs surround the study area (Fig. 11). Hot springs rise in the vicinity of faults but also occur in manifestations far from fault zones, which could then be interpreted as steam heated shallow groundwater. The hot springs M4, M9 and M13 can be regarded as examples for steam-heated

shallow groundwater since they are positioned right above the neutral-pH reservoir. Besides high concentrations of sulphate steam heated groundwater is normally associated with low concentrations of chloride and high dissolved metal contents (Arnorsson et al., 2007). They discharge at the surface as muddy hot springs often in combination with fumaroles at the flanks of stratovolcanoes (Utami, 2011). Moreover, the acid water dissolves the rock and forms collapse craters and caves (Nicholson, 1993).

River and lake waters differ from each other, depending on the location within the study area, with respect to their physicochemical properties, i.e. Lake Linau shows a pH of 2.7, located near acid hot springs and above the acid reservoir, and river water displays variable acidity depending on nearby hot springs feeding the creeks.

In typical geothermal systems neutral spring water is interpreted as surface discharge of the reservoir. Nevertheless, the Lahendong geothermal reservoir is a magmatic and fault controlled system. At the Lahendong site the neutral springs occur far from the reservoir. In between the reservoir and the discharge areas are low permeable faults. Therefore it is unlikely that they represent typical outflow areas. Moreover, the hydraulic head distribution supports this conceptual model. Hot spring discharges have higher hydraulic heads than the nearest well. Nonetheless, the flow direction suggests a typical outflow area in this area.

The presence of acid water in the reservoir and in thermal springs is interpreted to originate from fluids in contact with gases emanating from an old magma chamber, i.e. today's heat source (Fig. 12). The chamber is assumed to have remained from the eruption and evolution of the Linau Caldera (0.45 Ma years ago). The degassing magma contributes to the acidification of the aquifer by reaction of O₂-rich groundwater with H₂S and CO₂ to acids such as H₂SO₄ or H₂CO₃. A circulation process with infiltration of meteoric water through fault zones and mixing with deep acidified magmatic water is suggested for this acid aquifer beneath Lake Linau. Heating stimulates the rise and discharge of hot acid water to the surface. The infiltration of cold meteoric water occurs through fractures parallel to the fault. Moreover, the fault core itself can be assumed to be of low hydraulic conductivity, while the adjacent damage zone is believed to display considerable permeability. During infiltration cold water is heated up and together with gas components rises upward through parallel fractures to the surface, where it discharges in acid springs at the shore or the lake bottom. Hence, the lake water is a mixture of water from an acidified aquifer and acidic condensate water.

Fig. 11 Location of sampled spring, lake and river water in the study area and their location relative to faults (properties in Table 1)

The previous description of the Lahendong water types allows a preliminary classification and evaluation of the hydrochemistry of the study site. Nevertheless, a detailed hydrochemical and geochemical investigation is necessary to fully understand the Lahendong hydrothermal system. The study presented here was accompanied by an investigation of the hydrochemical, geochemical and isotopic characteristics (Brehme et al., submitted, Wiegand et al., in prep.). However, a short report of the main conclusions is presented in the following to support the preliminary characterisation in this publication.

Acid water occurring in Lahendong has to be divided into deep acid water and acid spring water discharging at the surface. Both are characterised by high sulphate (SO_4) concentrations due to the oxidation of H_2S , but deep acid water contains up to three orders of magnitudes higher chloride (Cl) concentrations and three times higher silicium (Si) concentrations (Table 1, Table 2). In contrast neutral waters have considerably lower concentrations of SO_4 but also lower Cl and Si (Brehme et al., 2011). Based on the ionic ratios of Cl/SO_4 , Cl/Si or Fe/Si the deep, shallow, acid and neutral waters can clearly be distinguished. Therefore, it is assumed that deep and acid waters from hot springs do not necessarily originate from the same source. Acid water in hot springs can also be interpreted as steam-heated groundwater.

Moreover, Utami (2011) showed different types of alteration and various alteration minerals for different production wells in Lahendong. The composition of reservoir water is controlled

by equilibration with the host rock. The contact of acid water with reservoir rocks rather results in a direct deposition than in a replacement of minerals. This is due to a higher salt content of acid reservoir water. Precipitating minerals from acid water contain mostly sulphates and alkaline earth silicates. Neutral water additionally causes precipitation of iron oxides. Likewise behaviour was observed in our own thin section analyses and XRD-analyses (section 2.2.3).

Fig. 12 Schematic explanation of the acid water evolution by degassing magma under Lake Linau. Meteoric water (blue) infiltrates through fractures along normal faults and mixes with gases (orange) from the magma source (red) and already acidified water (green) before rising again

Hydraulic characteristics

Local groundwater flow in the Lahendong area is obviously dominated by fault structures. Three different groundwater systems can be distinguished (Fig. 13). Nevertheless, directions are generally from SW to NE. Artesian conditions prevail at the southern well clusters and west of Lake Linau. Hydraulic heads in the SE show groundwater flow from the southern production cluster to the injection wells (SW – NE). Beneath Lake Linau the local flow is aligned approximately W – E. North of Lahendong the flow direction is SW to NE, i.e. parallel to the southern flow field. It is assumed that all three flow systems are independent from each other. The lowest water levels are observed near the injection cluster the highest

levels south of Lake Linau (Fig. 13). Slightly higher groundwater levels occur below Lake Linau, which matches the depth of permeable zones and hence the reservoir depth, displayed in Fig. 8.

Additionally, the reservoirs can be assumed to be vertically separated. Less permeable layers isolate the different reservoir horizons. In the Lahendong area andesites are believed to form aquicludes, while the reservoirs are located in the higher permeable breccias. As a result perched aquifer systems could also possibly develop. An example for a perched aquifer could be the local acid aquifer beneath Lake Linau. However, the horizontal separation is a result of the hydraulic properties of the fault zones. Independent groundwater flow systems are bordered by fault systems with a low permeability orthogonal to the fault plane.

To verify the assumptions of hydraulic properties of faults in the Lahendong area, the discharge of rivers and creeks was measured before and after fault zones. We qualitatively tested if the infiltration into fault zones is an issue at the site investigated. The discharge, which was obtained with a dilution method (Benischke and Harum, 1990) ranges between ca. 10 L/s and 190 L/s (Fig. 13). Influence of recharge from hot springs or anthropogenic discharge by farmers on the measurements was minimised by measuring if possible in unaffected areas. A significant drop of discharge in the vicinity of faults is observed. The water volume in the river decreases by 12 L/s while crossing the normal fault SW of Lake Linau. A similar trend is observed for the complementary NE fault zone (drop in discharge by ca. 5 L/s).

2.1.5 Permeability characteristics of fault zones

Various properties of the reservoir in Lahendong were already discussed in the previous paragraphs. Hydrochemical patterns, temperature anomalies, and hydraulic heads are strongly influenced by fault systems.

The different hydrochemical patterns in the study area suggest various origins of water. The superposition of the effects of the complex geological and tectonic history can possibly explain the proximity of the large contrast in water types. Furthermore, the subsequent differentiation of the hydraulic flow regime and the consequential characteristic hydrogeochemical development of the fluids support this model. The tectonic structural elements, i.e. fault zones, are considered as the most significant feature since they provide either fluid pathways or barriers and therefore explain easily flow paths to different rock types and therefore water types. In our study area the two reservoir types appear to be separated by low permeability faults; a strike-slip fault south of Lake Linau and a normal fault east of Lake Linau.

Furthermore, hydraulic heads in the geothermal system suggest three different flow regimes. Flow direction south and north of Lake Linau is from SW to NE but beneath the lake from WSW to ENE. Both the hydrochemical and the hydraulic patterns are isolated regimes, which are controlled by fault systems. Sinistral strike-slip as well as normal faults act as flow barriers (Fig. 13, Fig. 14).

Fig. 13 Different groundwater flow systems with hydraulic head distributions dominated by fault structures. Black numbers are elevations of wells where the hydraulic head was measured, to explain the location of artesian conditions. Discharge measurements in rivers with discharge in L/s show water losses in the river across normal faults

In contrast, the distribution of hot springs suggests some fault permeability. Since the southern wells display artesian conditions and because hardly any hot springs are observed in this area, it is conclusive that the hot water rise is limited to fault zones. Furthermore, hot springs are frequently located at fault intersections. Especially in the surroundings of Lake Linau the thermal springs are aligned in NE-SW direction (Fig. 9, Fig. 11). Hot springs regularly occur together with fumaroles and are associated with regions of substantially altered rocks. Along each fault only one type of hot spring occurs. Neutral-pH springs occur for example along the most north-western and most north-eastern strike slip fault. Acid springs appear along the sinistral strike slip fault near Leilem and south of Lake Linau. M4, M9 and M13 are assumed to be steam heated groundwater and therefore occur independently of fault zones mapped at the surface.

Furthermore, borehole temperature data show infiltration of cold meteoric water along the fault zones. A significant temperature drop was observed along a strike-slip fault in the south as well as along a normal fault in the north of reservoir area. The cooling process is most obvious close to the normal fault NE of Lake Linau. Isotherms uniformly drop in the vicinity of the fault, demonstrating a clear progress of cold water from the surface into the fault. At the same depth range the temperature drops about 50°C (Fig. 8). This phenomenon most likely also applies for the opposite normal fault and the strike-slip fault in the southern cross section (Fig. 8).

Moreover, the hydrochemical model in Fig. 12 supports the model of a permeability anisotropy with the main axis parallel to the fault strike. The acidic fluids below Lake Linau circulate in fractures sub-parallel to the main fault zone. Acidic fluids do not only discharge via hot springs but also contribute to the water budget and acidification of the lake. The rise of fluids can be observed in large gas bubbles visible in the western part of the lake. Discharge measurements have been carried out during the field campaigns in order to check out the hypothesis of infiltration of surface water into faults being permeable parallel to fault striking in the vicinity of Lake Linau. The loss of water from the river across the fault zones supports the assumption of vertical infiltration.

The hydraulic conductivity of fracture systems has been widely discussed in the scientific community. Different studies came up with various conclusions (Barton et al., 1995; Ferrill and Morris, 2003; Gudmundsson et al., 2001; Caine et al., 1996). Our field observations and relevant data analysis lead to the conclusion that faults in the Lahendong area are perpendicular to the strike less permeable irrespective of the stress regime and orientation of movement.

