Abstract

Dysferlinopathies are a heterogeneous group of congenital muscle disorders characterized by late-onset muscular dystrophy and increased muscle prowess before onset of symptoms. Mutations in the *DYSF* gene encoding the protein dysferlin have been identified as the common genetic cause of this rare disease spectrum. However, little is known about the pathomechanism leading to muscle degeneration and therefore, no curative treatment is available. Dysferlin is a tail-anchored multi-C2 domain protein belonging to the ferlin protein family. For a long time, it has mainly been implicated in membrane repair. In recent years, new evidence uncovered an additional and fundamental role for dysferlin: the formation of the T-tubule system in skeletal muscle.

The aim of this study was to further elucidate the cellular role in skeletal and heart muscle and the trafficking of dysferlin. This would help to reveal the molecular pathomechanism of dysferlin-deficient muscular dystrophy and give the possibility to identify new targets for the development of therapeutic approaches.

The finding of an abnormal T-tubule system in developing dysferlinopathy patient myotubes suggests that dysferlin is essential during a very early stage of T-tubule biogenesis in skeletal muscle. Not only the T-tubule system in skeletal muscle, but also the cardiac tubular system of dysferlin-deficient mice is altered with loss and axialization of membrane tubules. This finding, together with the localization and increased expression of dysferlin at the developing T-tubule system in cardiomyocytes, support the role of dysferlin as a key player of cardiac T-tubule biogenesis. Furthermore, these findings may explain the pathology of dysferlin-deficiency in skeletal and heart muscle. The investigation of the cellular trafficking shows that mutated dysferlin is retained in the endoplasmic reticulum or Golgi network and provides evidence that functional dysferlin follows the secretory pathway to reach the plasma and T-tubule membrane. Treatment with the chemical chaperone 4-phenylbutyrate (PBA) increases the steady-state protein levels and partially rescues functional deficits of dysferlin mutants. Thus, PBA might be a potential therapeutic for the treatment of dysferlinopathy. Another therapeutic approach is the induction of translational readthrough by aminoglycosides in patients harboring nonsense *DYSF* mutations. The systematic analysis of readthrough induction for all recurrent *DYSF* nonsense mutations revealed a high variety of readthrough efficiency and might provide a suitable prediction for the treatability of dysferlinopathy patients. This gives the possibility to selectively treat patients with high therapeutic potential as aminoglycosides are associated with severe adverse effects.

1 Introduction

1.1 Skeletal muscle anatomy and function

The skeletal muscle fiber is a syncytium originating from fusion of myogenic precursor cells, myoblasts, into elongated multinucleated myotubes during myogenesis (Holtzer and Abbott, 1958). The highly organized complex of large tube-shaped cells is one of the prerequisites for optimal force development. Another requirement for precise muscle function is the temporal coupling of the motor neuron signal to the contraction of the myofiber. Muscle fibers possess an extensive membrane system, the transverse tubule system (T-tubule system) (Franzini-armstrong and Porter, 1964), composed of tube-shaped plasma membrane (sarcolemma) invaginations with a diameter of approximately 20 – 40 nm which transversally penetrate the whole fiber (Franzini-Armstrong et al., 1975). The T-tubules conglomerate with the terminal cisternae of the longitudinally orientated sarcoplasmic reticulum (SR) to form anatomical and functional structures called triads. One triad is composed of one T-tubule enclosed by two SR cisternae (**Figure 1**). The T-tubule and SR membranes are located in very close proximity with a gap of 12 nm (Boncompagni et al., 2006).

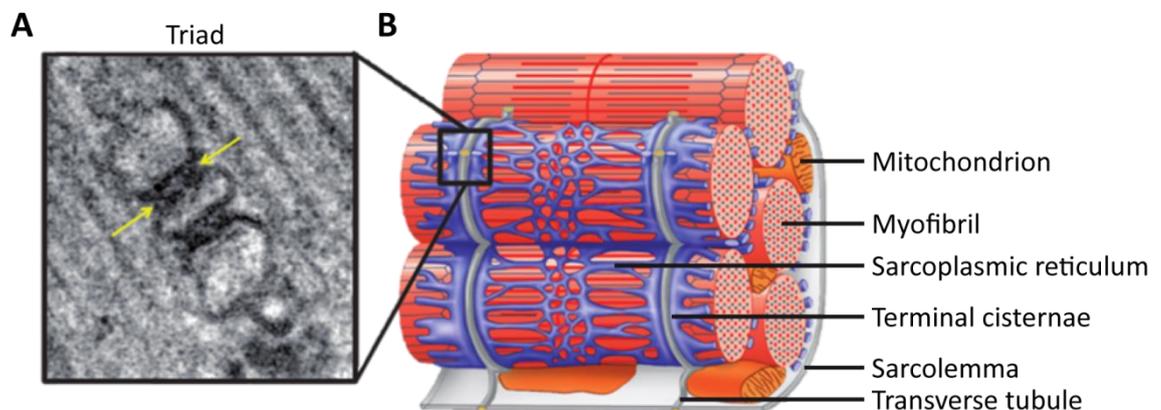

Figure 1 | Triad structure and T-tubule system in the skeletal muscle. (A) Electron micrograph of a triad structure. A central T-tubule is enclosed on both sides by one terminal cisterna of the SR. Arrows indicate electron-dense structures between the T-tubule and SR membrane representing the DHPR-RyR1 complex. (B) Schematic representation of a skeletal muscle basic unit and surrounding membranes. T-tubules (gray) are transverse invaginations continuous with the plasma membrane. The SR network (blue) expands longitudinally along the muscle fiber. Adapted from Marieb & Hoehn, 2007, © 2007 by Pearson Education, Inc.

The action potential, which is generated through electrochemical signal transduction, is not restricted to the sarcolemma but propagates along the T-tubule system into the interior of the muscle fiber to simultaneously excite the whole myofiber and to facilitate excitation-

contraction coupling (EC coupling). In this process, depolarization of the T-tubule membrane leads to activation of the voltage-sensitive L-type Ca^{2+} channel (Dihydropyridine receptor, $\text{Ca}_v1.1$) which is directly coupled to the Ca^{2+} -releasing ryanodine receptor 1 (RyR1) of the SR membrane. Opening of RyR1 allows fast release of Ca^{2+} from the SR, the main Ca^{2+} store of the muscle fiber, and muscle contraction (Ashcroft, 1991; Bezanilla et al., 1972) (**Figure 2**). When the coupling of these two receptors is disturbed for instance by an abnormally configured structure of T-tubule and SR membranes the process of EC coupling and directly Ca^{2+} homeostasis are affected (Tjondrokoesoemo et al., 2011).

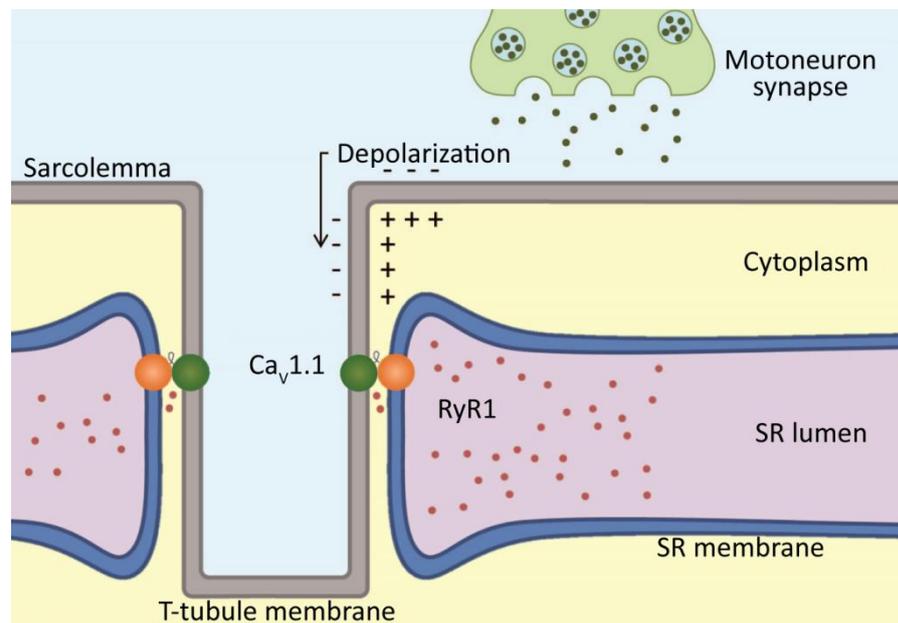

Figure 2 | Excitation-contraction coupling in skeletal myofibers. Scheme showing the connection between an electrical action potential and the cytoplasmic Ca^{2+} increase at the triad, finally, leading to contraction of the skeletal myofiber. The neurotransmitter released by terminal synapses of motoneurons leads to depolarization of the myofiber sarcolemma. The action potential propagates along the membrane of the T-tubule system into the inner of the fiber and activates voltage-sensitive Ca^{2+} channels of the skeletal muscle, $\text{Ca}_v1.1$. Conformational change of $\text{Ca}_v1.1$ leads via direct interaction with the Ca^{2+} release channel RyR1 to its opening and massive influx of Ca^{2+} from the SR into the cytoplasm.

1.2 Cardiac T-tubule system

Besides the skeletal, also the heart muscle is described as striated due to the highly organized arrangement of sarcomeres, the contractile units of muscle cells. Still, there are morphological, functional and molecular differences between skeletal myofibers and cardiomyocytes. Heart cells do not form a multi-nucleated syncytium upon final differentiation

but are mainly mono- or binucleated (Bensley et al., 2016). Ventricular cardiomyocytes possess a tubular membrane system which was initially thought to have exclusively a transverse orientation to the long axis of the myocyte (Lindner, 1957). These tubules occur periodically with regular spacing of approximately 2 μm and are anchored along sarcomeric Z-discs. They have a variable diameter of 200 to 400 nm (Fawcett and McNutt, 1969; Kostin et al., 1998; Savio-Galimberti et al., 2008; Soeller and Cannell, 1999; Wagner et al., 2012). In the 1970s, axially orientated membrane structures were detected for the first time in ventricular cardiomyocytes that interconnect transverse membranes within the cytoplasm (Sperelakis and Rubio, 1971) revealing a highly complex system of elongated membranes, called the transverse-axial tubule system (TATS) (Forbes et al., 1984). It has been estimated that the TATS is composed of 60% transverse and 40% axial membranes (Soeller and Cannell, 1999). Like in skeletal myofibers, also in cardiomyocytes membrane tubules are highly associated with the SR. Contrastingly, one transverse or axial tubule of the TATS is in close vicinity to only one terminal cisterna of the SR, an association called therefore cardiac dyad. The membranes of those two organelles are separated by a narrow cleft of approximately 15 nm (Cannell et al., 2006; Fawcett and McNutt, 1969; Nelson and Benson, 1963; Rostgaard and Behnke, 1965). The cardiac dyad is the contact site of voltage-gated Ca^{2+} channel $\text{Ca}_v1.2$ located at transverse and axial membranes of the TATS and the Ca^{2+} sense and release channel ryanodine receptor 2 (RyR2) at the membrane of the cardiac SR (Pinali et al., 2013; Swift et al., 2012). In cardiomyocytes contraction is initiated by a mechanism called Ca^{2+} -induced Ca^{2+} release (CICR). The sarcolemma of cardiomyocytes gets depolarized through electrochemically propagation of the action potential from adjacent cells. Due to its continuity with the plasma membrane, also the membrane of the TATS gets depolarized leading to activation and opening of $\text{Ca}_v1.2$. An initial influx of Ca^{2+} from the extracellular space through $\text{Ca}_v1.2$ triggers the opening of RyR2 and consequently the massive release of Ca^{2+} from the SR into the cytoplasm finally inducing contraction (Fabiato, 1983; Stern, 1992) (**Figure 3**).

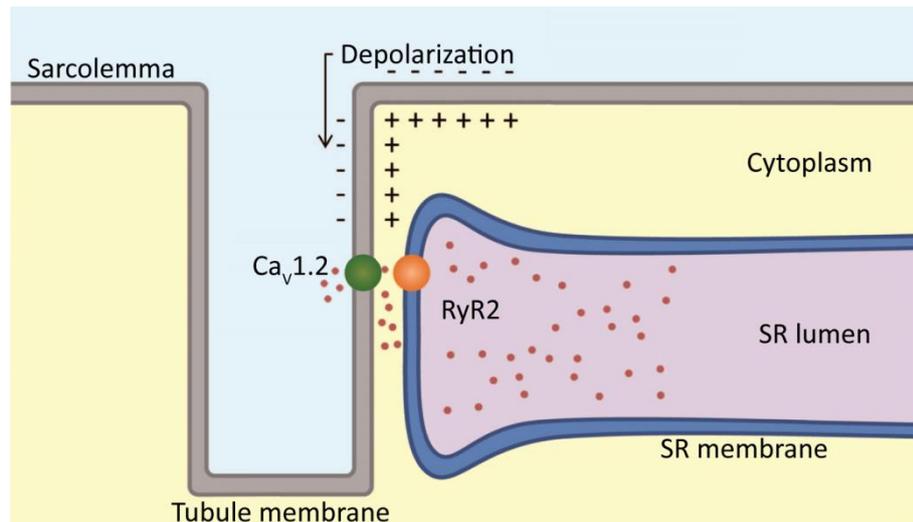

Figure 3 | Ca^{2+} -induced Ca^{2+} release in cardiomyocytes. Scheme showing a cardiac dyad and the increase of cytoplasmic Ca^{2+} as result of electric stimulation in cardiomyocytes. The sarcolemma of a cardiomyocyte gets depolarized through electrical coupling with adjacent myocytes. The depolarization propagates along the membrane of the transverse-axial membrane system and leads to opening of the cardiac voltage-gated Ca^{2+} channel $\text{Ca}_v1.2$. The moderate influx of Ca^{2+} from the extracellular space triggers opening of the cardiac Ca^{2+} sense and Ca^{2+} release channel RyR2 resulting in massive flow of Ca^{2+} from the SR into the cytoplasm of the cardiomyocyte.

1.3 Other functions of tubule system

Besides its direct importance for EC coupling, the T-tubule system functions in muscle fatigue, muscle differentiation, intracellular trafficking and plasma membrane repair. Experimental osmotic shock, for instance by treatment of single myofibers with glycerol, leads to tubule vacuolization with increase in tubule volume and partial detachment of T-tubules and tubule-derived vacuoles from the sarcolemma. Vacuolization was also observed after fatigue stimulation by induced contraction of *Xenopus laevis* myofibers (Krolenko and Adamian, 2000; Krolenko et al., 1998; Lännergren et al., 1999). Vacuolization is reversible and highlights the plasticity of the T-tubule system, a characteristic which may be important for water balance, transport and recovery from fatigue of skeletal myofibers (Krolenko and Lucy, 2001; Krolenko et al., 1998). Furthermore, the T-tubule system seems to serve as a membrane reservoir for the repair of membrane ruptures. The process involves protein-assisted recruitment of tubule-derived membranes to the sarcolemma wound (Fuson et al., 2014; Klinge et al., 2007; Lek et al., 2013). The TATS in cardiomyocytes possesses membrane folds creating a local slow diffusion zone for ions and thereby separating it from the bulk extracellular space. Through this specialized microanatomy, ion concentrations at the triads stay comparatively stable even

upon concentration changes around the myocytes, decreasing the risk for arrhythmias (Hong et al., 2014).

1.4 Biogenesis of the tubule system

Until now, the process of T-tubule development is only poorly understood. Several models exist which amongst others describe the biogenesis of T-tubules as an endocytosis-like mechanism with tubules deriving from the plasma membrane (Ishikawa, 1968). Another model suggests the formation of tubules by addition of newly synthesized vesicles similar to the process of exocytosis (Schiaffino et al., 1977). Short tubules are first detected in the chicken skeletal muscle at embryonic day 14, being continuous with the plasma membrane and showing a longitudinal orientation along the myotube at E15 (Flucher et al., 1993). Subsequently, at E16, a mainly longitudinal tubule network fills the whole myofiber. The SR develops and associates earlier with myofibrils than the tubule system. At E15 SR and tubule membrane attach to each other. The formation of the triads, at which from now on EC coupling occurs (Flucher et al., 1993), goes hand in hand with the translocation of $Ca_v1.1$ from the sarcolemma to membrane tubules (Romey et al., 1989). Much later during embryonic development, transverse branches are formed. The mature transverse structure of the T-tubule system is reached not earlier than several weeks after hatching (Flucher et al., 1993). Same is true for the biogenesis of the T-tubule system in mice. At birth, orientation of tubules is mainly longitudinal with some transverse connection. Final maturation is accomplished within the first 2 weeks of life (Franzini-Armstrong, 1991; Takekura et al., 2001). The exact molecular mechanism of T-tubule biogenesis is under investigation. Still, some proteins, including bridging integrator 1, junctophilin 2, caveolin 3 and dysferlin, have been directly implicated in this process.

1.5 Caveolin 3

Caveolins (CAVs) are the proteinaceous component and creators of flask-shaped plasma membrane invaginations with a size of 60 to 80 nm, the caveolae. Caveolae specifically function in several processes, such as signal transduction and lipid regulation (Parton and Simons, 2007), but also are involved in the development of the tubule system as first proposed in 1968 (Ishikawa, 1968). One of the CAV proteins, CAV3, is mainly expressed in the striated muscle (Tang et al., 1996). CAV3 expression is specifically induced during differentiation of the skeletal myoblast cell line C2C12, and CAV3 is localized to the developing T-tubule system as

shown by colabeling with Ca_v1.1 (Parton et al., 1997; Tang et al., 1996). Depletion of *CAV3* in mice is accompanied by alterations of the skeletal T-tubule system with dilation and longitudinal orientation of tubules (Galbiati et al., 2001). Mutations in the human *CAV3* gene are associated with skeletal and cardiac muscle diseases: autosomal dominant limb-girdle muscular dystrophy type 1C (LGMD1C, OMIM #607801), rippling muscle disease (OMIM #606072), familial hypertrophic cardiomyopathy (OMIM #192600) and long QT-syndrome (OMIM #611818) (Betz et al., 2001; Hayashi et al., 2004; Minetti et al., 1998; Vatta et al., 2006).

1.6 Junctophilin 2

Junctophilins (JPHs) 1 and 2 in skeletal and heart muscle, respectively, have a C-terminal transmembrane domain which is anchored in the SR membrane and an N-terminal phospholipid binding domain with specific affinity for the membrane of the tubule system (Takehima et al., 2000). The physical bridging of terminal SR membrane with T-tubule membrane by JPHs is a critical step during T-Tubule biogenesis as it occurs simultaneously with postnatal tubule maturation and strongly enhances EC coupling efficiency (Chen et al., 2013; Ziman et al., 2010). Cardiac-specific knockdown of *JPH2* in mice is associated with the development of heart failure and reduced CICR due to improper dyad formation (van Oort et al., 2011). *JPH1* deficiency in mice is lethal at birth. Muscles of embryos and neonatal mice show dramatic alterations in triad morphology, which is characterized by a reduced number of triads and by an increased junctional SR volume.

1.7 BIN1

The human *BIN1* gene encompasses 20 exons which can be spliced into several tissue-specific isoforms of the protein bridging integrator 1 (BIN1, Amphiphysin 2). Isoform 8 is expressed only in the skeletal muscle and includes the muscle-specific exon 11 (Wechsler-Reya et al., 1997), whereas inclusion of exon 13 is specific for the cardiac form. The N-terminal part of BIN1 including an amphipathic helix and the BAR domain, is able to form a crescent-shaped dimer with itself or with the N-terminus of amphiphysin 1 (Peter et al., 2004; Wigge et al., 1997a). The muscle-specific exon 11 encodes a short sequence called phosphoinositide (PI) binding motif, which increases the binding affinity of BIN1 towards phospholipids (Fugier et al., 2011). An Src homology 3 (SH3) domain is part of all BIN1 isoforms (Ramjaun and McPherson, 1998) and binds peptides with proline-rich motifs (Yu, 1994). In isoform 8, the SH3 domain

binds the BAR and PI domains intramolecularly and competes with the phospholipid phosphatidylinositol-4,5-bisphosphate (PI(4,5)P₂). The presence of PI(4,5)P₂ and binding to BAR and PI domains induce a conformational change of BIN1 and the release of the SH3 domain from BAR and PI binding. Subsequently, the SH3 domain can interact with proteins exhibiting an adequate proline-rich motif such as the GTPase dynamin 2 on PI(4,5)P₂-enriched membranes (Kojima et al., 2004). Amphiphysins are reported to play a role during the process of endocytosis in neuronal and non-neuronal cells through interaction with proteins such as dynamin which are associated with clathrin-coated pits (Bauerfeind et al., 1997; David et al., 1996; Shupliakov, 1997; Wigge et al., 1997b). It is assumed that BIN1 mediates the recruitment of effector proteins to the site of membrane fission during the endocytic process (Taylor et al., 2011).

BIN1 is reported to be involved in T-tubule biogenesis. It localizes to the developing T-tubule system in skeletal and heart muscle (Hong et al., 2010; Lee et al., 2002). The protein induces the formation of membrane invaginations and cytosolic tubules that are continuous with the plasma membrane upon heterologous expression in CHO cells and myoblasts. The BIN1 protein directly tubulates liposomes *in vitro* (Lee et al., 2002). This function is considered as analogous to membrane reorganization events during development of the T-tubule system. A direct sculpting function of BIN1 for the cardiac TATS has been established in recent years. BIN1 shapes the tubule system and generates microfolds of the T-tubule membrane leading to low ion diffusion inside the tubule. The separation of these microdomains from the bulk extracellular space is possibly a mechanism to protect the heart from arrhythmias (Hong et al., 2014). By forming these folded membranes, BIN1 assembles Ca_v1.2 molecules to form Ca_v1.2 clusters at the tubule membrane. Furthermore, BIN1 regulates Ca²⁺ channel trafficking and assembly by attracting and anchoring Ca_v1.2 molecules that are delivered via microtubule-mediated transport from the Golgi network to the tubular membrane (Hong et al., 2010). Upon activation of β-adrenergic receptor signaling BIN1 recruits phosphorylated RyR2 into dyads, thereby increasing Ca²⁺ release (Fu et al., 2016). An abnormally formed T-tubule system has been detected in *Drosophila melanogaster* upon gene knockout (Razzaq et al., 2001), in adult mouse skeletal muscle fibers after BIN1 knockdown (Tjondrokoesoemo et al., 2011) and in human muscle biopsies of BIN1-deficient patients (Toussaint et al., 2011). Reduced expression of BIN1 is detected in heart failure leading to impaired trafficking and clustering of Ca_v1.2 and RyR2 at cardiac dyads. Finally, contractility is reduced and arrhythmogenic risk is increased due to RyR2 uncoupling and Ca²⁺ leaks from the SR (Fu et al., 2016; Hong et al., 2012). *BIN1* mutations are implicated in a rare congenital myopathy called autosomal

recessive centronuclear myopathy (ARCNM, OMIM #255200) characterized by early disease onset, a proximal slowly progressive skeletal muscle weakness and centralized nuclei (Böhm et al., 2010, 2013, 2014; Claeys et al., 2010; Nicot et al., 2007).

1.8 Dysferlin

The *DYSF* gene encodes the 230 kDa protein dysferlin which belongs to the ferlin protein family (Anderson et al., 1999; Matsuda et al., 1999). The ferlins are named after their homology to the *Caenorhabditis elegans* protein Fer-1 that is essential for fusion of membranous organelles to the sperm plasma membrane during spermiogenesis (Achanzar and Ward, 1997). Human orthologs of dysferlin are myoferlin, otoferlin and Fer-1-like protein 5 (FER1L5). Otoferlin plays a role in exocytosis of synaptic vesicles in the inner ear hair cells and is crucial for Ca^{2+} -dependent fusion of vesicles to the plasma membrane (Ramakrishnan et al., 2014). Mutations in the gene encoding otoferlin and leading to a nonfunctional or absent protein result in nonsyndromic deafness (Yasunaga et al., 2000). Myoferlin is highly expressed in myogenic precursor cells during differentiation and plays a crucial role during myoblast-myoblast and myoblast-myotube fusion (Doherty et al., 2005). Until now, no pathogenic mutations have been described for the genes encoding myoferlin and FER1L5. All ferlins are type II transmembrane proteins and have a similar domain structure. Besides a C-terminal transmembrane domain, a DysF sequence and ferlin domains, they possess multiple C2 domains (Davis et al., 2002) (**Figure 4**). C2 domains, like the protein kinase C C2 domains, mediate Ca^{2+} -dependent membrane binding via phospholipid interaction (Coussens et al., 1986). The ferlin C2 domains are diverse as each C2 domain is more similar to its corresponding domain in paralogs than to the other C2 domains in the same ferlin (Washington and Ward, 2006). This indicates distinct domain functions within one protein. The C2A domain of dysferlin binds phosphatidylinositol-4-phosphate (PI(4)P) and PI(4,5)P₂, a phospholipid that is enriched in the membrane of the T-tubule system, in a Ca^{2+} -dependent manner (Hidalgo et al., 1986; Therrien et al., 2009).