Therefore, a more detailed consideration of fault structure is necessary to fully understand the internal fluid flow as the fault core can be 10^3 - 10^4 times less permeable than the surrounding damage zone (Evans et al., 1997; Faulkner et al., 2003). In other words, a detailed analysis of the fault and fracture pattern is crucial for the understanding of the fluid flow in the reservoir. These features are apparent at the surface in outcrops and manifestations, where the orientation, aperture width and possible sealing by mineral precipitation become visible. A simplified model as proposed by Caine et al. (1996) is also suggested for our study area. Independent from the fault slip orientation a sealing fault core hinders fluid flow across the fault (horizontally). Nonetheless, fracture patterns parallel to the fault plane allow fault-parallel fluids paths, most obviously by discharging hot springs adjacent to the faults and infiltration of surface water into the fault zones. According to our data, the fracture patterns are more prevalent along normal fault zones (at the extension basin at Lake Linau). We suggest a combination of stress analyses and fracture pattern analyses as the method to

thoroughly understand the potential fluid pathways in a geothermal reservoir. The results show that conceptual models of geothermal systems should always consider the effect of hydrotectonic features on subsurface flow.

The influence of contribution of magmatic history and processes will have to be considered in the interpretation of the hydrochemical fluid composition and in the analysis of structural elements such as calderas and their influence on fluid circulation. The presented methods can be generalised for the analysis of major hydrogeothermal systems.

Fig. 14 Hydrotectonic conceptual model showing the different reservoir compartments in Lahendong (acid: green colour and neutral: blue colour)

2.1.6 Conclusions

In this study a complex geothermal reservoir system was characterised by an integrated analysis of the hydrotectonic features and hydrogeological/hydrochemical characterisation of thermal groundwater.

The currently acting state of stress in the target area was captured by stress inversion of field observations. Faults zones subdivide the geothermal field into different sub-reservoirs. Fluid flow in the subsurface is controlled by the hydraulic characteristics of the fault zones, which

in turn determines the chemical composition and temperature of the thermal fluids and therefore the productivity of the geothermal field.

The subdivision into different sub-reservoirs was anticipated based on a conceptual fault model and confirmed by hydrochemical measurements performed at 12 hot springs, 10 wells, and 9 surface water samples. In addition to borehole measurements hydraulic heads from 23 wells were available for the analysis of the local flow regimes.

Fault zones can either act as flow barriers due to sealing, of the fault core, or as conductive pathways (damage zone) parallel to the fault strike. Fractures in the damage zone are more numerous in tension controlled dilative faults. Furthermore, two main phases of structural development were identified in the faulting history and the tectonic evolution. This new observation is describing the role of fault zones in geothermal fields, especially in the Lahendong area.

The main contribution of this study is its demonstration of the effect of a systematic structural geological analysis on the understanding of fluid flow in geothermal reservoirs. Integrating strain and present-day stress fields in a geothermal reservoir provide a better insight into the hydrogeological role of fault systems. Moreover, the spatial distribution of structural elements and their temporal evolution has been combined with their hydraulic properties to explain long-term physical processes. It has been confirmed that this hydrotectonic concept of combining tectonic and hydrogeological information is essential to understand the subsurface flow of hot fluids, which is the basic source of geothermal power plants. It is appropriate to be used for similar geological settings.

2.2 Geohydrochemical processes controlled by fault permeability in the Lahendong geothermal field

2.2.1 Introduction

Geothermal potential is nowadays an indispensable component to supply energy demands within a frame of future energy strategies built on renewable sources. Efficiency of this component requires using proper approaches for reservoir characterization to optimize reservoir performance. Usually, the characterization is done using geophysical, geological and hydrochemical measurements. In this study, geohydrochemical investigations are performed to evaluate the influence of fault zones on reservoir properties.

Understanding geohydrochemical properties is inevitable for the sustainable use of a geothermal site. Acidic fluids, i.e., bring high risk for the geothermal circuit because highly acidic water might lead to corrosion that extremely risks the stability of pipes and wells (Keserovic and Bäßler, 2015). Therefore, it is important to understand fluid properties, their distribution and source in order to set up a sustainable geothermal circuit. Geohydrochemical properties are strongly influenced by subsurface fluid flow. In tectonic active areas fluid flow, in turn, is controlled by distribution of permeable and impermeable faults. Therefore, geohydrochemical features provide reliable constrains for permeability of faulted areas. The aim of this study is to allocate these faulted areas based on geohydrochemical observations. Geohydrochemical characteristics are controlled by fluid-rock-interaction, which is enhanced in permeable areas.

The presented approach is applied at a geothermal site in Sulawesi-Indonesia. Lahendong is a high-enthalpy geothermal field operated by P.T. Pertamina Geothermal Energy. It has an installed capacity of 80 MW_e fed by 8,300 tons of steam per day through 10 production wells. Geohydrochemical investigations in the Lahendong geothermal field have started early 1970s. However, the evolution and distribution of thermal fluids within the target area is still in debate. The present day conceptual model that has been recently proposed for the Lahendong geothermal field is summarized as follows (Fig. 15, Brehme et al., 2014): The geothermal field consists of two sub-reservoirs separated by horizontally less permeable fault zones and permeable fault-parallel patterns. Hot springs arise often along or at junction of conjugate faults. Brine of low pH is predominantly seen in the north while moderate pH fluids exist in the southern and eastern margin of study area. Accordingly, production rates vary between the northern and southern parts by a factor of five. Lahendong area is characterized by basaltic andesites, tuff and volcanic breccia intruded by diorites at some locations.

Up to now, geohydrochemistry was used as an instrument to interpret the potential of a geothermal field. This study will make use of this information also to characterize the role of

fault zones in geothermal systems. Geohydrochemical investigations allow to characterize the geothermal field size, subsurface temperatures, water and rock composition and their physicochemical properties (Arnorrsson, 2000). Besides generating a conceptual model, subsurface fluid flow will be investigated to understand role of faults and their permeabilities.

2.2.2 Methods

Water sampling and analysis

Water samples have been collected from production wells and hot springs in the Lahendong geothermal field (Fig. 14, Fig. 15). Well water samples have been extracted from the mixture of brine and steam using a “miniseparator”, which excludes liquid phase from gas phase at wellhead. Sampling has been done according to the hydrogeological procedure, following the steps described by Brehme et al. (2010). Acidification has been done using hydrochloric acid. Major element concentrations have been analyzed by inductively coupled plasma atomic emission spectroscopy (ICP-AES, VISTA-MPX, Varian) and ion chromatography (ICS3000, Dionex). Quantitatively analyzed elements are Ca, Fe, K, Mg, Mn, Na, Si, Sr, Zn, Li, B, Ba, Al, Cs and As (using ICP-AES) and F, Cl, NO₂, Br, NO₃, SO₄, PO₄ (using ICS). Figures and tables show acidic and neutral water wells as labeled in green and blue, respectively.

Rock sampling and analysis

Rock samples have been taken from cores, outcrops and manifestations along the Lahendong area. Combining thin sections of core samples, XRD- and cutting-analysis allows constraining reservoir rock types in detail. Surface rock samples from outcrops are analyzed using X-ray diffraction (XRD) and X-ray fluorescence (XRF) methods in order to measure their contact rate with hot fluids. To quantify mineral composition as well as fraction of the rocks, the samples have been crushed and sieved to 63 μm . Powder XRD patterns have been recorded using a fully automated STOE STADI P diffractometer.

The diffractograms have been refined using the EXPGUI-GSAS method (Belsky et al., 2002; Larson and Von Dreele, 2004; Toby, 2001) and reference crystal structures from the ICDS database (Bergerhof and Brown, 1987). This refinement method allows a quantitative determination for amount of minerals in a rock sample. The accuracy of those measurements is up to 5 wt. % due to very late stage of alteration and occurrence of water in the samples (H_2O). The clay mineral fraction has not been quantified, but determined qualitatively. To identify the peaks of the XRD pattern the EVA diffraction suite method has been used, which is developed by Bruker (Giencke, 2007).

XRF analysis has been performed on a Bruker S4 Pioneer instrument, equipped with a 4kW Rh tube. Details about the measurement conditions and refinement procedures are described in Deon et al. (2013).

Geohydrochemical model

The aim of numerical modeling is to predict potential supersaturation (SI), precipitation and dissolution of the minerals. In the first step, each reservoir water analysis has been adapted to the predominant in-situ conditions, e.g., pressure, temperature and the gas phase equilibrium. Under these conditions, certain minerals became supersaturated. In a second step, the supersaturated mineral phases have been set into equilibrium with the reservoir water and allowed to precipitate.

Hot spring water has been simulated mixing reservoir water with cold low saline water by the factor of 10 reaching the measured temperature of hot springs. This average factor has been estimated from the difference of Cl concentrations in hot spring and reservoir water. CO_2 and H_2S have been degassed at atmospheric conditions and the spring water has been equilibrated with O_2 . Neutral and acidic water has been set into equilibration with silica-minerals. Neutral water has been represented using M3 and M11, acidic samples are M1, M2, M10. After these steps, oversaturated minerals have been assumed to precipitate under the given conditions. Eventually, these simulated mineral phases have been compared with observed mineral phases from surface and subsurface samples.

For the simulation, the geochemical code PHREEQC with the included database (phreeqc.dat, Parkurst et al., 1980, Parkhurst and Appelo, 2013) has been used which allows calculating the pressure impact on the equilibrium constants of chemical reactions. The reaction of gas

phases with the solutions has been calculated using the Peng-Robinson's state equation (Robinson et al., 1985). The mineral reactions have been calculated as equilibrium reactions.