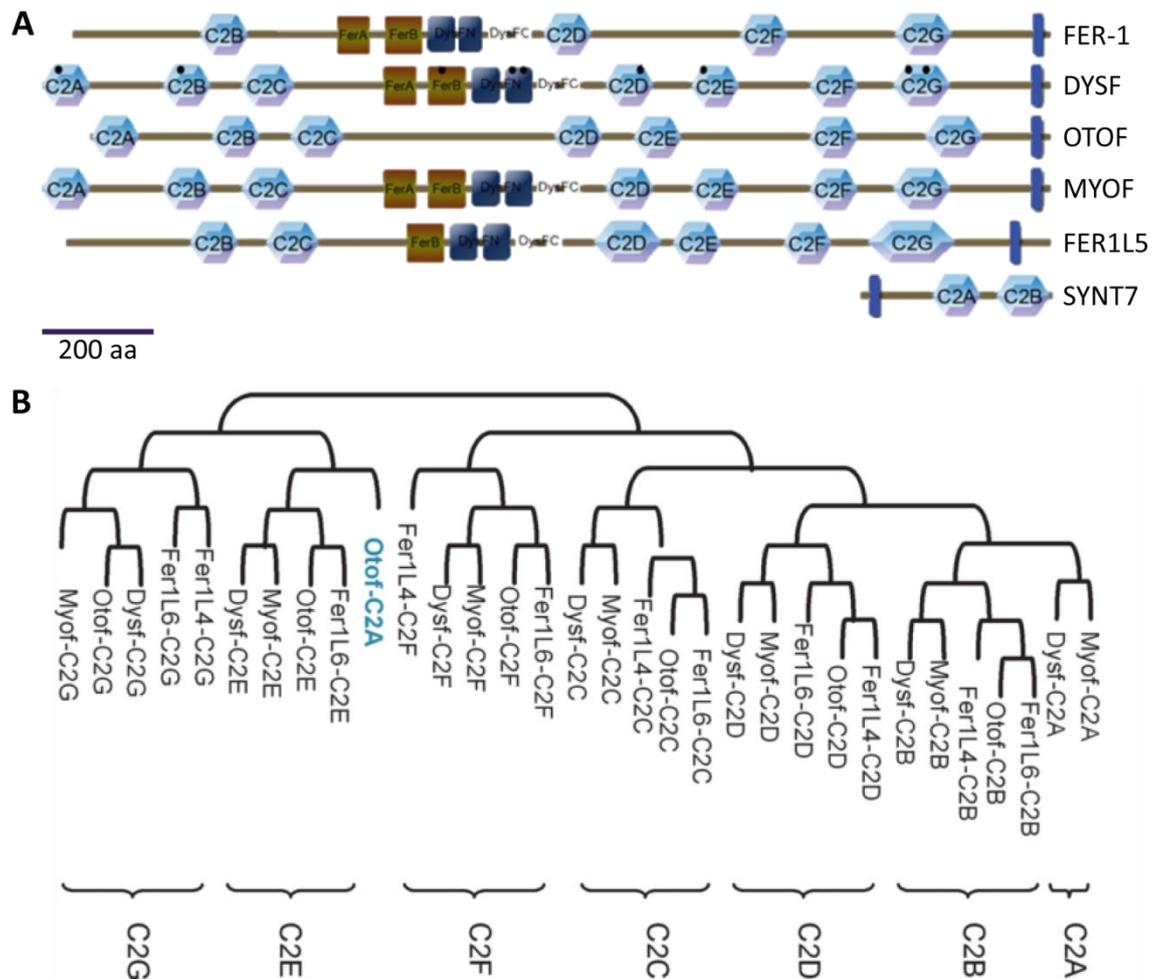

Figure 4 | Structural characteristics of C2 domain proteins. (A) Protein domain structure of Fer-1 and mammalian ferlin-like proteins showing high similarity. **(B)** Phylogenetic tree based on alignment of individual ferlin C2 domain sequences. Adapted from Han & Campbell, 2007.

Dysferlin's single transmembrane domain is located at the extreme C-terminus (13 amino acids upstream of the C-terminus), characterizing dysferlin as a tail-anchored (TA) protein (Borgese et al., 2003a). The large N-terminal part is directed into the cytosol and the very short C-terminus is protruded into the extracellular space or organelle lumen (Kerr et al., 2013). Many integral membrane proteins initially pass the ER before being transported to the plasma or organelle membrane (Shao and Hegde, 2011). Due to the domain topology, TA proteins cannot be integrated into the membrane of the ER by the classical co-translational signal recognition particle (SRP)-dependent pathway involving the Sec61-complex (Borgese et al., 2003b; Kutay et al., 1993). As the transmembrane domain is located at the extreme C-terminus it emerges from the ribosome just prior to completion of translation. The mechanism for TA insertion includes both, a cytosolic component shielding the hydrophobic transmembrane domain from the aqueous environment, and an ER-associated component

integrating the protein into the membrane (High and Abell, 2004). The conserved pathway required for the insertion of TA proteins involves the cytoplasmic chaperone ATPase transmembrane domain recognition complex 40 kDa (TRC40/Asna-1) which posttranslationally interacts with the C-terminal hydrophobic stretch of the TA protein (Favaloro et al., 2008; Stefanovic and Hegde, 2007). TRC40 delivers the TA protein to the ER membrane-integrated receptor complex consisting of WRB (Tryptophan Rich Basic protein) and the mammalian specific CAML (Calcium signal-modulating cyclophilin ligand) (Vilardi et al., 2011; Yamamoto and Sakisaka, 2012) which leads to subsequent insertion into the ER. The nature of dysferlin as a TA protein suggests that it might be integrated into the ER before trafficking to its target membrane. Though, it is not known whether and how dysferlin enters the ER on its way through the cell. It is suggestive that the long N-terminal stretch of dysferlin is interacting with chaperones during translation to ensure accurate folding of the protein. Also, the hydrophobic transmembrane domain emerging from the ribosome at the end of translation has to be shielded by chaperones to avoid aggregation.

1.9 Dysferlin function

The best characterized role of dysferlin is its function in membrane repair. The skeletal muscle is able to adapt to functional requirements like repetitive and continuous contractions. Therefore, the plasma membrane needs to be both, flexible and robust, as it is stressed by myofiber contractions. Still, small membrane ruptures, so called microlesions, can occur upon exceeded stress and have to be repaired immediately to protect the cell from massive Ca^{2+} influx and Ca^{2+} -induced cell damage (Reviewed in (Tidball, 2011)). Upon entry of Ca^{2+} into the cell, several processes conglomerate in the accumulation of vesicles and other membraneous organelles to form a membrane patch which seals the ruptured plasma membrane by fusion of vesicles with each other and with the sarcolemma (Allen et al., 2010; McDade and Michele, 2014). Ultrastructural analysis of damaged dysferlin-deficient myofibers reveals disruption of the plasma membrane and subsarcolemmal accumulation of vesicles indicating diminished ability of vesicles to fuse and repair membrane lesions (Bansal et al., 2003; Cenacchi et al., 2005; Selcen et al., 2001). Direct disruption of the plasma membrane repair mechanism due to dysferlin-deficiency was reported for skeletal and heart muscle in mouse and human (Bansal et al., 2003; Han et al., 2007; Lostal et al., 2012; Philippi et al., 2012). In dysferlin-competent myofibers the membrane repair process is dependent on the orchestrated interaction of several proteins, of which dysferlin is a key player. Upon membrane rupture, initially, mitsugumin 53 (MG53) accumulates at injury sites in a Ca^{2+} -independent manner (Cai et al.,

2009; Matsuda et al., 2012). Subsequently, dysferlin-containing vesicles arrive strongly Ca^{2+} -dependently together with cytoplasmic annexin A6 at the membrane lesion and form a tight patch (McDade et al., 2014; Roostalu and Strähle, 2012). It has been shown that not the full-length dysferlin is directly involved in membrane repair. Instead, dysferlin is Ca^{2+} -dependently cleaved by calpains resulting in a so called mini-dysferlinC72 peptide that is decorating the accumulating injury-induced vesicles (Lek et al., 2013; Redpath et al., 2014) (Lek et al., 2013). Finally, vesicle fusion is induced by dysferlin-dependent recruitment of annexin A2 and A1 (Lennon et al., 2003).

In addition to membrane repair, dysferlin is involved in other processes of the myofiber that involve vesicle trafficking and fusion such as cytokine and receptor exocytosis (Chiu et al., 2009; Demonbreun et al., 2011). This function is supported by the observation that dysferlin's C2A and C2B domain interact with α -tubulin and microtubules in the skeletal muscle (Azakir et al., 2010).

1.10 Dysferlin's involvement in T-tubule biogenesis

In addition to the above mentioned indications such as analogy to the membrane modeling Fer-1 and binding to $\text{PI}(4,5,)\text{P}_2$, further observations point to the involvement of dysferlin in the biogenesis of the T-tubule system in skeletal muscle. Dysferlin expression can be detected at the earliest stages of human development examined at 5 - 6 weeks of embryonic age, the stage when regional differentiation of the limbs can be detected (Anderson et al., 1999). Thereby, dysferlin localizes to the plasma membrane and especially the T-tubule system (Ampong et al., 2005; Anderson et al., 1999; Klinge et al., 2008). In differentiating myotubes dysferlin associates with the developing T-tubule network and is only recruited to plasma membrane lesions upon muscle fiber injury (Klinge et al., 2007). In addition to localization at the adult skeletal T-tubule system (Kerr et al., 2013), dysferlin shows localization at T-tubules in regenerating myofibers and only in later stages of regeneration it translocates to the sarcolemma (Klinge et al., 2010a). This lead to the suggestion that dysferlin is involved in T-tubule development of the skeletal muscle. Further evidence for this hypothesis was provided by the observation of a highly abnormally configured T-tubule system with dilated and longitudinally orientated tubules in predystrophic dysferlin-deficient mice (Klinge et al., 2010a) and increased sensitivity of the T-tubule system upon damage (Demonbreun et al., 2014; Kerr et al., 2013). Recent work of our group uncovers a direct shaping role of dysferlin during biogenesis of the skeletal T-tubule system (Hofhuis et al., 2017). Upon heterologous expression in non-muscle cells, dysferlin is able to *do novo* induce tubular structures. The

depletion of these structures by cholesterol suggests that they are composed of membrane probably deriving from the plasma membrane. Additionally, dysferlin protein alone is capable of tubulating liposomes *in vitro*. Comparison of dysferlin and BIN1 revealed that the mechanism underlying tubulation is distinct. While BIN1-induced tubulation is dependent on the GTPase dynamin 2, dysferlin tubulates membranes independently of dynamin 2. Furthermore, the recent work links dysferlin-induced tubulation necessarily to the phospholipid PI(4,5)P₂, which is enriched in the T-tubule membrane. The tubulation ability of dysferlin is abrogated by pathogenic mutations emphasizing that this function is physiologically relevant (Hofhuis et al., 2017).

1.11 *DYSF* gene and mutations

The *DYSF* gene is located on chromosome 2p13 and encompasses 55 exons (Liu et al., 1998). *DYSF* is conserved among mammals with a sequence similarity of 90% between the human and mouse gene (Vafiadaki et al., 2001). 80 recurrent mutations, occurring in at least three unrelated patients, are described for the *DYSF* gene (UMD-DYSF mutations database, http://www.umd.be/DYSF/W_DYSF/mutation.html). Mutations include mainly point mutations and small insertions or deletions and cover the entire coding region without any mutational hotspot regions. No genotype-phenotype correlation with respect to the distinct clinical manifestations exists (Klinge et al., 2008, 2010b; Krahn et al., 2009). Approximately a quarter of *DYSF* mutations comprise nonsense mutations that lead to the generation of a premature termination (stop) codon. Dysferlin mutations may lead to degradation of the altered mRNA through nonsense-mediated mRNA decay (Fujita et al., 2007) or mutant protein aggregation (Wenzel et al., 2006), thus causing total absence or reduction and altered localization of the protein, respectively. One patient has been identified with a truncated variant of dysferlin composed of the transmembrane domain, the last C2 domains and an out-of-frame N-terminal sequence. This patient showed late onset of disease and moderate progression compared to other dysferlin-deficient patients (Krahn et al., 2010).

1.12 Dysferlinopathy

Muscular dystrophies are a heterogeneous group of inherited muscle diseases characterized by progressive wasting and weakness of skeletal muscles. The age of disease onset is very variable spanning from late childhood to adolescence. Dystrophic muscle is designated by degeneration of muscle fibers, centrally located nuclei, increased fiber size variation and

substitution of muscle tissue by fat and connective tissue (Flanigan, 2012). Dysferlin-deficient muscular dystrophy (Dysferlinopathy) is a rare disease (incidence 1/100,000 – 200,000, (Moore et al., 2006) caused by mutations in the *DYSF* gene and comprises mainly three clinically distinct skeletal muscle disorders: autosomal recessive limb-girdle muscular dystrophy type 2B (LGMD2B, OMIM #253601, (Bashir et al., 1998), Miyoshi myopathy (MM, OMIM #254130 (Liu et al., 1998) and distal anterior compartment myopathy (OMIM #606768, (Illa et al., 2001). Until now, no curative treatment is available. Initial symptoms occur mostly in the first or second decade of life and involve muscle weakness and pain in the proximal or distal limb muscles for LGMD2B and MM, respectively. Additionally, a massive increase of serum creatine kinase levels is detectable indicating destruction of muscle tissue (Linssen et al., 1997; Mahjneh et al., 1996; Weiler et al., 1999). The diagnosis of dysferlinopathy is based on strongly reduced or absent expression of dysferlin protein in muscle biopsies and subsequent confirmation by genetic analysis. The disease course of dysferlin-deficiency is typically slowly progressive with propagation of the symptoms and dystrophic changes to other than primarily affected muscle groups, finally leading to affection of all limb-girdle muscles (Nguyen et al., 2007). In contrast to muscular dystrophies involving defects in the dystrophin-glycoprotein complex (DGC) with instability of the plasma membrane (Koenig et al., 1988), dysferlin-deficient muscle maintains a functional DGC, indicating that dystrophic changes do not result from an instable plasma membrane structure but arise from a different pathomechanism (Bansal et al., 2003). Dysferlin-deficiency leads to disturbed myogenic differentiation (De Luna et al., 2007) and accumulation of subsarcolemmal vesicles (Cenacchi et al., 2005; Piccolo et al., 2000). Furthermore, a diminished membrane repair capacity of dysferlin-deficient muscle has been reported (Bansal et al., 2003; Hofhuis et al., 2017). Taking into consideration that dysferlinopathy patients are without symptoms in their first decades of life and that restoration of membrane repair is not sufficient to prevent the dystrophic phenotype (Lostal et al., 2012), it consequentially eliminates the possibility that the dystrophic changes are exclusively caused by a defective membrane repair system (Hofhuis et al., 2017). The function of dysferlin in formation of membrane tubules is linked to the development of the T-tubule system and is defective for pathological mutants leading to the conclusion that dysferlinopathy is caused by the inability of mutant dysferlin to properly form the T-tubule system in skeletal muscle (Hofhuis et al., 2017). Interestingly, dysferlin-deficient patients show a high level of fitness during childhood before onset of symptoms, an observation that is unique among all forms of muscular dystrophy (Klinge et al., 2010b). This phenotype could be reproduced by analyzing the performance of dysferlin-deficient mice in a voluntary running

wheel experiment (Hofhuis et al., 2017). The explanation for increased muscle prowess upon dysferlin-deficiency might be an alteration in channel function due to deformation of the T-tubule system and redistribution of dysferlin-controlled PI(4,5)P₂ (Hofhuis et al., 2017).

1.13 Dysferlin in the heart

A lot of research has been performed to analyze the role of dysferlin and the effects of dysferlin-deficiency in skeletal muscle. Much less is known about the importance of dysferlin for the heart muscle. Dysferlin is mainly regarded as skeletal muscle disease because only in a few patients, diagnosed with dysferlinopathy, cardiac involvement is reported (Kuru et al., 2004). As in skeletal muscle, dysferlin is also involved in membrane repair of cardiomyocytes and exhibits a cytoprotective function in the model of ischemia/reperfusion injury (Han et al., 2007; Tzeng et al., 2014). The examination of mouse models for dysferlin-deficiency reveals that no or only a very mild cardiac phenotype is found under normal conditions (Chase et al., 2009; Rubi et al., 2015; Wenzel et al., 2007). In contrast, excessive strain such as ischemia/reperfusion injury, physical stress exercise or β -adrenergic activation by isoproterenol treatment of mice leads to signs of cardiac dysfunction (Chase et al., 2009; Han et al., 2007; Tzeng et al., 2014; Wei et al., 2015; Wenzel et al., 2007). These include the release of creatine kinase and Evans blue dye uptake as indications of membrane damage (Han et al., 2007; Tzeng et al., 2014), cardiac fibrosis, reduced fractional shortening (Wenzel et al., 2007), decreased stroke volume and relaxation velocity (Wei et al., 2015). Thus, systolic as well as diastolic cardiac functions are altered upon stress in dysferlin-deficient mice.

1.14 Tubule system in heart failure

Amongst the cardiovascular diseases, heart failure (HF) is one of the most frequent diseases leading to death. HF might be caused by chronic hypertension, acute myocardial infarction or ischemic heart disease and is more a secondary syndrome than a primary disease. HF is chronically progressive and described as condition in which heart function is decreased and insufficient to fulfil the metabolic demands of the body (Levy et al., 1996). HF is characterized by diminished cardiomyocyte contraction resulting from uncoupling of Ca_v1.2-RyR2 dyads and reduced systolic Ca²⁺ release (Gómez et al., 1997; Pieske et al., 1999). Several studies report that the cardiac TATS is altered in failing hearts and that disturbed Ca²⁺ handling might result from these morphological abnormalities. Confocal imaging of failing cardiomyocytes shows disruption and reduced density of membrane tubules, which can be directly linked to

asynchronous EC coupling and reduced delayed Ca^{2+} release from the SR (Heinzel et al., 2008; Louch et al., 2004, 2006). *In situ* confocal visualization of whole hearts has the beneficial aspect that tissue integrity is preserved. Analysis of rat hearts from a pressure overload model shows that loss and redistribution of the T-tubule system starts early in compensated hypertrophy before progression to heart failure (Chen et al., 2015; Wei et al., 2010). Scanning ion conductance microscopy (SICM) provides information about the surface topology and reveals detachment of tubules from the sarcolemma in human and rat failing cardiomyocytes (Lyon et al., 2009). Detailed 3D analysis of a porcine myocardial infarction model shows loss of tubule structures in the peri-infarct zone and branching and axialization of remaining tubules (Pinali et al., 2017). Human failing cardiomyocytes show sheet-like rather than tubular invaginations of the sarcolemma and again decrease in T-tubule density. Additionally, Ca^{2+} release is delayed and asynchronous in cardiomyocytes from patients with HF (Seidel et al., 2017). Asynchrony might be due to uncoupling of T-tubules from the sarcomeres and left-behind, so called, orphaned RyRs leading to uncontrolled Ca^{2+} handling as shown in spontaneously hypertensive rats developing HF (Song et al., 2006). Cannell and colleagues analyzed fixed myocardium from HF patients and found redistribution of TATS with dilated and mainly longitudinally orientated tubules (Cannell et al., 2006). Regularity of T-tubule alignment was analyzed by Wei and colleagues using Fourier transformation of confocal images and assessment of obtained power spectra (Song et al., 2006). Therefore, whole rat hearts were staining with the membrane dye FM 4-64 and analyzed by confocal microscopy. The T-tubule power index (TT_{power}) revealed global reorganization of the tubule system which correlated with disease progression (Wei et al., 2010).

1.15 Therapeutic strategies for dysferlinopathy

Several studies have investigated different therapeutic approaches for the treatment of dysferlinopathy. Until now, none of these approaches could be developed into a curative treatment.

1.15.1 Immune modulation

Muscle inflammation with infiltration of T-cells and macrophages as well as enhanced phagocytic activity of peripheral monocytes is a typical sign of dysferlinopathy (Gallardo et al., 2001; Nagaraju et al., 2008). Thus, several studies aimed to ameliorate disease progression through modulation of the immune system. No B-cell infiltration was detected in dysferlin-

deficient muscle (Gallardo et al., 2001), still Lerario and colleagues observed a slight increase in muscle force after depletion B-cells with Rituximab® in two dysferlinopathy patients, indicating that B-cells might be involved in the pathogenesis (Lerario et al., 2010). Inhibition of the Rho-kinase, which has a key signaling function in immune activation, using the substance fasudil was conducted in two mouse models of dysferlinopathy. Treatment resulted in suppressed immune response, but no or exacerbating muscular disease phenotype was observed (Rayavarapu et al., 2010). Another important signaling molecule of the inflammatory response, NF- κ B, was inhibited by the treatment of dysferlin-deficient mice with celastrol for 4 months. The muscle inflammation was reduced without a beneficial effect on physical muscle function (Dillingham et al., 2015). Within the framework of a clinical trial immune suppression of dysferlinopathy patients was achieved by treatment with the glucocorticoid deflazacort. This led to severe steroid-associated side effects and no improvement or even exacerbation of muscle strength (Walter et al., 2013). Consequently, immunosuppression in dysferlin-deficient muscular dystrophy seems not to be a promising therapeutic approach.

1.15.2 Influencing Ca^{2+} homeostasis

Dysferlin associates with Ca^{2+} handling proteins in the membrane of T-tubules (Ampong et al., 2005) and contributes to the maintenance of Ca^{2+} homeostasis (Hofhuis et al., 2017; Kerr et al., 2013). Therefore, the alteration of Ca^{2+} handling was handled as therapeutic possibility to ameliorate disease progression. Dantrolene, which is binding to RyRs and thereby reducing Ca^{2+} release from the SR (Krause et al., 2004) was used to treat two patients with MM. Beside of a slight decrease of creatine kinase level, no positive effect was detected. Treatment of one patient had to be terminated prematurely because of suspected hepatopathy, a common side effect (Hattori et al., 2007; Montané et al., 2004). Furthermore, inhibition of $\text{Ca}_v1.1$ by diltiazem in dysferlin-deficient isolated myofibers and treated mice was reported to prevent contraction-induced membrane damage probably through reduced injury-induced Ca^{2+} influx and activation of Ca^{2+} -mediated cytotoxicity. Diltiazem is approved for clinical use and might be a potential therapeutic for the treatment of dysferlinopathy (Kerr et al., 2013).

1.15.3 Gene therapy

Another field, which is extensively investigated as therapeutic strategy for dysferlin-deficient muscular dystrophy, is the modulation of dysferlin expression either through import of dysferlin coding genes or through restoration of endogenous dysferlin expression. These

approaches have been analyzed at preclinical level and seem to be promising strategies for further clinical development (Barthélémy et al., 2011). Delivery of coding genes into gene-deficient organisms is a gene therapeutic approach for the treatment of genetic diseases. Adeno-associated virus (AAV) is currently the best vector for this purpose. Though, the encapsulation capacity is limited to a size of 5 kb (Pryadkina et al., 2015) and classical AAV-mediated gene delivery of *DYSF* with about 6.2 kb is unfeasible. Therefore, different types of AAV-mediated gene delivery have been developed. Lostal and colleagues divided the *DYSF* cDNA sequence into two parts and cloned them into separate AAV vectors with appropriate splicing sequences. After combined intramuscular injection of both vector variants, the full-length cDNA is generated by overlap of the two parts through homologous recombination. This method leads to expression of full-length dysferlin protein in the muscle leading to improvement of membrane capacity and locomotor activity as well as reduced dystrophic phenotype and necrotic fibers (Lostal et al., 2010). Safety concerns with regard to this method were addressed by Sondergaard and colleagues (Sondergaard et al., 2015). A comparison of gene transfer techniques for large genes revealed that the overlap strategy described above is the most effective approach in the generation of full-length dysferlin (Pryadkina et al., 2015). A dysferlinopathy patient with late onset and moderate disease progression was reported to express a so called minidysferlin, consisting of an out-of-frame N-terminal domain, the last 2 C2 domains and the transmembrane domain (Krahn et al., 2010). Delivery of genes encoding truncated variants of dysferlin is technically more feasible than delivery of full-length dysferlin. Thus, the gene therapeutic delivery of minidysferlins is being investigated as approach to ameliorate the symptoms of patients with complete absence of the full-length protein. Several truncated dysferlin variants have been designed and analyzed for their functionality in a membrane wounding assay after AAV-mediated delivery showing that C2B, C2C, C2E and to a lesser extent C2D are not oblige for the membrane repair function (Azakir et al., 2012). Another gene delivery system that has been analyzed for therapy of dysferlin-deficiency is the Sleeping Beauty (SB) transposon system which is already used in clinical trials. It is composed of a synthetic non-viral vector and a transposase that can insert specific DNA fragments into vertebrate genomes. The advantage in comparison with AAV vectors is that DNA with more than 10 kb can be integrated into the target genome. Full-length dysferlin cDNA was delivered into dysferlin-deficient myoblasts resulting in proper protein expression. Subsequently, dysferlin-expressing myoblasts were successfully transplanted into a skeletal muscle of dysferlin- and immune-deficient mice.

Often, *DYSF* mutations lead to reading frame shifts or the generation of premature stop codons leading to truncated and dysfunctional proteins that are prone for degradation. In the exon skipping approach, mutated mRNA is targeted and the exon harboring a highly pathologic mutation is removed by alternative splicing. Though, only exons, which are not essential for protein function, can be targeted. The in-frame suppression of a certain exon or multiple adjacent exons is achieved by the application of antisense oligonucleotides (AON) (van Ommen et al., 2008). Currently, this approach seems to be promising for the treatment of Duchenne muscular dystrophy with mutations in the dystrophin-coding gene (Niks and Aartsma-Rus, 2017; van Ommen et al., 2008). A patient with late-onset mild dysferlinopathy due to a mutation leading to natural skipping of exon 32 has been reported. In this case, the loss of one *DYSF* exon leads to a mild phenotype suggesting that the function of dysferlin is not completely abrogated. This hints to the idea that *DYSF* exons may be dispensable or their loss causes only a mild disease phenotype (Sinnreich et al., 2006). Therapeutic exon skipping is optimal to target mutations that are homozygous to obtain maximal protein expression. Increase of wild-type dysferlin protein level to 10% in an originally dysferlin-deficient myofiber seems to be enough to partially ameliorate the disease phenotype. This suggests that the exon skipping approach might also be beneficial for heterozygous mutations if one allele is not targetable by this approach and normal dysferlin levels cannot be obtained (Aartsma-Rus et al., 2010; Sinnreich et al., 2006). AON-induced exon skipping in human myoblasts was efficient and led to rescue of myoblast fusion deficiency and disturbed membrane repair supporting this therapeutic approach (Barthélémy et al., 2015; Wein et al., 2010).

1.15.4 Reallocation of mutated dysferlin

Mutations in the *DYSF* gene might lead to alterations in protein structure and folding, ER homeostasis, trafficking and stability causing dysfunctionality and mislocalization of the protein (Fujita et al., 2007; Wenzel et al., 2006). Schoewel and colleagues developed dysferlin-derived fluorescently-tagged peptides and introduced them through coupling to the cell penetrating peptide TAT (trans-activator of transcription from human immunodeficiency virus type 1) either into C2C12 cells transfected with mutant dysferlin or primary patient myoblasts. This strategy resulted in reduced ER stress response, localization of mutant dysferlin at the sarcolemma and rescue of membrane repair.