Geothermometer

Temperature estimations using geothermometers have been calculated for well water and hot spring samples. Out of four quartz and six cation-geothermometers the best two/three fits are chosen and presented in this study. Following Powell and Cumming (2010), formulas are as follows:

Chalcedony (conductive): $T [^{\circ}\text{C}] = 1032 / (4.69 - \log[\text{Si}]) - 273.15$ (Fournier, 1981)

Quartz (conductive): $T [^{\circ}\text{C}] = 1309 / (5.19 - \log[\text{Si}]) - 273.15$ (Fournier, 1981)

Quartz (adiabatic): $T [^{\circ}\text{C}] = 1522 / (5.75 - \log[\text{Si}]) - 273.15$ (Fournier, 1981)

Na/K: $T [^{\circ}\text{C}] = 1217 / (1.483 + \log[\text{Na/K}]) - 273.15$ (Fournier, 1983)

Na/K: $T [^{\circ}\text{C}] = 856 / (0.857 + \log[\text{Na/K}]) - 273.15$ (Truesdell, 1976)

Na/K: $T [^{\circ}\text{C}] = 1390 / (1.75 + \log[\text{Na/K}]) - 273.15$ (Giggenbach, 1988)

Theoretical temperatures from hot spring samples are compared to the nearest maximum and average measured well temperatures in reservoir depth. Theoretical temperatures calculated from well samples serve as verification for geothermometry calculation, measured temperatures and water source.

2.2.3 Results

Water

Water has been sampled from ten production wells and eleven hot springs. In general, water is found to be either highly acidic (pH of 1.8 – 3.2) or neutral (pH of 4.2 – 7.0). Reservoir water is of chloride type or acid sulphate-chloride type, while hot springs discharge bicarbonate type waters or sulphate type waters. Waters have been classified according to Arnorsson et al. (2007), Ellis and Mahon (1977), Nicholson (1993), Utami (2011) and White (1957).

Major ions in acidic reservoir water are Cl, SO₄, Na, Si (as total silica) and K. Anions have concentrations of 991 to 1,559 mg/L for Cl and of 523 to 1,609 mg/L for SO₄. Neutral reservoir water mainly consists of Cl, SO₄, HCO₃, Na, Si (as total silica) and K. Cl ranges between 12 and 452 mg/L, SO₄ between 17 and 114 mg/L and HCO₃ between 6 and 68 mg/L. Main gas phases are CO₂ and H₂S (Table 3).

Major ions in acidic springs are Cl, SO₄, Fe, Ca and Si (as total silica). Cl concentrations reach from 1 to 116 mg/L, while SO₄ has concentrations of 653 to 3,236 mg/L. Neutral spring water mainly consists of Cl, SO₄, HCO₃, Na, Si (as total silica) and Ca. Bicarbonate ranges between 104 and 186 mg/L, Cl between 1 and 122 mg/L and SO₄ has values between 7 and 151 mg/L (Table 3).

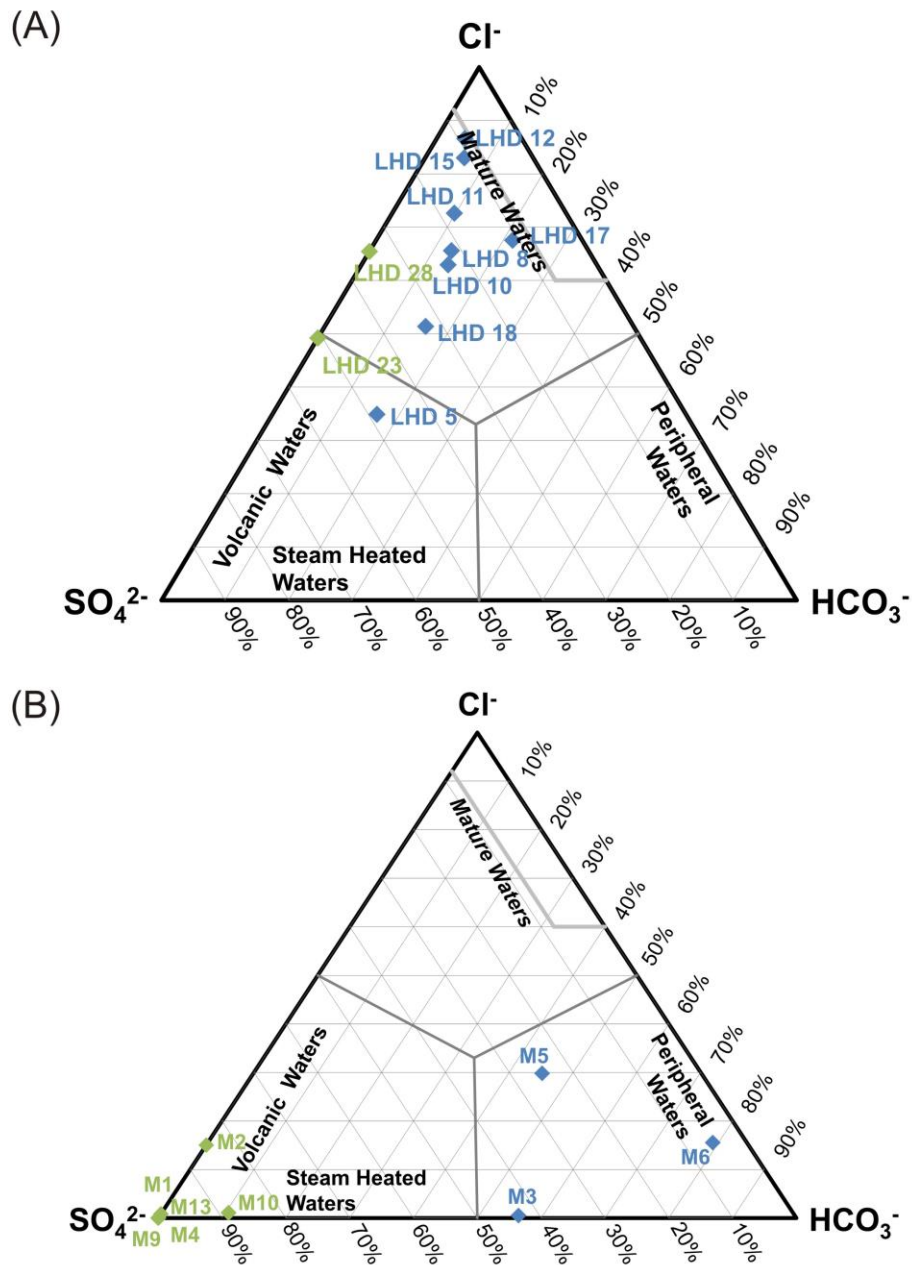

Fig. 16 Plot of water samples in Giggenbach-diagram correlating Cl⁻, SO₄²⁻ and HCO₃⁻, (A) well water, (B) spring water. Green: acidic water, blue: neutral water. M11 and M14 are not shown due to missing HCO₃⁻ concentrations

The ternary Giggenbach-diagram displays the relation between Cl⁻, SO₄²⁻ and HCO₃⁻ concentrations in geothermal waters (Giggenbach, 1988). Plotting the samples from the Lahendong geothermal field reveals a clear distinction between two types of reservoir and hot spring water (Fig. 16). Neutral reservoir samples show mostly pre-dominant Cl⁻ concentrations and therefore are classified as mature waters. On the other hand, non-HCO₃ acidic reservoir waters remain between volcanic and mature waters. Neutral

springs with high chloride and bicarbonate concentrations host peripheral water while acidic springs host volcanic or steam heated water (Fig. 16).

Accordingly, the correlation of pH with SO_4 and Cl with B reveals a clear separation between acidic and neutral waters (Fig. 17, Fig. 18). In the Cl/B-plot three different water groups have been observed in our target area: Most neutral waters show a linear trend with low B concentrations (1- 4 mg/L). Wells LHD 8 and LHD 17 are shifted to the left, while LHD 23 shows the highest Cl and B concentration as well as the highest ratio. The smallest concentrations and ratio occur in well LHD 5.

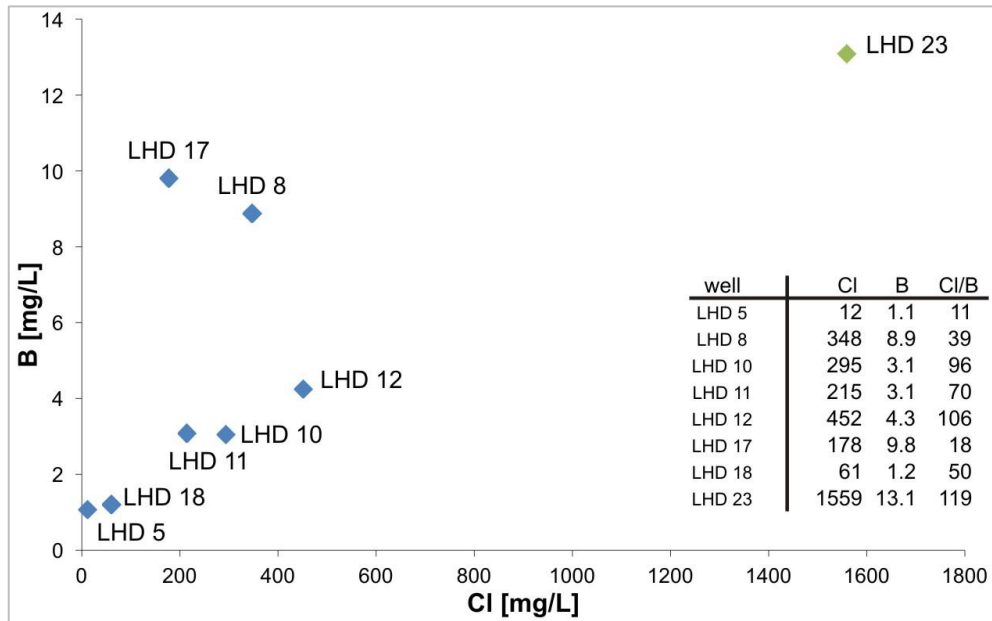

Fig. 18 Correlation of B with Cl of reservoir water with respective concentrations and ratios. Green: acidic water, blue: neutral water, concentrations in mg/L

Rocks

Rock specimen collected from the reservoir and the surface have been analyzed on type and composition of rocks, and occurrence of fluid pathways. The Lahendong area is typically characterized by andesite and volcanic breccia. Andesitic reservoir rock mostly bears altered and unaltered plagioclase, quartz, epidote, pyroxene and olivine (Fig. 19 Top B). However, volcanic breccia consists of different rock fragments and minerals (e.g. plagioclase, quartz) hosted in a microcrystalline matrix (Fig. 19 Top B). Both rock types show hydrothermally altered colorful minerals under the cross nichols light in thin sections (Fig. 19 Bottom B and D).

Fig. 19 Top: Photographs of core samples from geothermal wells representing different rock types (breccia and andesite) with their main components (B&C) and examples for porosity (A&D)

Bottom: Thin sections of core samples showing unaltered (A and C) to highly altered minerals (B and D) as well as types of fluid pathways (pores and veins)

Potential fluid pathways in reservoir rocks are unfilled primary pore spaces (Fig. 19 Top A) or veins. However, veins are often filled by secondary minerals (Fig. 19 Top D). Comparable examples have been observed in thin sections (Fig. 19). Unaltered andesite shows pores between quartz and plagioclase (Fig. 19Top A). Altered andesite shows a partly filled vein among altered minerals (Fig. 19 Top D).

XRD- and cutting-analyses, furthermore, report phyllosilicates, e.g. chlorite and clays, to be more abundant in rocks hosting acidic water (Fig. 20). Surface sample GS9 is a fresh andesite sample (Fig. 20). The most abundant phases of the GS9 XRD pattern belong to plagioclase, diopside and forsterite. GS5-1, GS5-3, GS5-5 and GS15-A samples represent altered material from manifestations in the Lahendong area hosting acidic hot springs and fumaroles. Alteration products from those samples are mainly sulphur (GS5-1) and clay minerals, i.e. kaolinite (GS15-A) (Fig. 20). Kaolinite indicates a hydrothermal alteration of a pre-existing plagioclase. Further alteration minerals are goethite, antigorite and alunite (observed in GS5-3 and GS5-5). Rutile appears most likely as relict from the pre-altered rock (Fig. 20). Minority of rutile type of minerals is seen in XRF data where the chemical content of whole rocks show 1.45% of TiO₂ (Table 4).

Table 4 (A) Reservoir rock composition from core samples, (B) Surface rock composition from XRD analysis, (C) Selected XRF analysis from surface samples, locations see Fig. 15

(A)

Sample	Analysis method	Major mineral phases
Neutral reservoir (LHD2,4,5,7)	Cores, thin sections	quartz, plagioclase, olivine, biotite, pyroxene, epidote, pyrite, muscovite
Acid reservoir (LHD1)	Cores, thin sections	quartz, plagioclase, pyroxene, biotite, epidote, muscovite
Acid reservoir (LHD23,24,28)	XRD, Mudlog, Cutting-Report	quartz, plagioclase, chlorite, pyrite, clay (smectite, illite), epidote, muscovite

(B)

Sample	Rock type	XRD Refinement method	Major mineral phases
GS 5-1 (manifestation with acid springs)	Altered material	Rietveld	sulphur
GS 5-3 (manifestation with acid springs)	Red alteration on andesite	EVA	christobalite, quartz, antigorite, goethite
GS 5-5 (manifestation with acid springs)	Green alteration on andesite	EVA	christobalite, alunite
GS 9 (fresh andesite)	Unaltered andesite	Rietveld	plagioclase
GS 15-A (manifestation with fumaroles)	Highly altered material	EVA	quartz, kaolinite, rutile

(C)

Sample	SiO ₂	TiO ₂	Al ₂ O ₃	Fe ₂ O ₃	MnO	MgO	CaO	Na ₂ O	K ₂ O	P ₂ O ₅	Total

Models

Geohydrochemical model

Geohydrochemical modeling with PHREEQC intends to predict possibly precipitating minerals under certain pressure and temperature conditions. The first modeling step is to adjust the reservoir water samples for the physical conditions of reservoir and main gas phases of CO_2 and H_2S (Table 5A). Under these theoretical conditions, supersaturation is controlled by Fe-, S-, Al- and K-concentrations forming muscovite, kaolinite, pyrite, sulphur, chalcedony/quartz, alunite and gibbsite (Table 5). In a second step, reservoir water has been set into equilibrium with these supersaturated minerals. However, the acidic reservoir water (LHD23) remained supersaturated with respect to clay minerals such as chlorite, chrysotile or talc. Hydrochemical simulation of hot spring water was in a first step cooling, degassing and mixing of reservoir water. This water has been set into

mineral equilibration with supersaturated SiO₂ minerals. After this second step, the water is supersaturated in a high variety of mineral phases dominated by chlorite, muscovite, silica-minerals (chrysotile, talc) and pyrite (Table 5).

Table 5 PHREEQC calculations of equilibrated and supersaturated minerals (A) in reservoir water (B) in hot spring water, SI: Saturation Index

(A)

Sample	In first step supersaturated mineral phases	Reservoir T [°C]	Reservoir p [bar]	Gas Phases [mmol/kg steam]	In final step supersaturated mineral phases (SI)
Neutral reservoir	muscovite (3), pyrite (3), kaolinite (1), sulphur (0.9), gibbsite (0.4), quartz (0.3), chalcedony (0.14)	232-387	89-159	40-135 CO ₂ 9-30 H ₂ S	-
Acid reservoir	muscovite (5), pyrite (4), kaolinite (1), alunite (0.9), sulphur (0.8), gibbsite (0.7)	200-274	121-139	356 CO ₂ 24 H ₂ S	chlorite (5.53), chrysotile (0.16), talc (5.04)

(B)

Sample	In first step equilibrated mineral phases	In final step supersaturated mineral phases (SI)
Neutral springs	quartz (1.4), chalcedony (1), amorphous silica (0.16)	albite, anorthite, aragonite, calcite, chlorite (11), chrysotile, dolomite, fluorite, goethite, hematite (8), illite, k-feldspar, muscovite (11), mackinawite, pyrite, quartz, rhodochrosite, talc (7)
Acid springs	quartz (1.8), chalcedony (1.3), amorphous silica (0.5)	albite, anorthite, aragonite, ca- montmorillonite, calcite, chlorite (22), chrysotile (11), dolomite, fluorite, gibbsite, goethite, hematite, illite, k-feldspar, muscovite (7), kaolinite, mackinawite, pyrite (7), quartz, siderite, talc (15)

Geothermometer calculations

Calculated reservoir temperatures based on well water sample composition mostly underestimate the measured borehole reservoir temperature (Fig. 21). The best fit for calculations in acidic regime has been achieved by adiabatic quartz geothermometry. Na/K-Giggenbach cation geothermometry resolves the second best results. In neutral conditions, the smallest discrepancies to measured reservoir temperatures are satisfied with Na/K-Giggenbach geothermometry. Na/K-Fournier geothermometry achieves the second best results (Fig. 21).

Calculated reservoir temperatures based on hot spring samples using the quartz conductive geothermometer mostly underestimate observed reservoir temperatures from borehole-measurements. However, they are overestimated by Na/K Giggenbach geothermometry (Fig. 21). The error ranges are the smallest in case of quartz conductive geothermometry for acidic springs and in case of Na/K Giggenbach for neutral springs (Fig. 21).

Fig. 21 Comparison of modelled and measured reservoir temperatures based on well water samples (A) and hot spring samples (B). Acidic samples in green, neutral samples in blue

2.2.4 Discussion

Characterizing fault zones in geothermal systems plays a key role to improve the reservoir performance. As faults might behave as barriers or conductors against the fluids, they basically control the subsurface fluid flow processes (Moeck and Dussel, 2007). This fluid flow determines the retention period of fluids in the reservoir rock, which significantly affects the water-rock interaction. Water-rock-interaction, in turn, is one of the main processes leading to variety in geochemical properties of fluids and rocks (Arnorsson, 2000). Therefore, geochemical parameters can be used to locate and characterize fault zones. In this study, several examples are presented to exemplify how to trace fault zones using geochemical investigations.

This study shows faults in the Lahendong reservoir acting as barriers in horizontal direction preventing fluids from diluting each other. Faults are boundaries between two reservoir compartments containing acidic and neutral water, respectively (Brehme et al., 2014; Fig. 15, Fig. 22). On the other hand, faults open vertical pathways for fluids to rise towards the surface. At the surface, hot springs are located along the faults, especially at fault intersections, e.g. acidic springs appear on top of acidic section of the reservoir (Fig. 15). There, the deep acidic water exists due to H_2S degassing from a magma chamber beneath Lake Linau (Brehme et al., 2014). However, meteoric water infiltrates through faults and therefore dissolves H_2S , which lowers the pH and increases SO_4 content. In detail, H_2S reacts with O_2 -rich meteoric water to SO_2 and H_2O , which results in acid

H₂SO₃. On map view, M9 and M13 show acidic springs, which are located off-fault spots (Fig. 15). These spots are off the fault because their rise is not related to permeable fault zones. These are steam-heated springs, where the shallow groundwater is heated and acidified by deeper-originated rising gases. In the steam-heated springs pH and Cl⁻ concentrations are typically substantially low. The acid water dissolves minerals, especially metals, from the volcanic host rocks leading to increased SO₄⁻, Fe-, Mn- and Al-concentrations (Arnorsson et al., 2007).

Another approach to specify the water origin would be to focus on Cl⁻ and B-concentrations. In thermally heated water, such concentrations are much higher compared to fresh cold water. This is probably due to the long existence period of thermally heated water in the reservoir (Arnorsson, 1985). In the Lahendong reservoir, thermally heated water is produced through the well “LHD 23”. This well brings Cl⁻ concentration of 1559 mg/L and B-concentration of 13.1 mg/L. However, the rest of the neutral water wells show mostly lower concentrations of Cl and B. The lowest Cl and B concentrations are seen at the well “LHD 5” (Fig. 18). The content of the water produced at this well is diluted with cold water near the surface infiltrating through a nearby fault (Fig. 22, Brehme et al., 2014). Similar trends have been observed for correlation of electrical conductivity with Cl⁻ and B-concentrations, because Cl is the dominating element in water composition. Observations are interpreted to represent that the composition and the location of reservoir water is controlled by fluid flow along the vertically permeable fault zones in Lahendong field.

Fig. 22 Conceptual geohydrochemical model of the study area, described by cross-sections with geological layering, fault location, temperature distribution, sample points and alteration patterns, (modified after Brehme et al., 2014; Utami, 2011)

The faults and fractures have an effect also on temperature and productivity of the reservoir. In Lahendong, the northern section of the reservoir is 60°C cooler than the southern section while its productivity is five times higher. Despite the lower temperature, this substantially high productivity is probably due to existence of vertically permeable fractures increasing the fluid flow. These fractures allow also infiltration of cold surface water into the reservoir, which leads to lower reservoir temperatures in this particular area (Fig. 22).