1.16 Translational readthrough

One therapeutic approach for the treatment of genetic diseases caused by premature stop codons is the application of aminoglycosides, their derivatives or other small molecules which are able to induce translational readthrough of stop codons. Instead of translational termination the incorporation of an amino acid at the position of the premature stop codon takes place leading to continued translation until the original stop codon is reached and production of the full-length protein (Yang et al., 2016).

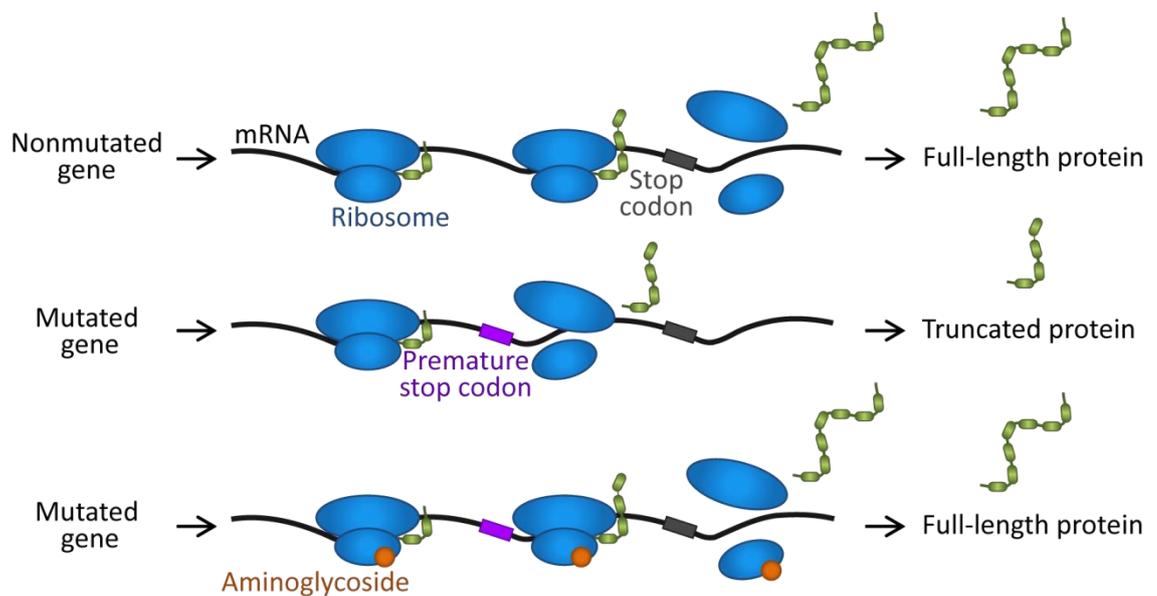

Figure 5 | Aminoglycoside-induced readthrough therapy of diseases caused by nonsense mutations.

Translation of the mRNA encoded by a gene without premature stop codons leads to the generation of a functional full-length protein (top). Nonsense mutation causes the premature termination of translation and generation of a truncated, probably unfunctional and/or degradation-prone protein. Aminoglycosides induce translational readthrough of a premature termination codon, thereby leading to continuation of translation and the generation of a full-length protein with a probable exchanged amino acid at the position of the premature stop codon.

The concept of translational readthrough as a therapeutical approach for genetic diseases with premature stop codons was initially investigated for cystic fibrosis applying the aminoglycosides G418 (geneticin) and gentamicin (Bedwell et al., 1997; Howard et al., 1996). This approach is also under investigation for the treatment of Duchenne and Becker muscular dystrophy (Barton-Davis et al., 1999; Loufrani et al., 2004) as approximately 10% of patients harbor a nonsense mutation in the gene encoding dystrophin (UMD TREAT-NMD DMD mutations database, http://umd.be/TREAT_DMD/). However, these substances have a

narrow therapeutic window and dosage has to be assessed very carefully upon systemic administration due to oto- and nephrotoxicity. Therefore, studies developing new readthrough inducing substances with less adverse effects are ongoing.

2. Aims of this work

For a long time, dysferlin had been mainly described as mediator of muscle membrane repair (Bansal and Campbell, 2004; Cai et al., 2009; Lek et al., 2013). Though, a defective membrane repair caused by dysferlin-deficiency cannot be the only pathomechanism of dysferlin-deficient muscular dystrophy (Bansal et al., 2003). This assumption is supported by the observation that the restoration of membrane repair in dysferlin-deficient myofibers does not impede disease progression (Krahn et al., 2010) and patients are asymptomatic and above-average athletic until the second decade of life (Klinge et al., 2010b). In the recent years, new evidence supports an additional role of dysferlin during the biogenesis of the T-tubule system. The tubulation of membranes into elongated structures is proposed to be the primary cellular function of dysferlin. Mutations, which are found in dysferlinopathy patients, interfere with the tubulation capacity of dysferlin leading to the hypothesis that the inability of mutated dysferlin to tubulate membranes results in an abnormal T-tubule system and is the primary cause of muscular dysfunction (Hofhuis et al., 2017). Dysferlin localizes to the skeletal muscle T-tubule system and is essential for proper T-tubule formation in skeletal muscle (Klinge et al., 2010a), but the exact mechanism of dysferlin's T-tubule shaping function is unknown. Thus, the aims of this study were the following: The cellular fate of normal and mutated dysferlin should be investigated to get insight into the possible mechanisms of T-tubule formation and to understand the pathological events leading to muscular dysfunction. The effect of dysferlin-deficiency should be further analyzed in a human model of early myogenesis to uncover the primary alterations resulting from the loss of dysferlin. Dysferlin is also highly expressed in the heart muscle and dysferlin-deficient mice show signs of cardiac dysfunction under stress conditions (Chase et al., 2009; Han et al., 2007; Tzeng et al., 2014; Wei et al., 2015; Wenzel et al., 2007). Thus, the involvement of dysferlin in the biogenesis of the cardiac T-tubule system and the effects of dysferlin loss on the morphology of this cellular compartment should be investigated. As little is known about the pathomechanism of dysferlinopathy, no curative treatment is available. Therefore, this thesis aimed to address two different approaches, the stabilization of mutated dysferlin and the induction of full-length protein expression by translational readthrough, as therapeutic options for the treatment of dysferlin-deficient muscular dystrophy.

3 Materials and Methods

3.1 Materials

3.1.1 Bacterial strains

For cloning procedures and plasmid preparation the chemically competent *Escherichia coli* strain BioBlue (BIO-85036 \geq 108cfu/ μ g of pUC19, Bioline GmbH) was used.

3.1.2 Mammalian cell lines

HeLa is a human epithelial cell line derived from a cervix adenocarcinoma.

HEK293 is a cell line derived from human embryonic kidney cells.

COS-7 cells are adherent fibroblast-like cells from the kidney of the African green monkey.

CHO-K1 is an epithelial cell line derived from the ovary of the Chinese hamster.

C2C12 is a murine myoblast cell line clonally derived from leg muscles of an adult C3H mouse. This cell line is capable of differentiating into contractile myotubes and thereby expressing various skeletal muscle proteins. Therefore, C2C12 cells are used in this study as model system for skeletal muscle differentiation.

3.1.3 Human myoblasts

Primary human myoblasts from LGMD patients and healthy controls were kindly provided by the Muscle Tissue Culture Collection (MTCC). I thank MTCC for providing the samples. The MTCC is part of the German network on muscular dystrophies (MD-NET, service structure S1, 01GM0601) and the German network for mitochondrial disorders (mito-NET, project D2, 01GM0862) funded by the German ministry of education and research (BMBF, Bonn, Germany). The MTCC is a partner of EuroBioBank (www.eurobiobank.org) and Translational Research in Europe for the Assessment and Treatment of Neuromuscular Disease (TREAT-NMD, www.treat-nmd.eu).

3.1.4 Animals

Dysf-gene deleted mice

B6.129-Dysf^{tm1Kcam}/J (*Dysf*-gene deleted) mice were kindly provided by Prof. Kate Bushby, Newcastle University, UK (Bansal et al., 2003)) with approval of the Mutant Mouse Regional Resource Centers (MMRRC), USA. Mice were housed under standard conditions and were treated in accordance with the European convention for the protection of vertebrate animals used for experimental and other scientific purposes.

Rats

Wistar rats were kindly provided by the central animal facility (Zentrale Tierexperimentelle Einrichtung, ZTE), University Medical Center Göttingen.

3.2.1.1 Cell culture

Culture of mammalian cell lines

For freezing purposes, cells at confluency of approximately 70% were washed with 1x PBS and detached by incubation with 0.5 -1 mL trypsin/EDTA for 2 min at 37 °C. Cells were resuspended in 10x volume of culture medium and centrifuged at 800 rpm for 5 min. The cell pellet was diluted in 1 mL freezing medium and transferred into cryo tubes, which were placed into freezing containers at -80°C overnight (o.n.) to allow slow freezing. For long-term storage, cryo tubes were transferred to -150 °C. For cultivation, cells were thawed in a water bath at 37 °C and transferred into 10 ml culture medium. After centrifugation at 800 rpm for 5 min, cell-pellets were resuspended in culture medium and seeded in culture flasks and cultivated at 37 °C in a 5% CO₂/ 95% humidity atmosphere. Depending on their confluency cells were split 1:5 to 1:10 every 3 to 5 days. Therefore, cells were detached with 1 mL trypsin/EDTA after washing with 1 x PBS. Detached cells were resuspended in culture medium and seeded into new culture flasks.

Culture of C2C12 cells

C2C12 were cultured in culture flasks and grown at low confluency (maximum 70%) to avoid unintentional differentiation of cells. Differentiation of myoblasts into myotubes was induced at a cell confluency of 90%. Therefore, the cultivation medium was replaced with differentiation medium after washing once with 1x PBS. C2C12 myoblasts were differentiated for 5 days. The medium was replaced by fresh differentiation medium every day.

Culture of human myoblasts

Primary human myoblasts were cultured in culture flasks and grown at low confluency (maximum 70%) to avoid unintentional differentiation of cells. Differentiation of myoblasts into myotubes was induced at a cell confluency of 90%. Therefore, the cultivation medium was replaced with differentiation medium after washing once with 1x PBS. Human myoblasts were differentiated for 7 days. The medium was replaced by fresh differentiation medium every day.

3.2.1.2 Isolation of ventricular cardiomyocytes from rats for immunofluorescence staining

The isolation of ventricular rat cardiomyocytes was performed in cooperation with the group of Prof. Viacheslav Nikolaev, formerly department for Cardiology and Pneumology, University Medical Center Göttingen. Ventricular cardiomyocytes from rat hearts were isolated by retrograde perfusion according to the Langendorff technique (Bell et al., 2011). 11-, 14-, 17-, 20-, 23-day old or adult rats were anesthetized with isoflurane and sacrificed by cervical dislocation. The hearts were extracted quickly and connected to the perfusion system by putting the aorta onto the perfusion cannula. Hearts were perfused with 8 mL/min at 37 °C. After initial perfusion with Ca²⁺-free buffer for 2 min, hearts were digested with collagenase type II (2 mg/mL, approximately 300 U/mg) in 40 µM calcium chloride for 9 min at 37 °C. Following perfusion, the ventricles were separated from the atria and minced in digestion buffer. The tissue was carefully resuspended with a 10 mL serological pipette and the digestion process was stopped by adding stop buffer before again resuspending. The cardiomyocytes were washed three times with stop buffer. Therefore, cells were allowed to sediment by gravity for 8 min at RT. The supernatant containing cell debris was discarded and cells were again resuspended in stop buffer. For immunofluorescence staining, cells were seeded on laminin-coated glass coverslips and incubated for 30 min at 37 °C, before proceeding with the staining protocol. Laminin coating was performed by incubation of glass cover slips with 20 µg/mL laminin in PBS at 37 °C for 2 h. Subsequently, cover slips were washed and allowed to dry at RT.

3.2.1.3 Isolation of rat hearts for preparation of protein lysates

11-week old rats were anesthetized by isoflurane and sacrificed by cervical dislocation. 14-, 17-, 20-, 23-week old rats and adult rats were euthanized by carbon dioxide inhalation and immediate opening of the thorax. The ventricular part of the heart was separated from the atrial part, transferred into reaction tubes and frozen in liquid nitrogen. Ventricular heart tissues were stored at -80 °C until preparation of protein lysates.

3.2.1.4 Transfection of cell lines

HeLa, HEK293, COS-7 and CHO-K1 cells were transfected with plasmid DNA using Effectene Transfection Reagent according to manufacturer's instructions. 48 h after transfection, cells

were either harvested for the isolation of proteins or fixed for immunofluorescence staining. C2C12 cells were transfected with plasmid DNA using Viromer® YELLOW transfection reagent according to manufacturer's instructions. 72 h after transfection, cells were harvested for the isolation of proteins.

3.2.1.5 Treatments of HeLa cells

PBA treatment

For stabilization experiments, HeLa cells were treated with 5 mM PBA for 24 h. Therefore, the medium was replaced 24 h after transfection and culture medium containing PBA was added for another 24 h. Transfected and PBA-treated cells were used for analysis of protein steady-state level and localization.

G418 treatment

For readthrough analysis, HeLa cells were transfected with DNA plasmids encoding dual fluorescence reporters. 6 h after transfection, the medium was changed to culture medium containing 100 µg/mL of G418 and incubated for another 18 h. 24 h after transfection, cells were harvested for flow cytometric analysis.