Another important process changing the properties in a geothermal reservoir is the interaction between water and rock. Basically, mineral composition of reservoir rock changes during chemical reactions with water. The main requirement for such reactions is enhanced fluid flow. The modification of rock depends on the fluid type. In Lahendong, the rocks hosting the acidic water contain more clay and sulphur minerals. Numerical modeling results from this study show that acidic and neutral content play different roles on chemical reactions. This confirms that the acidic water alters the host rock more than the neutral water does (Fig. 22). Clay minerals, such as chlorite, mica and illite exist in rocks hosting acidic waters due to the chemical process leading to hydrothermal alteration of primarily abundant minerals. Primary minerals (i.e. feldspar) are altered to secondary minerals, which are more stable, such as clays, i.e., illite, kaolinite or smectite (John, 2007; Utami, 2011). Mineral modifications have been intensively studied in the

Lahendong geothermal field. Alteration patterns are particularly widespread in the northern section of the reservoir, which is acidic and highly fractured (Utami, 2011, Fig. 22). To sum up, rock alteration is mainly controlled by water-rock-interaction in highly fractured and therefore permeable areas accommodating increased fluid flow. Therefore, zones of high alteration indicate areas of increased fluid flow. However, alteration of the host rock can later decrease the permeability by filling of fractures with secondary minerals.

Furthermore, the increased fluid flow leads to slow equilibration of waters. Geothermal waters being in equilibrium stage are suitable for geothermometer calculations. In other words, large error ranges in geothermometer calculations give a constrain regarding the equilibration and therefore the fluid flow of a geothermal field. In Lahendong, geothermometer temperatures have been calculated using the Na/K Giggenbach geothermometer even though the wells do not satisfy the fully equilibrium stage. Therefore, the temperature calculation shows high errors ranging between 10% and 30%. In Lahendong, only water from the well “LHD 10” shows equilibration stage. The well is located away from fault zones. Calculated temperatures at well “LHD 10” and “LHD 12” represents the best case, where the errors range at 3-11% bounds compared to the measured values. Increased fluid flow prevents the wells from equilibration stage in the Lahendong geothermal field.

Degassing and boiling due to pressure release are the further processes driving the fluid flow/phase change in this geothermal system. Degassing is mainly observed in the northern section of the acidic reservoir. This area hosts the highest CO₂ and H₂S concentrations, as measured in discharge at the well “LHD 23”. At the surface, gas discharge is seen at several fumaroles around the Lake Linau. Furthermore, increased electrical conductivity has been measured in the northern section of the reservoir. This suggests a high salinity content that is caused by subsurface boiling evaporating the water and wasting the heat from the geothermal fluid (Arnorsson, 2000). Eventually, the increased electrical conductivity and therefore high salinity locates low temperature regions in that area.

In the Lahendong geothermal system, hydraulic conductivity of fault zones strongly influences geohydrochemical reservoir characteristics. The observations mentioned above show that the permeability controls fluid flow and distribution of water types. The fluid flow in fractures influences reservoir-temperature, alteration degree of host rocks and productivity of the geothermal field. Main processes controlling the fluid flow and phase change in this environment are degassing and water-rock-interaction.

2.2.5 Conclusion

In this study, geohydrochemical data are investigated to understand hydraulic conductivity of fault zones. Investigated geohydrochemical properties are fluid- and rock-composition and the interaction between fluids and rocks. These properties depend strongly on fluid flow, which is increased in high permeable areas.

Geohydrochemical properties are analyzed using on-site measurements, samples and verified by results from numerical modeling. Measurements show two reservoir sections reflecting different geohydrochemical properties and therefore suggesting a horizontally impermeable fault representing a boundary between different chemical regimes. One section is characterized by acidic water, considerable gas discharge, high productivity and strongly altered rocks. The other section hosts neutral waters, high temperatures and less altered rocks. Those reservoir conditions observed on-site have been confirmed by numerical models.

The combination of methods in this study suggests that the geohydrochemical reactions are mainly controlled by fluid flow through the faults/fractures. Fluid flow increases in permeable areas and causes rise or infiltration of fluids at such vertically permeable spots. Therefore, the location of hot springs or fluid loss is used to investigate permeability of fault zones.

Subsurface fluid flow causes enhanced water-rock-interaction. Increased chemical activity results in alteration of rocks. Hence, altered rocks give evidence for areas with primary permeability reflecting increased water-rock-interaction. Reactions between water and rock, and the thermal environment are reasonably converged by numerical models. Combination of all those approaches allows characterizing the permeability distribution along the geothermal reservoirs.

Investigating the permeability distributions along the geothermal reservoir is crucial for site selection and smart drilling strategies. They support a sustainable exploitation of the geothermal field avoiding risks, such as low-productive wells or the production of highly corroding waters. In this frame, the developed conceptual models allow reconstructing observed patterns and therefore forecasting potential physical developments in response to the use of a geothermal field.

2.3 Influence of fault zones and fluid-properties on subsurface fluid flow in the Lahendong geothermal field - insights from numerical simulations

2.3.1 Introduction

Geothermal energy is an essential component to supply future energy demands. However, it is required to develop new geothermal sites and improve the performance of existing systems to satisfy this demand. Different geoscientific approaches are combined to assess the potential of new sites as well as to improve existing geothermal systems.

The productivity of a geothermal field mainly depends on subsurface fluid flow, which is in active tectonic regions controlled by permeability of fault zones (Moeck, 2014). In that frame, the primary focus is to locate and characterize faulted areas in geothermal fields. Subsurface fluid flow is controlled by pressure and temperature in the reservoir. Those parameters control the phase transition, density and viscosity of the fluids and therefore provide additional constraints for reservoir characterization. This study employs numerical modeling for reservoir analysis to quantify influence of fault zone permeability, physical fluid properties and phase transition on subsurface fluid flow in geothermal reservoirs.

The test ground for this study is the Lahendong geothermal field located in Sulawesi, Indonesia. The field is owned and operated by P.T. Pertamina Geothermal Energy and has an installed capacity of 80 MWe. Geothermal exploration started in the early 1970's including geophysical and geochemical approaches. It is a magmatic structurally controlled system. Faults generally act as horizontal fluid barriers and vertical fluid conductors (Brehme et al., 2014). As a result, hot springs mainly arise upward along the vertically permeable faults. Numerous drilling data and surface measurements allowed a detailed characterization of the geological and hydrogeological setting of the study area (Fig. 23, Brehme et al., 2011, 2013, 2014; Wiegand et al., 2013). The presented models here are developed for investigating subsurface fluid flow including the fault zones in the Lahendong geothermal field. The preconditions of the field are presented and followed by an introduction to the modeling approach. The results reproduce measured pressure, temperature and 2-phase proportion in the model domain.

Numerical models for hydraulic, thermal and fluid phase conditions have been increasingly used to understand the set up and productivity of geothermal systems. A general overview of geothermal models has been given by O'Sullivan et al. (2001). Additionally, there are several sites exemplifying similar characteristics. The Kakkonda

geothermal site consists of two reservoirs in various depths with different fluid properties. There, results from fluid flow analysis show the importance of fractures for fluid transport enhancing the recharge into or discharge from the reservoir (McGuinness et al., 1995). Models for the Seferihisar–Balçova field focus on the fluid flow inside of faults. Results show an enhanced upward heat transport through fluids from bottom of the geothermal system (Magri et al., 2011). Dachny geothermal models show fault controlled temperature, pressure and phase propagation in this reservoir. Taking everything into account, phase transition-based consideration of fluids allowed a more realistic simulation of fluid/head flow compared to the assumption of stable water phase in the reservoir (Kiryukhin, 1996).

Detailed investigation of subsurface fluid flow is a crucial step for site selection and smart drilling strategies. The presented numerical simulations will provide insight into understanding the subsurface fluid flow considering hydraulic conductivity of faults and physical properties of the fluids. It ensures productive as well as sustainable operation of geothermal fields avoiding risks, such as wells drilled on non-fractured or cold zones, and the circulation of highly corroding waters. Although the target area is Lahendong, the models are applicable for other geothermal sites consisting of similar boundary conditions.

Fig. 23 Topographic map of the study area with geological features, water and rock sample locations and model cross section

2.3.2 Precondition

Hydrogeological set-up

The overall driving force for the fluid flow in the Lahendong geothermal system is the SW-NE oriented natural hydraulic gradient. Beneath Lake Linau, the direction of fluid flow is slightly rotated to WSW – ENE. The direction of fluid flow varies through the geothermal site due to horizontal partitioning of reservoir by relatively less permeable fault zones. The basic sections are located in the south, in the east and beneath of Lake Linau. The types of fluid change from one section to another, e.g., an acidic highly saline type beneath Lake Linau and a neutral low saline type south and east of Lake Linau. The horizontally impermeable faults prevent the fluids from diluting each other. However, faults are rather permeable in vertical axis, which allows recharge of the system through the faults. Rainwater infiltrates at a fault in the NW, at Mt. Lengkoan, and creek water infiltrates into the normal faults at Lake Linau. The hydrothermal system discharges into Lake Linau and towards the NE, as driven by the hydraulic gradient.

The fracture network along the area is characterized by strike slip faults and normal faults. The sinistral faults strikes N 40° clockwise and dips towards the SE. Left step over on the strike slip faults forms an extension basin in the central study area. Normal faults at the extension basin strike NW and dip 70° - 80° beneath Lake Linau (Brehme et al., 2014).

Lithology

Lahendong area is mainly characterized by Pre-, Post- and Tondano formation of Plio- to Pleistocene age (Koestono et al., 2010). The rocks are typically andesite, volcanic breccia and tuff. Those types have been sampled from borehole-cores and used to determine porosity, permeability and thermal conductivity. Effective porosity and matrix permeability has been analyzed using cylindrical shaped specimen with a dimension of 5cm x 5cm x 2.5cm parallel to the bedding. Thermal conductivity has been measured on plain sections of dried cores. The experimental set-up consists of a gas-permeameter for determining matrix permeability, of a helium pycnometry for effective porosity measurements and of an optical scanner for thermal conductivity measurements (Popov et al., 1999). These parameters have been measured and averaged for the three rock types (Table 6). Andesite has an effective porosity of 3.7%, a permeability of $5.26\text{E-}15\text{ m}^2$ and a thermal conductivity of 1.782 W/m/K. Tuff has a porosity of 7.7% but the lowest permeability of $1.97\text{E-}15\text{ m}^2$ and a thermal conductivity of 1.615 W/m/K. Volcanic breccia is the most permeable layer with an effective porosity of 10.5%, a permeability of $2.32\text{E-}14\text{ m}^2$ and a thermal conductivity of 1.624 W/m/K. Reservoir rocks reflect

generally low matrix permeability suggesting fracture-controlled fluid flow through the aquifer.