3.2.1.6 Immunofluorescence staining

Immunofluorescence staining of cell lines

For immunofluorescence staining, HeLa cells were seeded on glass coverslips in multi-well plates and C2C12 cells were seeded in Nunc™ Lab-Tek® Chamber Slides. 48 h after transfection, cells were washed once with PBS, fixed with 4% PFA by incubation for 20 min at RT and washed once with blocking solution (3% horse serum and 0.5% saponin in PBS). Following incubation in blocking solution for 30 min at RT, cells were incubated with the primary antibody diluted in blocking solution for 1 h at RT in a moist chamber. Cells were washed three times for 5 min with PBS and incubated with the secondary antibody as outlined above. Following washing three times for 5 min, cells were mounted with mowiol containing DAPI (1:2,000). Cover slips were transferred on microscope slides. Nunc™ Lab-Tek® Chamber Slide bottoms were covered with glass cover plates. Immunofluorescence samples were allowed to cure at RT o.n. and were long-term stored at 4 °C. Cells were visualized by epifluorescence or confocal laser scanning (Inverted IX81 Olympus) microscopy using 100x or 63x oil objectives, respectively.

Immunofluorescence staining of mouse ventricular cardiomyocytes

Langendorff-isolated ventricular cardiomyocytes from 8 week-old cardiomyocyte-specific tamoxifen inducible WRB knockout mice (MerCreMer - (Cre-) and MerCreMer + (Cre-, knockout)) were provided by Dr. Jhon Rivera-Monroy, department of Molecular Biology, University Medical Center Göttingen (For isolation protocol see Rivera-Monroy et al., 2016). The staining of cardiomyocytes were performed were carefully to avoid detachment of the cells. Cardiomyocytes were fixed with 4% PFA for 5 min at RT and washed twice with PBS before blocking with 10% FBS in PBS for 60 min at RT. Primary antibody was diluted in 5% FBS/PBS and incubated in a moist chamber at o.n. at 4 °C. After washing once for 5 min with PBS, incubation with the secondary antibody was performed for 1 h at RT in the dark in a moist chamber. Cells were washed twice for 5 min with PBS, briefly washed with water and mounted with mowiol containing DAPI (1:2,000). Immunofluorescence samples were allowed to cure at RT o.n. and were long-term stored at 4 °C. Cells were visualized by confocal laser scanning microscopy using a 63x oil objective. Dysferlin expression level was analyzed on the basis of confocal immunofluorescence images and calculated as corrected total cell fluorescence (CTCF) by subtracting the background multiplied with the cell area from the integrated cell intensity.

Immunofluorescence staining of rat ventricular cardiomyocytes

Langendorff-isolated ventricular rat cardiomyocytes were fixed in 4% PFA for 5 min at RT and blocked in 5% horse serum and 0.2% Triton® X 100 in PBS for 1 h at RT. Primary antibody was diluted in the blocking solution and incubated in a moist chamber o.n. at 4 °C. After washing twice shortly and once for 10 min with blocking solution, cells were incubated with secondary fluorescently-labeled antibody for 4 h at RT in a moist chamber. Cells were washed as described above with PBS and mounted with VECTASHIELD® containing DAPI. After burdening o.n. at RT, cells were visualized by confocal laser scanning microscopy (Inverted IX81 Olympus).

3.2.1.7 Membrane staining

Membrane staining of human myoblasts with DiI16(3)

Undifferentiated human myoblasts were seeded in μ -Slide 4 Well cell dishes. After differentiation of 7 days, cells were washed with sucrose cacodylate buffer and incubated with DiI16(3) diluted to 12.5 μ g/mL in sucrose cacodylate buffer for 10 min at RT. Cells were visualized by confocal laser scanning microscopy (Inverted IX81 Olympus).

Membrane staining of mouse ventricular cardiomyocytes with di-8-ANEPPS

The isolation of ventricular cardiomyocytes from *Dysf* gene-deleted and control mice was performed by Ines Müller, group of Prof. Niels Voigt, institute of Pharmacology and Toxicology, University Medical Center Göttingen. Ventricular cardiomyocytes from mouse hearts were isolated by retrograde perfusion according to the Langendorff technique (Bell et al., 2011). For membrane staining, cells were gently resuspended in stop buffer containing 50 μ M di-8-ANEPPS. Immediately, cells were seeded in laminin-coated microscopy cell dishes (μ -dish, 35 mm, glass bottom, ibiTreat) and incubated for 30 min at RT in the dark. Laminin coating was performed by covering the bottom of the microscopy cell dishes with 20 μ g/mL of laminin in PBS and incubation at 37 °C for 1 h. Subsequently, cover slips were washed and allowed to dry at RT. After the staining, the di-8-ANEPPS solution was removed carefully to not detach the cells from the bottom. After washing once with stop buffer, cells were overlaid with stop buffer and imaged by confocal laser scanning microscopy (LSM 710 NLO equipped with a 63x/1.4 NA oil objective). For the imaging protocol see (Wagner et al., 2014).

3.2.1.8 Analysis of TATS morphology of di-8-ANEPPS-stained mouse ventricular cardiomyocytes

The confocal images of di-8-ANEPPS-stained ventricular cardiomyocytes from *Dysf* gene-deleted and control mice were processed and analyzed as described by Wagner and colleagues (Wagner et al., 2014) with minor changes: For background subtraction, the rolling ball radius was set to 15. The amount of axial and transversal structures was calculated as the sum of structures with an orientation of -5° to $+5^\circ$ (axial) and $+85^\circ$ to $+95^\circ$ (transversal).

3.2.1.9 Flow cytometric analysis of readthrough using dual reporter assay

For the analysis of readthrough of stop codon contexts (stop codon +/- 10 nucleotides upstream and downstream) from all *DYSF* nonsense mutations, a dual fluorescent reporter was used and coupled to flow cytometric analysis of fluorescence. The dual reporter consists of an N-terminal TagRFP and a C-terminal EGFP tag flanking the stop codon context. A construct without a stop codon between the fluorescent tags served as 100% readthrough control. HeLa cells were transfected with the dual reporter and readthrough was either not induced (basal readthrough) or induced by the treatment with G418. 24 h after transfection, cells were harvested by trypsin/EDTA and centrifugation. The cell pellet was resuspended in 700 μ L PBS containing 10% FCS and cells were filtered through a cell strainer. The cells were

analyzed by flow cytometry using a LSRII (Becton Dickinson) flow cytometer equipped with 488 nm and 561 nm lasers. Living cells were selected by gating according to side scatter (SSC-A, corresponds to cell granularity) and forward scatter (FSC-A, corresponds to cell size). Additionally, cells were gated according to TagRFP and EGFP fluorescence intensity by setting a threshold which excludes non-transfected cells. Finally, the readthrough was calculated as the EGFP over TagRFP fluorescence ratio normalized to the untreated 100% readthrough control.

3.2.2 Protein biochemistry

3.2.2.1 Isolation of proteins from cells for SDS- polyacrylamide gel electrophoresis (SDS-PAGE)

Whole cell protein lysates were obtained from confluent cell cultures. After washing once with PBS, 1 mL PBS was added. Cells were detached by cell scrapers and transferred into reaction tubes. After centrifugation at 2000 rpm for 5 min, cell pellets were resuspended in cell lysis buffer and incubated for 20 min on ice. The cell debris was separated from the protein lysate by centrifugation at 14,000 rpm for 20 min at 4 °C. The protein lysate was transferred into a new reaction tube and either protein concentration was measured or protein lysates were frozen. Cell lysates were kept for short-term storage at -20 °C and for long-term storage at -80 °C. Protein concentrations were assessed by BCA assay according to manufacturer's instructions. Protein lysates with appropriate amount of protein were mixed with 4x SDS-PAGE sample buffer to obtain 1x concentration. The samples were boiled either at 70 °C for detection of full-length dysferlin or 95 °C for detection of truncated dysferlin and stored at -20 °C prior to SDS-PAGE.

3.2.2.2. Thrombin and Endo H treatment of HeLa cell culture lysates

For cleavage of full-length dysferlin, cell lysates with appropriate protein amount were mixed with 20 µL of protease thrombin (stock: 100 NIH units/mL in 0.1% BSA/ 50 mM Tris/HCl, pH 6.8) and incubated for 1 h at 37 °C. Subsequently, removal of N-glycosylation modifications was performed by treatment of cell lysates with the endoglycosidase Endo H using the supplemented buffers according to manufacturer's instructions. Shorty, proteins were denatured for 10 min at 95 °C prior to Endo H cleavage for 1 h at 37 °C.

3.2.2.3 Isolation of proteins from rat ventricular heart tissue for SDS-PAGE

Ventricular heart tissue from rats of different age was used for the preparation of protein lysates. Therefore, the tissue was weighted and 1.5 mL homogenization buffer per 100 mg tissue was added. The cardiac tissue was homogenized 5 times for 5 sec on ice. The homogenate was centrifuged two times at 1,300 x g for 10 min at 4 °C and in between centrifugation steps the supernatant was transferred into a new reaction tube. The final protein lysate was stored at -80 °C or immediately used for the determination of protein concentration by BCA assay according to manufacturer's instructions. SDS-PAGE samples were prepared by pooling 10 µg of protein from each rat of the same age and mixing the proteins with 4x SDS-PAGE sample buffer to obtain 1x concentration. The samples were boiled at 90 °C and stored at -20 °C prior to SDS-PAGE.

3.2.2.4 SDS-PAGE and western blot

SDS-PAGE was used for the separation of protein samples according to the molecular weight of proteins. For efficient separation, a 5% acrylamide stacking gel and, depending on the size of proteins to be detected, a resolving gel of 8-15% acrylamide concentration was used. Volume of stacking and resolving gel was adjusted to the gel size (small/large gels). Subsequently, western blot was performed to determine the protein level of specific proteins. The molecular weight of the separated proteins was determined by comparison with a pre-stained protein ladder.

Table 13 | Protocol for preparation of stacking and resolving gels for SDS-PAGE

Component	5% stacking gel	8% resolving gel	15% resolving gel
Total volume	2 mL	5 mL	5 mL
Water	1.4 mL	2.3 mL	1.1 mL
30% acrylamide solution	330 µL	1.3 mL	2.5 mL
1.0 M Tris, pH 6.8	250 µL	/	/
1.5 M Tris, pH 8.8	/	1.3 mL	1.3 mL
10% SDS	20 µL	50 µL	50 µL
10% APS	20 µL	50 µL	50 µL
TEMED	4 µL	6 µL	4 µL

Proteins were concentrated in the stacking gel at 15 mA/25 mA (for small and large gels, respectively), followed by separation at 25 mA/45 mA.

Following SDS-PAGE, proteins were electrotransferred to a nitrocellulose membrane. Therefore, a sandwich consisting of 3 layers of blotting paper, membrane, gel, 3 layers of blotting paper was prepared. The sandwich was placed into the semi-dry blotting system with the membrane facing the anode and soaked with transfer buffer. Blotting was performed at 1.25 mA per cm² of sandwich area for 1.5 h. Transferred total proteins were visualized by Ponceau-S staining.

For immunostaining the membranes were previously blocked for 1 h with 5% milk, 1% Tween[®] 20 in TBS (TBS-T) to avoid unspecific binding of the primary antibody which was incubated o.n. at 4 °C. The membranes were washed 3 times for 5 min with TBS-T and incubated with horseradish peroxidase (HRP)-coupled secondary antibody diluted in 5% milk/TBS-T for 1h at RT. After washing 3 times for 5 min with TBS-T, proteins bound to antibody-complexes were visualized by enhanced chemiluminescence (Lumi-Light Western Blotting Substrate) using a western blot documentation system LAS-4000. Protein signal was quantified using Fiji software.

3.2.3 Molecular biology

3.2.3.1 Generation of EGFP-*DYSF*-ops-pcDNA4

The plasmid containing an ops-tagged *DYSF* cDNA sequence was generated by the amplification of a C-terminal fragment of the *DYSF* sequence containing the opsin tag sequence, which was incorporated into the reverse primer, and cloning of the amplicon into the preexisting plasmid EGFP-*DYSF*-pcDNA4.

3.2.3.2 Generation of EGFP-L1431P-ops-pcDNA4 by DpnI-mediated site-directed mutagenesis

The pathogenic mutation L1431P was introduced into the plasmid EGFP-*DYSF*-ops-pcDNA4 by site-directed mutagenesis and subsequent DpnI digestion. Therefore, KAPA HiFi DNA polymerase and primers OST 581 and OST 582 were used. For the mutagenesis reaction, 10 ng of template DNA were mixed with 5 µL GC buffer, 0.75 µL of dNTP mix (3.75 mM), 0.75 µL per

primer (10 μ M) and 0.5 μ L KAPA HiFi DNA polymerase in a total volume of 25 μ L. The reaction was performed applying the following program:

95 °C	3 min	} 25 cycles
98°C	20 sec	
55 °C	20 sec	
72 °C	6:30 min	
72 °C	3 min	

Subsequently, the template DNA was removed by digestion of the total reaction mixture with 1 μ L of DpnI for 1:30 h at 37 °C.