Table 6 Thermal and hydraulic parameters of the Lahendong reservoir rocks measured in laboratory

Sample	Rock type	Effective Porosity [%]	Thermal conductivity dry [W/m/K]	Matrix-Permeability [m ²]

2.3.3 Model set-up and parameter estimation

Numerical models developed for the study area represent the initial condition of the reservoir. In this study, the commercial finite-element software FEFLOW is used to model pressure-driven and thermally induced density- and viscosity-driven fluid flow. Details on the software and the parameterization can be found in (Diersch, 2014). TOUGH2 and the equation of state module for water is used for modeling 2-phase-propagation in the reservoir (Pruess, 1991).

FEFLOW-model

The FEFLOW model geometry is a 2D vertical NE-SW trending cross section extending 6 and 3 km in horizontal and vertical axis, respectively. The homogeneous and isotropic geological layers are layered horizontally. Two faults in the middle of the model, striking perpendicular to the cross section, dip with 84° towards a magma chamber beneath Lake Linau (Fig. 24). Details on structural and geological components of the modeled region have been already explained in section 2.1 (Brehme et al., 2014).

The mesh used for the numerical simulation in FEFLOW consists of 81,579 nodes and 150,723 elements that are more intensified surrounding the faults because of expected gradients due to parameter contrast. Accordingly, physical properties of the faults are slightly adapted, e.g. lower and higher permeability in horizontal and vertical axis, respectively. The definitions for the modeled grids along the faults are as follows: Vertical permeability of $1.3\text{E-}11 \text{ m}^2$, horizontal permeability within the range of $1.3\text{E-}13 \text{ m}^2$ - $1.04\text{E-}19\text{m}^2$, porosity at 30%, and a thermal conductivity of 1.782 W/m/K . The Lake Linau is included in the model and the corresponding grids are defined by a porosity of 30%, a permeability of $1.3\text{E-}11 \text{ m}^2$ and a thermal conductivity of 0.597 W/m/K . Grids for remaining geological layers have been defined based on the laboratory measurements (Table 6). The model simulates transient flow and thermohaline transport in saturated media. The modeling is done for 1,000,000 years of time period with an increment of $1\text{E-}06$ days at the beginning.

Hydraulic boundary conditions in the model describe groundwater heads and recharge amounts. The hydraulic head at the left model border is 860 m and at the right border 485 m. The left hydraulic head represents infiltration of surface water into a fault, striking perpendicular to the model. Hydraulic head at the right border is adapted to borehole measurements in that area (Brehme et al., 2014). Fluid movement is constrained by no-flow boundary at the bottom, recharge through the surrounding fault zones and the spots of low hydraulic heads in the right model area. Infiltration into the fault zone to the southwest of Lake Linau is described by limited fluid-influx. The quantity is depending on the hydraulic head throughout simulation and at maximum $1037 \text{ m}^3/\text{d}$. Injection into the fault right of Lake Linau is constant $432 \text{ m}^3/\text{d}$ as described by an injection well. Groundwater recharge is set at the NE top surface to 1.13 mm/d . Discharge of the system is in the central study area mainly towards Lake Linau and across the NE model boundary. Initial hydraulic head condition is 500 m (Fig. 25).

Initial temperature is set to 200°C . The thermal boundary conditions are time-invariant and fixed temperatures and heat flux. Thermal gradient is 120°C/km at the model boundary on the left and constant temperature is 350°C at the magma chamber. Temperature of water infiltrating into faults and groundwater recharge is 28°C . Heat flux is set to 60 mW/m^2 at the bottom model boundary. This value is fixed based on the results from Neben et al. (1998) and Delisle et al. (1998). Increased heat flux in volcanic areas, as mentioned by Nagao and Uyeda (1995), is incorporated in this model by high temperature at the magma chamber (Fig. 24).

TOUGH2-model

Geometry of the TOUGH2 model is similar to the FEFLOW set up besides the top and bottom model boundary. Top surface is at the bottom of the lake and bottom model boundary is the top of the magma chamber. The model consists of 10,254 elements that are more intensified surrounding the faults. The modeling is done for a time period of 1,000,000 years. The model set up is held simple with four different geological elements, e.g. two faults, area between the faults and the rest of the model. The porosity, permeability and heat conductivity is averaged for each element.

Boundary and initial conditions have been fixed according to the FEFLOW model despite some slight changes, e.g., infiltration in TOUGH2 is fixed at the top of the faults and expressed by mass flow and enthalpy and the temperature gradient of $120^{\circ}\text{C}/\text{km}$ is set throughout the entire model (Fig. 24).

Fig. 24 Cross section of the modelled area with boundary conditions and location of observation points

2.3.4 Results

Numerical simulation is performed to obtain the best fit to the measured data changing the permeability, physical properties and 2-phase propagation of fluids. Simulated pressure, temperature and 2-phase patterns giving the best data fit are considered to generate the final model developed for the Lahendong.

Parameter testing

Parameters tested are temperature, permeability and infiltration rates. Porosity change and heat flux variation is negligible and therefore remained constant (Ondrak et al., 1998). Initial values are defined based on bore log data and laboratory measurements. The parameters are adjusted in a stepwise way according to the modeling results. Temperature conditions tested in the model are the thermal gradient and temperature at the magma chamber. The natural thermal gradient of 120°C/km is found to be the best fitting simulated gradient. A temperature range of 100 – 150°C/km has been tested during the simulation. The temperature of magma chamber is tested within a range of 50°C – 400°C, and the optimum value is found at 350°C. Permeability has been tested at different sections of the model, separately, e.g. faults and the rest of the model area. Simulation results show strong discrepancies between modeled and measured pressures and temperatures beneath Lake Linau. These large misfits are minimized including an additional fault zone, which is not seen at the surface in this area. The permeability test range varies between 1E-05 and 1E-20 m² in horizontal direction and between 1E-03 and 1E-20 m² in vertical direction. In general, defining a direction dependent permeability improves the data fit rather than using similar permeabilities in all directions. This is probably due to the fractures increasing the permeability mostly in vertical axis. The best directional combinations of permeability are not the same for FEFLOW and for TOUGH2 model. The permeability range (x/y) for the faulted/fractured zones: 1E-13/1E-11 m² (FEFLOW) and 1E-12/1E-10 m² (TOUGH2); for the area falling between the faults: 1E-15/1E-13 m² (FEFLOW) and 1E-19/1E-15 m² (TOUGH2) and for the model rest: 1E-17/1E-13 m² (FEFLOW best fit for temperature) or 1E-13/1E-13 m² (FEFLOW best fit for pressure) and 1E-10/1E-13 m² (TOUGH2). Surprisingly, TOUGH2-values for the model rest vary from the assumption, that the vertical permeability is higher than the horizontal. Infiltration rates have been tested considering water recharge through the faults. The tested range is 0.0007 – 12 kg/s at 28°C. The best fitting values of 5 and 12 kg/s are in good agreement with measured rates. The total number of models run is 100 (Table 7).

Pressure

The pressure distribution in the study area is controlled by groundwater flow in low permeable rocks and vertically high permeable fault zones. Isobars drop following the natural hydraulic gradient from SW to NE. The SW section of the system is over-pressurized, which is caused by infiltration into low permeable layers. The wells existing in this region are artesian-type. Overpressure releases through the fault zone southwest of Lake Linau and discharge towards surface. The pressure drops occur up to 20 bars while entering the faults. Nevertheless, the constrained fluid flux boundary condition on top of

the fault causes limited outflow and pressure increase in the upper part of the fault (Fig. 25).

Temperature

Convective heat transport dominates the temperature distribution along the Lahendong geothermal reservoir. Isotherms generally follow the SW-NE oriented flow pattern, the rise and the infiltration of fluids. Upwelling of isotherms between the faults verifies water rise towards the Lake Linau. Infiltration of cold water causes down welling of isotherms particularly on the northeast section of the model. Temperature is locally increased at the bottom of the model surrounding the magma chamber. The highest temperatures therefore appear at the bottom of the model in the southwest (Fig. 25).

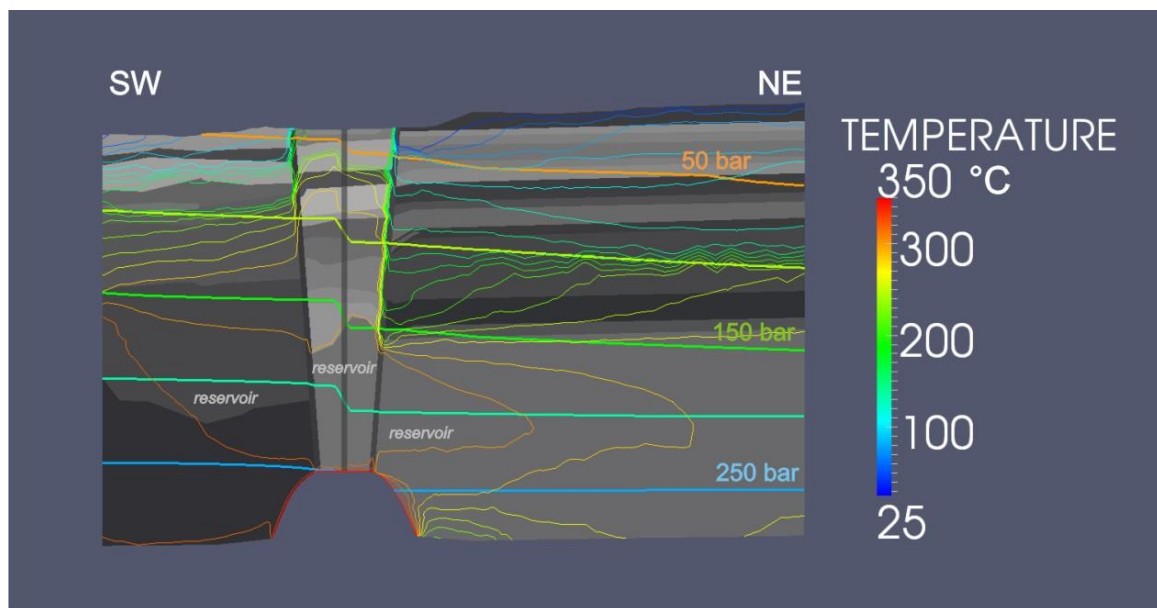

Fig. 25 Modelled temperature and pressure distribution in the study area

2-phase

2-phase propagation of fluids through the reservoir depends on local pressure and temperature distribution. Due to high pressure at depth, the fluid remains in liquid phase. Pressure release in shallower depths causes phase transition to steam, especially near the faults. Steam proportion goes up to 100% inside the faults and remains at 40% to 70% at off-fault locations (Fig. 26).