3.2.3.3 Amplification of DNA by polymerase chain reaction (PCR)

The amplification of the C-terminal *DYSF* fragment and coupling to the opsin tag sequence was performed by PCR using PRECISOR High-Fidelity DNA Polymerase. EGFP-*DYSF*-pcDNA4 was used as template. Primers OST587 and pKB17 were used for the amplification. Coupling of *DYSF* to opsin tag was achieved by incorporation of the opsin tag sequence into the reverse primer pKB17 and removal of the *DYSF* stop codon. For the PCR, 10 ng of template DNA were mixed with 10 μ L of GC buffer, 2.7 μ L of dNTP mix (3.75 mM), 1 μ L per primer (10 μ M) and 1 μ L of polymerase in a total volume of 50 μ L. The amplification was performed applying the following PCR program:

98 °C	2 min	} 25 cycles
98°C	30 sec	
49 °C	30 sec	
72 °C	1 min	
72 °C	10 min	

3.2.3.4 Restriction of DNA with restriction endonucleases

DNA fragments and plasmids were cleaved using restriction endonucleases from New England Biolabs® Inc. according to manufacturer's instructions. For cloning of EGFP-*DYSF*-ops-pcDNA4 enzymes *AfeI* and *NotI* in CutSmart® buffer were used. For test digestion of clones, *BamHI*-HF® in CutSmart® buffer was used. DNA fragment were separated by agarose gel electrophoresis and extracted by NucleoSpin® Gel and PCR Clean-up.

3.2.3.5 Ligation of DNA fragments

For cloning of EGFP-*DYSF*-ops-pcDNA4 the digested amplicon and plasmid EGFP-*DYSF*-pcDNA4 were ligated using T4 DNA Ligase. Ligation was carried out by mixing 50 ng of digested plasmid DNA with three-fold molar mass of digested amplicon with 1 µl of T4-ligase and 2 µl 10x ligase buffer in a total reaction volume of 20 µL. The ligation mixture was incubated at RT for 30 min and subsequently used for transformation of competent *E. coli*.

3.2.3.6 Transformation of *E. coli*

Plasmid DNA was introduced in *E. coli* bacteria using heat shock. For cloning purposes, 1 µl ligation reaction was added to 10 µl of competent *E. coli* bacterial solution. For transformation of mutagenized DNA, 2 µl of mutagenesis mixture was added to 20 µL of competent *E. coli* bacterial solution. Following 20 min of incubation on ice, the transformation mix was set to 42°C for 70 s. Subsequently, the solution was cooled down on ice for 2 min and 400 µl of LB medium were added. After incubation at 37 °C and 300 rpm for 1h, the mixture was plated on LB agar plates containing 100 µg/mL ampicillin and cultivated o.n. at 37 °C. Single colonies were picked and small bacterial cultures were prepared by inoculation of 3 mL LB medium containing 100 µg/mL ampicillin and o.n. incubation at 37 °C and 200 rpm.

3.2.3.7 Isolation of plasmid DNA from *E. coli*

Isolation of plasmid DNA from small *E. coli* cultures

Plasmid DNA was isolated from 3 mL o.n. *E. coli* cultures. Therefore, bacteria were harvested at 8000 rpm for 1 min. The pellet was resuspended in 200 µL of buffer P1 and 300 µL buffer of P2 was added and the samples were inverted and incubated for 5 min at room temperature. 300 µL of buffer P3 was added, the samples were inverted and centrifuged for 10 min at 14,000 rpm. The supernatant was transferred into a new reaction tube and the DNA was precipitated with 0.7 volumes of isopropanol and 20 min centrifugation at 14,000 rpm. The pellet was washed with 70% ethanol, dried for 10 min at 37 °C and resuspended in 30 µL dH₂O.

Large bacterial cultures were prepared by inoculation of 100 mL LB medium with 100 µL of small o.n. bacterial culture and incubation o.n. at 37 °C and 200 rpm

Isolation of plasmid DNA from large *E. coli* cultures

Plasmid DNA was isolated from 100 mL o.n. *E. coli* cultures. Bacteria were harvested by 20 min centrifugation at 3,000 rpm and isolation of DNA was performed according to the manufacturer's instructions using the NucleoSpin® Plasmid kit. DNA was eluted from columns with dH₂O.

3.2.3.8 DNA sequencing

For DNA sequencing (Sanger method) the BigDye Terminator v3.1 Cycle Sequencing Kit according to manufacturer's instructions was used. 300 ng of DNA were mixed with 0.5 µL sequencing primer (10 µM), 2 µL BigDye 5x buffer and 1 µL BigDye® Terminator v3.1 Ready Reaction Mix in a total volume of 10 µL. The reaction was performed as follows:

96 °C 10 sec
60°C 4 min, 24 cycles

For purification of the cycle sequencing product 220 µL of 100% ethanol, 120 µL of dH₂O and 10 µL of 3 M sodium acetate (pH 4.6) were added. The mix was vortexed and incubated for 15 min at RT before centrifugation for 20 min at 14,000 rpm. The pellet was washed with 70% ethanol, dried and resuspended in 10 µL formamide. DNA sequencing was performed by Andreas Ohlenbusch, department for Child and Adolescent Medicine, University Medical Center Göttingen.

3.2.4 Statistics

Experimental data is presented as mean ±SEM. Statistical analysis was performed using Microsoft Excel 2010, GraphPad Prism 4 or SAS® software by student's t-test assuming normal distribution or two-way ANOVA for repeated measurements with Bonferroni's post hoc multiple comparison test. If P-values are smaller than 0.05, significance is assumed.

4 Results

4.1 Dysferlin and BIN1 localize to different parts of the T-tubule system in C2C12 cells

Previous work of our group demonstrated that dysferlin is able to induce tubular structures upon heterologous expression in non-muscle cells and that these induced structures are newly formed membrane tubules (Hofhuis et al., 2017). This and other observations such as dysferlin binding to PI(4,5)P₂ (Hofhuis et al., 2017; Therrien et al., 2009), an abnormally configured T-tubule system upon dysferlin-deficiency (Klinge et al., 2010a) and localization of dysferlin to the developing and regenerating T-tubule system (Klinge et al., 2007, 2010a) lead to the hypothesis that dysferlin is involved in membrane remodeling and biogenesis of the T-tubule system in skeletal muscle. The BAR domain protein BIN1 may function in a similar fashion. BIN1 induces formation of membrane tubules (Lee et al., 2002), a function which is dependent on PI(4,5)P₂ binding (Fugier et al., 2011), and BIN1-deficiency also leads to muscle disease (Nicot et al., 2007). It seems that the tubulation properties of both, BIN1 and dysferlin, observed in *in vitro* and cell experiments, might be the basis for their membrane organizing function during myogenic differentiation. To characterize dysferlin and BIN1 during T-tubule development, both proteins were immunolabeled in C2C12 cells, a murine myoblast cell line which is differentiated into myotubes, and thereby used as model system for muscle development and T-tubule biogenesis. As previously reported, endogenous dysferlin and BIN1 localize to vesicular and tubular structures constituting membranes of the developing T-tubule system. Thereby, they partially colocalize especially at the tubular compartment (Klinge et al., 2007). Confocal microscopy of colabeled C2C12 myotubes reveals that a fairly large amount of dysferlin and BIN1 is not colocalizing but is expressed at distinct cellular areas. Dysferlin is mainly located at central and perinuclear areas forming a longitudinal tubule network. In contrast, BIN1 is rather distal localizing to the sarcolemma and longitudinal membrane structures in the proximity of the sarcolemma (**Figure 6, A and B**). A 3D-volume model of a myocyte shows that the inner cell area is mainly composed of dysferlin-labeled membranes and the outer area is like a shell which is dominated by BIN1. Furthermore, a layer in between the two described areas is characterized by membrane structures at which dysferlin and BIN1 proteins colocalize (**Figure 6, C**).

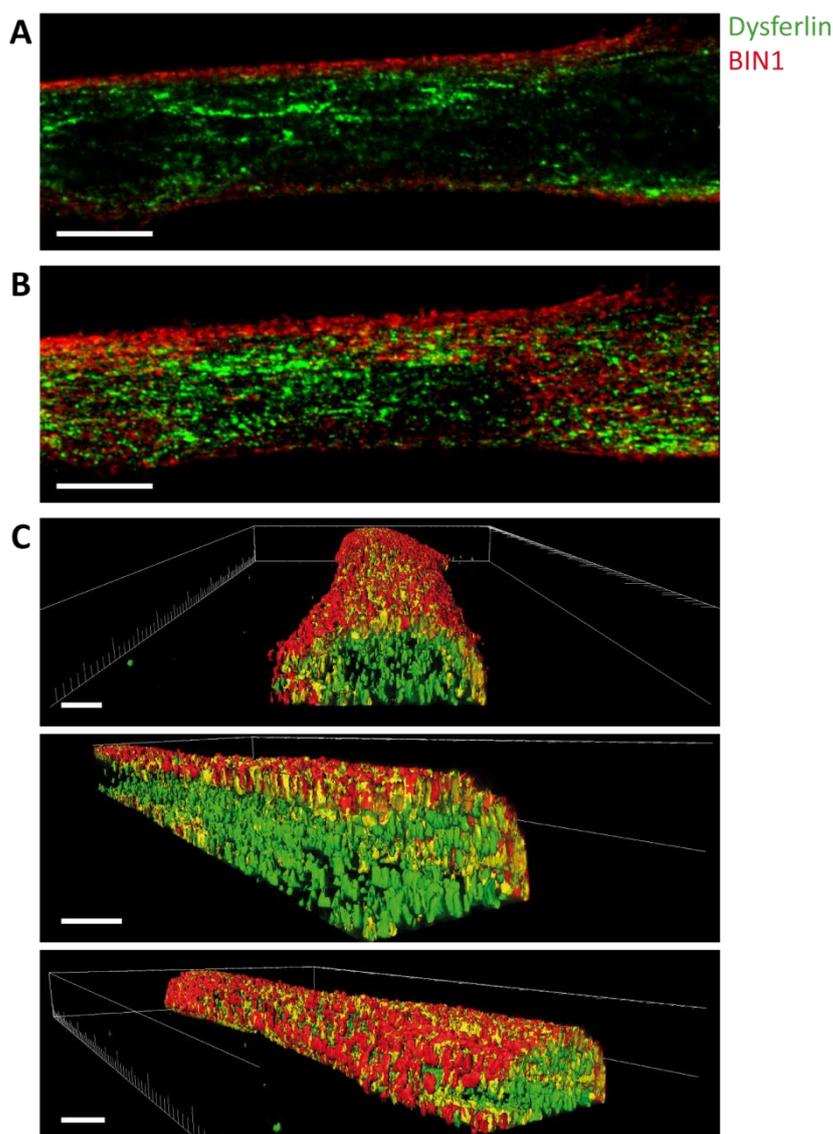

Figure 6 | Differential localization of dysferlin and BIN1 in developing myotubes. C2C12 myotubes were differentiated for 5 days and co-labeled with antibodies against endogenous dysferlin (green) and BIN1 (red). Immunofluorescence samples were visualized by confocal microscopy. **(A)** Confocal image of a single plane of a C2C12 myotube. **(B)** Single slices of a confocal image stack were combined generating an overlay of the myotube (Software Imaris). **(C)** Confocal image stack was converted into a 3D-volume model of the labeled structures (Software Imaris). Scale bars 10 μm .

4.2 Abnormal development of the T-tubule system in LGMD2B patient myoblasts

As previously reported by our group, dysferlin-deficiency does not only lead to a typically dystrophic muscle phenotype and an impaired membrane repair (Bansal et al., 2003), but also disturbs the T-tubule structure (Klinge et al., 2010a). Labeling of T-tubules from skeletal muscles of dysferlin-null mice with calcium potassium ferrocyanide and electron microscopic

analysis of the muscle tissue reveal irregularity and dilatation of this membrane organelle (Klinge et al., 2010a), features that are even enhanced upon notexin-induced muscle regeneration (Hofhuis et al., 2017). These results indirectly suggest an important role of dysferlin for proper biogenesis of the T-tubule system as they originate from the examination of adult mouse muscles. To analyze the effects of dysferlin-loss more directly, myoblasts from a LGMD2B patient harboring a splice site mutation in the *DYSF* gene (c.1939-6T>A) were analyzed. Myoblasts can be differentiated in culture, a process during which the cells fuse to form multinucleated myotubes and develop a premature T-tubule system. Thereby the cells serve as model system for T-tubulogenesis. Human myoblasts were differentiated by serum deprivation for 7 days in culture and subsequently analyzed. The homozygous mutation leads to a nearly complete loss of dysferlin protein expression as detected by western blot of differentiated myoblast lysates (Figure 7, A).