Fig. 26 Modelled 2-phase distribution in the study area. 1 is 100% steam and 0 is 100% fluid

2.3.5 Discussion

Investigation of subsurface fluid flow in geothermal reservoirs is crucial for sustainable exploitation avoiding drilling into less productive areas. Subsurface fluid flow may be locally diffused by fault zones, fluid phase transition or physical properties of water (e.g. density or viscosity). The influence of these parameters on the fluid flow has been investigated in Lahendong geothermal reservoir using hydrothermal- and 2-phase simulations.

Fault-controlled fluid flow processes have been simulated by numerical modeling aiming to get the best-possible fit to the measured data. Misfit has been iteratively measured at several observation points (Fig. 27). Generally, modeled values are in good agreement to measured ones. Nevertheless, observation points near to fault zones give relatively large errors (LHD 5, LHD 28). This is probably due to the complicated flow processes or strong structural variation in faulted areas. Average deviation of simulated hydraulic head and the temperature are 4% and 22%, respectively. Deviation of heat and fluid budget for the whole model is 1% and 0.01%, respectively.

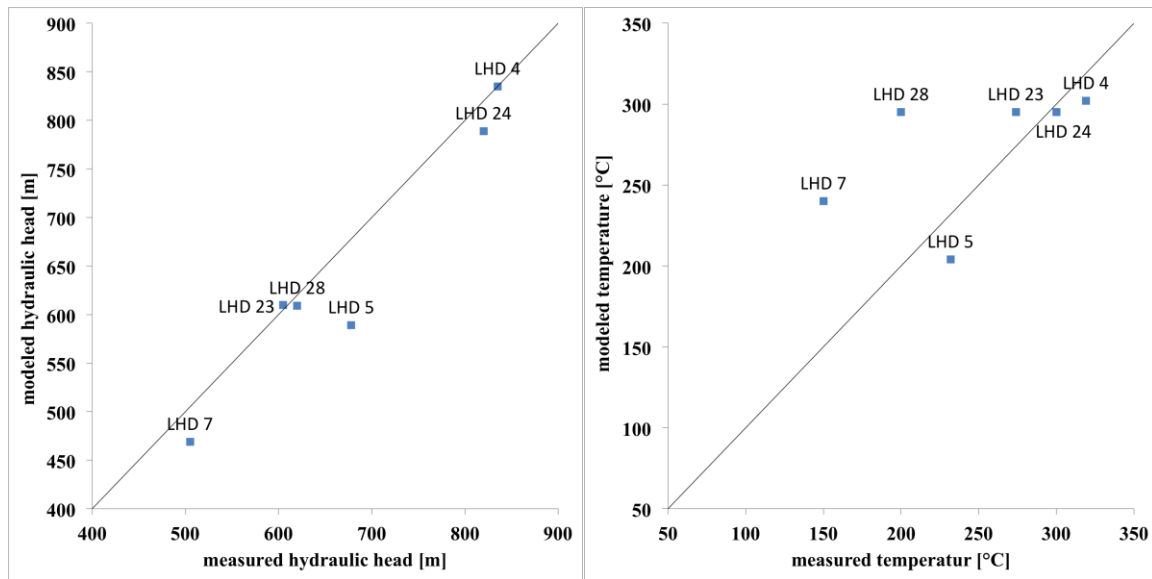

Fig. 27 Modelled versus measured hydraulic head and temperature at selected observation points

Adjusted model parameters are porosity, permeability and heat conductivity. From those parameters, only permeability has been tested in a specific range during simulation. The influence of porosity and heat conductivity on fluid flow is negligible (Ondrak et al., 1998). Measured permeabilities represent matrix permeability of rocks. Nevertheless, the permeability in reservoir rocks might be locally increased due to fracture formation. It might also be decreased due to alteration and sealing in faults. The measured permeability is $7.4E-15 \text{ m}^2$ on average, which remains within typical permeability range for fractured igneous rocks (Schön, 2004). Permeability for volcanic breccias ranges typically between $5.1E-12 \text{ m}^2$ and $3E-15 \text{ m}^2$ and tuff permeabilities range between $7E-12 \text{ m}^2$ and $7E-17 \text{ m}^2$ (Klavetter and Peters, 1987). In the Wairakei geothermal field, simulating the impermeable layers resulted in permeabilities of $E-14 \text{ m}^2$ and $E-18 \text{ m}^2$, in horizontal and vertical axis, respectively (Mercer and Faust, 1979).

Permeability is the main factor influencing subsurface fluid flow and temperature distribution in the Lahendong reservoir area. Subsurface fluid flow is characterized by local hydraulic heads, which shows high variations at different sections of the study area. Each section has its own flow regime. The sections are separated by faults in the south and the north of Lake Linau, acting as fluid barriers. Across these barriers, the hydraulic head drops by 150 m. A similar pattern has been observed beneath the Lake Linau. In this area, another fault zone has been implemented into the model in order to get a reasonable fit between the modeled and the measured data. The fault zone beneath Lake Linau remains under lake water and therefore is not traced at the surface. The low permeability in horizontal axis through the faults pushes the fluids vertically towards the hot springs at surface. It also allows surface water to infiltrate into the reservoir in case the pressure

within the fault zone is low enough. This vertical fluid movement eventually controls the temperature distribution in the reservoir. Upward migration of deep hot water increases the temperature, while infiltration of cold surface water causes local drop of temperature within the fault damage zone.

Also, fluid phase transition has a major effect on fluid flow and temperature field in the reservoir. Modeling the 2-phase flow requires adapting the permeability in a parameter range in the order of magnitude 4 compared to models based on pure water. This is because fluid flow properties, especially density, dramatically change during the phase transition. The area reflecting the most prominent phase change remains beneath Lake Linau. Especially, the modeled permeabilities are substantially low in this area. Average error for temperature simulation remains at 25% adjusting the best possible permeability range. The best fit for pressure simulation is 69%. Here, relatively high error bounds are probably due to a simplified model setup in TOUGH2. Furthermore, it might be caused by more complicated flow characteristics in comparison to pure water simulation in FEFLOW. The simplification has no influence on the overall understanding of the system based on the direction of fluid flow as well as the distribution of pressure, which remain almost identical in all models.

Table 7 Parameters of the best models obtained in FEFLOW and TOUGH2

	Geology	Porosity [%] according to laboratory measurements	Heat conductivity [W/m/K] according to laboratory measurements	Permeability x best fit [m ²]		Permeability z best fit [m ²]
				<i>best temperature fit</i>	<i>best pressure fit</i>	
FEFLOW						
	Andesite	3.7	1.782	1.30E-18	1.3E-14	1.3E-14
	Volcanic breccia	10.5	1.624	1.30E-16	1.3E-12	1.3E-12
	Tuff	7.7	1.615	1.30E-17	1.3E-13	1.3E-13
	Faults	30	1.782	1.3E-13	1.3E-13	1.3E-11
	between faults	according to layer	according to layer	1.3E-15	1.3E-15	1.3E-13
	Lake	30	0.597	1.3E-13	1.3E-13	1.3E-13
TOUGH2						
	rest of model	7.3	2	1.3E-10		1.3E-13
	faults	30	2	1.3E-12		1.3E-10
	between faults	7.3	2	1.3E-19		1.3E-15

In summary, the most important factors influencing the reliability of numerical reservoir models are permeability and fluid phase transition. The permeability of fractures directly influences the productivity of the reservoir (Blöcher et al., 2010). Permeabilities should be decreased to realize similar flow behavior in 2-phase regimes because flow behavior of steam and pure water is similar only in case of low permeability. Pure water cannot move at permeabilities below 5E-18 m² (Pruess and Narasimhan, 1982).

A previous numerical model for the Lahendong site has been set up in TOUGH2 and aimed at forecasting the reservoir behavior during exploitation until 2036. With a

production of 60 MW_e it predicts a pressure drop of 10 bar. However, the forecast results are uncertain due to lack of measured pressure draw down data (Yani, 2006).

2.3.6 Conclusion

The primary focus of this study is to understand the influence of fault zones and fluid properties on subsurface fluid flow in geothermal reservoirs. This is done using numerical reservoir simulation. Understanding the fluid flow is important for analyzing the productivity of geothermal sites. The fluid flow mainly depends on rock and fault zone permeability, and also fluid properties. These processes have been considered in numerical models, which simulate local temperature and pressure conditions.

The numerical models represent the initial reservoir conditions, which refers to the case before production starts. Models are developed based on the conceptual models of the study area, which explain reservoir geometry, geological structures, temperature and hydraulic conditions. Temperature and pressure well-logs have been used for model calibration. The models are used to investigate the effect of permeability and fluid phase transition on fluid flow behavior.

Vertical and horizontal fluid flow is controlled by fault permeability. This characteristic is used to simulate different reservoir sections and vertical fluid rise towards the surface. Fluid flow is also influenced by fluid phase transition. Steam propagation at top of faults stimulates vertical fluid rise. However, in case of 2-phase flow simulations, permeabilities have to be lower to achieve same pressure and temperature conditions.

The overall shape of fluid flow direction trends in a SW-NE direction. Main recharge occurs by infiltration the surface water into the faults, especially in the SW and near to Lake Linau. Discharge is enhanced in highly fractured areas towards Lake Linau. Vertical permeability of faults allows fluids rising towards the hot springs at surface.

Results show that permeability and fluid properties have a similar weight to consider for simulation of a geothermal system. The geothermal system is mainly controlled by fluid flow in fractures/faults as well as phase transition depending on temperature and pressure conditions. The locally modified fluid flow can considerably influence the productivity of a geothermal field. Results also guide reservoir management in case of a potential for field extension, as performed in Lahendong.

3 Conclusions and outlook

The most efficient way for characterizing geothermal systems is the combination of methods to one multidisciplinary approach. This approach aims primarily at assessing the energy potential of a geothermal system. The energy potential is controlled by several reservoir conditions, while the most important one is fluid flow. Fluid flow in geothermal reservoirs is characterized by composition of fluids and permeability distribution along the field.

The composition of fluids and its effect on fluid flow is commonly considered to characterize geothermal reservoirs. However, the distribution of hydraulic conductivity in the subsurface, which is in active tectonic regimes mainly controlled by fault zones, is underestimated in geothermal reservoir characterization. Therefore, in this study, we addressed essential questions regarding characterization of geothermal fields, i.e., “What is the role of fault zones in geothermal fields?” or “What is the best combination of methods to characterize the efficiency of fault zones at geothermal sites?”. Test ground for this study is the Lahendong geothermal field. The approach integrates geological and geochemical results with numerical simulation.

Geological methods used in this study consist of structural-geological mapping, physicochemical measurements in fluids, surface tracer experiments and well-log analysis. Results from these investigations are combined in a conceptual fault model, which shows that the Lahendong reservoir is subdivided into different sections. The subdivision occurs at fault zones, which either act as fault-normal flow barriers due to sealing of the fault core, or as conductive pathways in the damage zone sub-parallel to the fault strike. The damage zone, especially in case of extensional faults, is characterized by fractures. Two fundamental phases of faulting have been identified by the structural investigations. These new observations describe the role of fault zones in geothermal fields, especially in the Lahendong area.

The main contribution of this study is to show that systematically performed structural analysis helps to understand the fluid flow in geothermal reservoirs. In that frame, present-day stress field provide insights into the hydrogeological role of fault systems. The spatial distribution of structural elements and their temporal evolution has been combined with their hydraulic properties to explain subsurface fluid flow. It has been confirmed that the hydrotectonic concept combining the tectonic and hydrogeological information essentially improves the understanding of subsurface flow of thermal fluids, which is the basic source of geothermal power plants.

Geohydrochemical methods used in this study consist of on-site physicochemical measurements, chemical analysis of samples and verification of those observations by the results from numerical modeling. Those investigations allow characterizing fluid- and rock-composition and the interaction between fluids and rocks. Measurements show two reservoir sections reflecting different geohydrochemical properties and therefore suggesting a horizontally impermeable fault representing a boundary between different chemical regimes. One section is characterized by acidic water, considerable gas discharge, high productivity and strongly altered and fractured rocks. The other section hosts neutral waters, high temperatures and less altered rocks. These reservoir conditions observed on-site have been confirmed by numerical models.

The results from geohydrochemical analysis show that the chemical reactions are mainly controlled by fluid flow through the faults/fractures. Fluid flow increases in fractured permeable areas and causes enhanced water-rock-interaction. Hence, evidences for enhanced water-rock-interaction, such as alteration patterns or type and location of hot springs, allow characterizing the permeability distribution along the geothermal reservoirs. This is crucial for site selection and smart drilling strategies, which supports a sustainable exploitation of the geothermal field avoiding risks, such as low-productive wells or the production of highly corroding waters with low pH values.

Numerical hydraulic simulations consider rock and fault zone permeability as well as fluid properties for the study area. Numerical analysis is performed built on the previously derived conceptual models in order to simulate local temperature and pressure conditions. Temperature and pressure well-logs have been used for model calibration. The main conclusion is that vertical and horizontal fluid flow is controlled by fault permeability. This characteristic behavior is used to simulate different reservoir sections with a general fluid flow in SW-NE direction. Recharge and discharge occurs along the faults, especially in the SE and near to Lake Linau. Fluid flow is also influenced by fluid phase transition. Steam propagation at top of faults stimulates vertical fluid rise, because steam propagates faster due to lower density. Therefore, in case of 2-phase flow simulations, permeabilities have to be lower to satisfy same pressure and temperature conditions.

Results from numerical simulations show that permeability and fluid properties has a similar weight to consider for simulation of a geothermal system. The geothermal system is mainly controlled by fluid flow in fractures/faults as well as phase transition depending on temperature and pressure conditions. Those parameters must be carefully considered for a sustainable exploitation of a geothermal reservoir. In summary, numerical

simulations allow predicting reservoir conditions in areas without measurements and for future scenarios.

The main conclusion of this study is that fault zones have an essential influence on geothermal reservoir behavior. The hydraulic conductivity of fault zones controls the subsurface fluid flow. To characterize hydraulic conductivity of fault zones, it is proposed to combine structural geological mapping with hydrogeological investigations. Furthermore, geochemical analysis of fluids and rocks broadens the understanding of flow directions and of quantity of fluid flow while numerical simulations allow modeling the permeability distribution in sparsely sampled spots of the target area.

The subsurface permeability distribution can also be characterized by tracer tests in wells or geophysical measurements at the surface. Tracer tests cover the local permeability distribution around the tested well or between several wells. Seismic investigations reveal subsurface distribution of geological layers and fault zones based on impedance-contrasts. Magnetotellurics measure the electrical conductivity and give information on geological layer properties. However, the resolution often does not allow to detect small heterogeneities on reservoir scale.

Understanding the permeability distribution along a geothermal reservoir is crucial for a sustainable exploitation of the reservoir. It allows managing a profitable set-up for production and injection locations before production starts. On the other hand, it ensures the constant fluid flow towards production wells in producing geothermal fields and reduces the risk for further drilling in the frame of field extension.

Acknowledgements

First of all I would like to thank my supervisors Prof. Dr. Martin Sauter and Prof. Dr. Günter Zimmermann for their support, encouragement and supervision. They gave me the chance to conduct the Ph.D. within the excellent research group of Prof. Dr. Huenges „International Research Centre for Geosciences (ICGR)“ at GeoForschungsZentrum Potsdam. Special thanks go to Prof Dr. Inga Moeck, Dr. Simona Regenspurg, Dr. Bettina Wiegand and Dr. Guido Blöcher for co-supervising my study.

The work has been funded by the German Federal Ministry of Education and Research under grant 03G0753A. This support is gratefully acknowledged. However, this study would not have been possible without support from Pertamina Geothermal Energy, who gave me access to the field and to data in Lahendong. Thanks a lot for the warm welcome and support during my visits to Indonesia, especially to Yustin Kamah and his team, to Harry, Agung, Marihot as well as Pudyo, Cici, Dhanie, Syamsul, Anggo, Imam, Wahyu, Sigit, Uus and all the teams from Lahendong, Ulubelu and Sibayak.

Special thanks to my colleagues at GFZ, especially to those involved in the project and those who assisted me during my accident in Indonesia: Ernst, Kemal, Makky, David, Philippe, Andhika, Nukman, Amela, Fiore, Sintia, Muksin, Yodha, Wiyono and to Bettina Wiegand, Ikhlas, Firman and Rasi at Georg-August-Universität Göttingen. I would like to appreciate Andhikas help during my first stay in Indonesia and the further support while communicating with our Indonesian colleagues. Special thanks to Kemal for always facing me with challenging questions and having a good word in hard times. Thanks to Alireza and Luca for the nice atmosphere in our office, which made it always easier to work. Special thanks go to Henning for teaching me fundamental physical laws if not accompanying me on a crazy trip through Iceland or North-Germany.

Prof. Dr. Manfred Hochstein is acknowledged for the fruitful discussions on geochemistry. Dr. Mauro Cacace and Dr. Warwick Kissling setting up the basis for the TOUGH2-model and always being a helping throughout improving the models and Dr. Till Francke for support in experimental setup of the tracer tests. I thank I.Piper, S. Tonn and K. Günther for fluid-analyses, R. Naumann, A. Gottsche, Mr. Liep and Ms. Ospald for geochemical analyses at GFZ Potsdam and TU Berlin. I acknowledge Prof. Dr. Dresen for access to the Helium-pycnometer, Dr. A. Förster for access to the optical scanning instrument and Dr. Harald Milsch, Bendix and Daniel for helping at the Gas-Permeameter. Thank you Harald for giving us advises how to handle the permeameter and answering all the questions coming up while interpreting the data.

I am very happy to have had my parents, my sister, the rest of my family and my friends by my side during the last four years. I would like to thank them for their continuous and unconditional support, encouragement and understanding. Thank you Christian for always trusting in me.

Finally, I owe a special gratitude to Fatih Bulut, who reviewed all the thesis one by one, took care of linguistic issues, provided me with matlab scripts, discussed scientific problems and questioned my conclusions. Fatih thank you for coming into my life and staying there.

Curriculum vitae

Maren Brehme

Personal details

Date and place of birth October 14 1983, Berlin

Nationality German

Positions held

10/2010 – 08/2014 Research assistant within the project “Sustainability concepts for exploitation of geothermal reservoirs in Indonesia – capacity building and methodologies for site deployment”

Helmholtz-Center Potsdam, German Research Centre for Geosciences (GFZ-Potsdam), International Centre for Geothermal Research

11/2009 – 10/2010 Research assistant within the project “Research Network Water in Central Asia (CAWa)” studying the “Dynamics of Ground-Surface-Water Interaction in the Aral Sea Region”

GFZ-Potsdam, Climate Dynamics and Landscape Evolution

09/2009 – 10/2009 Project engineer

KWS Geotechnik GmbH, Berlin, (Consulting Engineers for Hydrogeology)

03/2009 – 06/2009 Project coordination assistant

GFZ-Potsdam, Scientific Executive Board

12/2005 – 10/2007 Student research assistant

GFZ-Potsdam, Scientific Executive Board

Education

Since 10/2010 Georg-August-Universität Göttingen; PhD-Student

“The role of fault zones on structure, operation and prospects of geothermal reservoirs - A case study in Lahendong, Indonesia”

10/2003 – 11/2008 Technische Universität Berlin; Dipl.-Ing. (Hydrogeology)

“Groundwater composition and groundwater flow in the area of Dörtyol/Hatay/Turkey”; grade: 1.7

09/1996 – 06/2003 Droste-Hülshoff-Gymnasium; Abitur