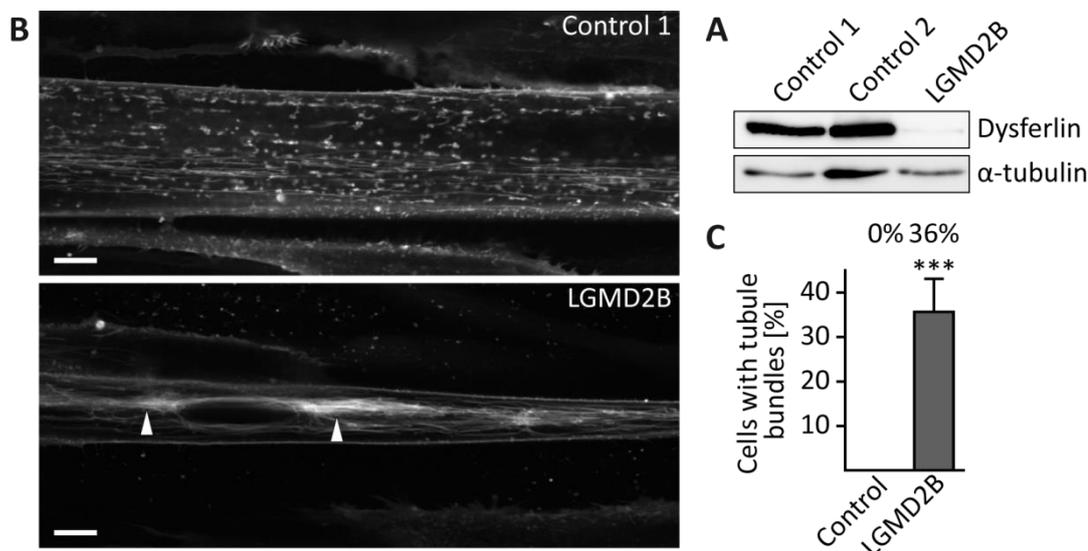

Figure 7 | Tubular membrane bundles in LGMD2B patient myotubes. (A) Dysferlin expression was analyzed via western blot using 30 μg whole cell lysate obtained from human control and dysferlin-deficient (LGMD2B) myotubes after a differentiation time of 7 days. Dysferlin was detected by anti-dysferlin (NCL-Hamlet) antibody. α -tubulin served as loading control. (B) Representative images of human control and dysferlin-deficient (LGMD2B) myotubes after 7 days of differentiation stained with the dye DiIC₁₆(3) (12.5 $\mu\text{g}/\text{mL}$ in sucrose cacodylate buffer) for 10 min at 37 $^{\circ}\text{C}$ to visualize the membrane system. Cells were imaged by confocal microscopy. Arrowheads indicate tubular membrane bundles. Scale bars 10 μm . (C) Quantification of cells with tubular membrane bundles as indicated in (B). N=3 (15-24 cells/experiment) \pm SEM, ***=P \leq 0.001 (Student's t-test).

The membrane system of living cells was stained with the lipophilic red-fluorescent dye DiIC₁₆(3) and visualized by confocal microscopy. DiIC₁₆(3) stained the sarcolemma, but also vesicular and longitudinal tubular membranes inside the cells (Figure 7, B). In contrast to the

control fibers, compact tubular membrane bundles were observed in 36% of dysferlin-deficient fibers (**Figure 7**, B and C). These dense formations were located mainly in the transverse center and often in the perinuclear region of the myotubes. The compact membrane bundles which were observed only in dysferlin-deficient myotubes might be the result of an abnormal formation of the T-tubule system due to absence of dysferlin.

4.3 Dysferlin is expressed at the cardiac T-tubule system during maturation

Results showing that dysferlin localizes to the sarcolemma and the T-tubule system (Ampong et al., 2005; Anderson et al., 1999; Chase et al., 2009; Klinge et al., 2010a) demonstrate the importance of this protein for this organelle in skeletal muscle. Abnormal configuration of the adult (Klinge et al., 2010a) and developing (**Figure 7**) T-tubule system upon dysferlin-deficiency gives insight into the pathophysiological mechanisms of muscular dystrophy due to dysferlin loss. Dysferlinopathy is mainly described as skeletal muscle disease but there are reports suggesting that the heart muscle is also affected by dysferlin-deficiency. Thus, the question arises whether dysferlin is not only essential for the biogenesis of the transverse membrane system in skeletal muscle but also plays a role in the development of the cardiac T-tubules. To answer this question, a time course experiment was performed analyzing dysferlin expression in the rat heart at different time points during the first three weeks of life, the time window of cardiac T-tubule maturation (Han et al., 2013; Reynolds et al., 2013). Single ventricular cardiomyocytes of 11, 14, 17, 20, and 23 days old rats and of adult rats were isolated by Langendorff-perfusion (Bell et al., 2011) and endogenous dysferlin as well as Ca_v1.2 as T-tubule marker were immunolabeled. The cells were visualized by confocal microscopy. At the beginning of the analyzed time period (P11 - P14) cardiomyocytes were comparably small with roundish edges. No Ca_v1.2-labeled structures resembling the T-tubule system were detectable, instead Ca_v1.2 is localizing to the sarcolemma at P14. Over time, cardiomyocytes enlarged and developed characteristic sharp edges. Ca_v1.2 expression increased and localized to transverse elements of the maturing T-tubule system. Simultaneously, the dysferlin signal showed a similar expression pattern as the T-tubule marker Ca_v1.2 (**Figure 8**, A). To quantify expression of dysferlin at the T-tubule system, colocalization with Ca_v1.2 was assessed by Mander's M1 and M2 coefficients (**Figure 8**, B). Thereby, M1 corresponds to the dysferlin signal that is overlapping with Ca_v1.2 signal normalized to the total dysferlin labeling (M2 *vice versa*). At P11 M1 and M2 values are only 0.14 indicating very low colocalization of dysferlin and

Ca_v1.2. Over time (P11 - P23), both, M1 and M2 coefficients increase and respective values stay similar. Adult cardiomyocytes show the highest M1 and M2 colocalization coefficients of 0.64 and 0.55, respectively. These values show that the proportion of dysferlin signal overlapping with Ca_v1.2 is higher than the Ca_v1.2 signal overlapping with dysferlin. To further characterize dysferlin expression in developing cardiomyocytes, the protein level was assessed by western blot (**Figure 8, C**). Therefore, hearts were isolated from 11-, 14-, 17-, 20-, 23-day old or adult rats and homogenates of the ventricular muscle tissue were prepared. Dysferlin was detected by anti-dysferlin (NCL-Hamlet) antibody. GAPDH served as loading control. Western blot signal was densitometrically quantified (**Figure 8, D**) and shows a 7-fold increase in dysferlin protein level from P11 to P20. After the peak at P20, dysferlin expression decreases again. Analysis of dysferlin in maturing rat cardiomyocytes shows peaked expression at P17 - P20 and localization to the developing T-tubule system.

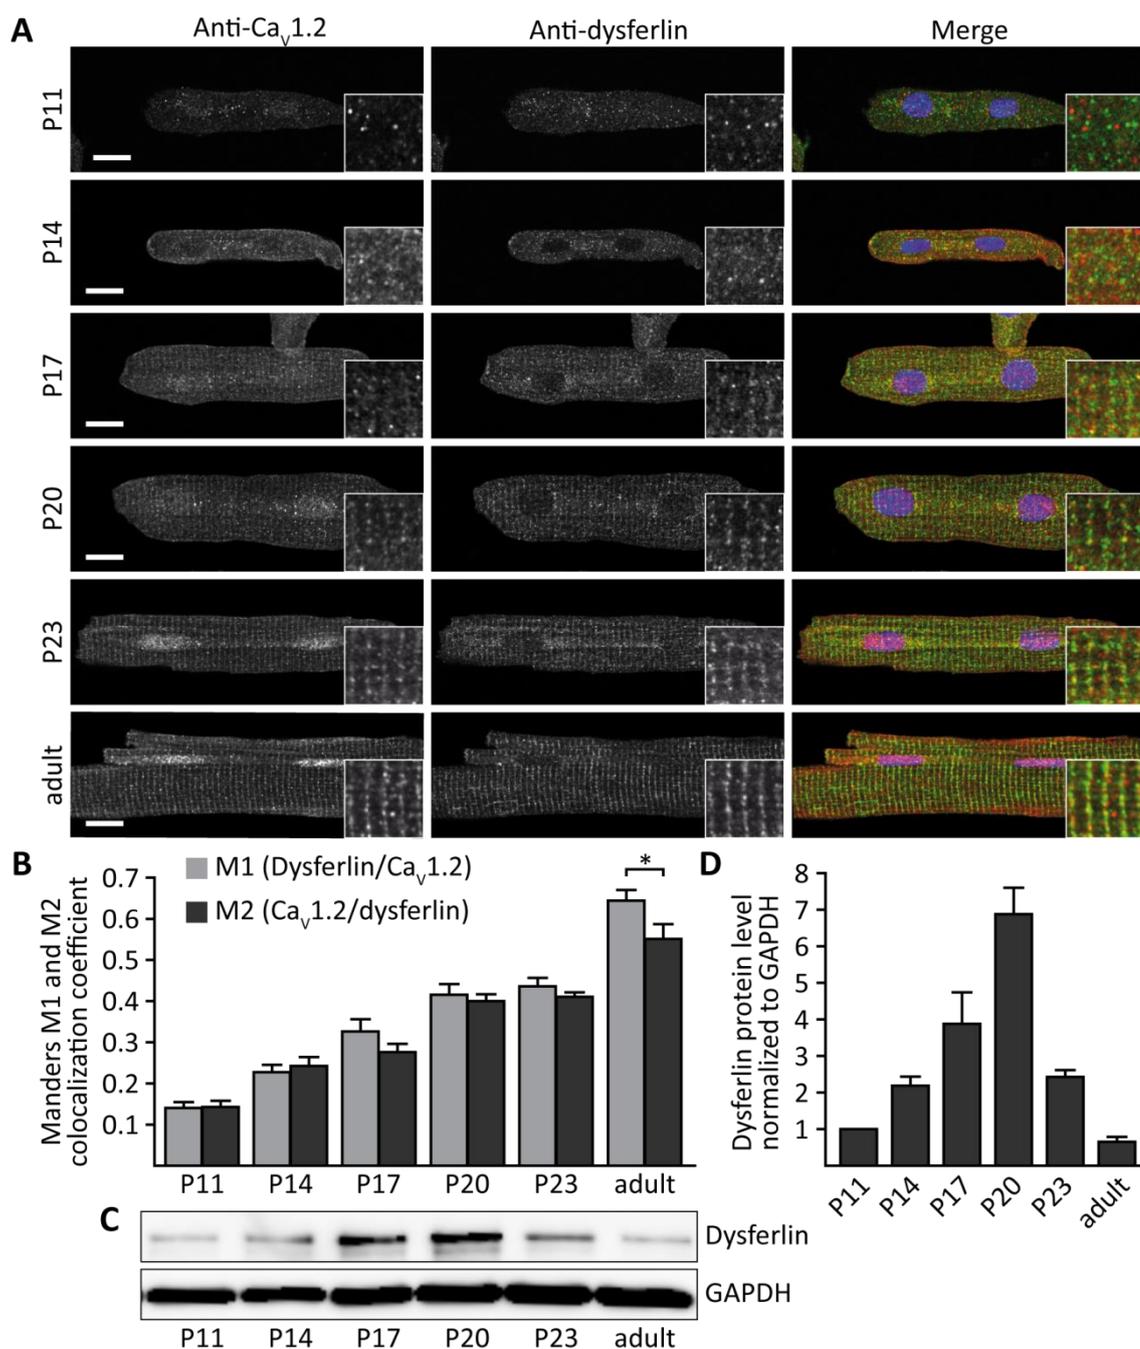

Figure 8 | Dysferlin colocalizes with Ca_v1.2 in postnatal rat cardiomyocytes and dysferlin expression peaks after birth. P=days after birth. **(A)** Rat cardiomyocytes were Langendorff-isolated at the indicated time points and dysferlin localization was analyzed by confocal microscopy. Representative images of rat cardiomyocytes immunolabeled with anti-dysferlin (NCL-Hamlet, green) and anti-Ca_v1.2 (red) as T-tubule marker. Scale bars 10 μm. **(B)** Colocalization of dysferlin and Ca_v1.2 was analyzed using the JACoP plugin of ImageJ and calculating the Manders coefficient. M1=(sum of green pixels colocalizing with red)/total green pixels. M2=(sum of red pixels colocalizing with green)/total red pixels. N=1-3 rats (5-8 cells/rat) +/- SEM (Student's t-test). **(C)** Rat hearts were isolated at the indicated time points and ventricular tissue was used for western blot analysis. Dysferlin was detected by anti-dysferlin (NCL-Hamlet), anti-GAPDH served as loading control. A representative western blot is depicted. **(D)**

Quantification of dysferlin expression based on western blots. Dysferlin level was normalized to GAPDH and related to P11. N=3 +/- SEM.

4.4 Dysferlin-deficiency leads to altered transverse-axial tubule system in adult cardiomyocytes

Dysferlin localizes to the developing T-tubule system in rat cardiomyocytes and dysferlin expression peaks in a narrow time frame during which maturation of the tubular membrane system takes place (Figure 8). Consequently, the effect of dysferlin loss on the morphology of this membrane system should be analyzed. Therefore, ventricular cardiomyocytes of control (*Dysf*^{+/+}) and dysferlin-deficient (*Dysf*^{-/-}) adult mice were Langendorff-isolated (Bell et al., 2011) and living cells were stained with the red-fluorescent lipophilic membrane dye di-8-ANEPPS (Wagner et al., 2014). Cell integrity criteria such as transverse striation, sharp cell edges and lack of membrane blebs were applied to guarantee that only cells that withstood the isolation procedure without apparent damage were used for subsequent acquisition of the labeled membrane system (Figure 9, top).

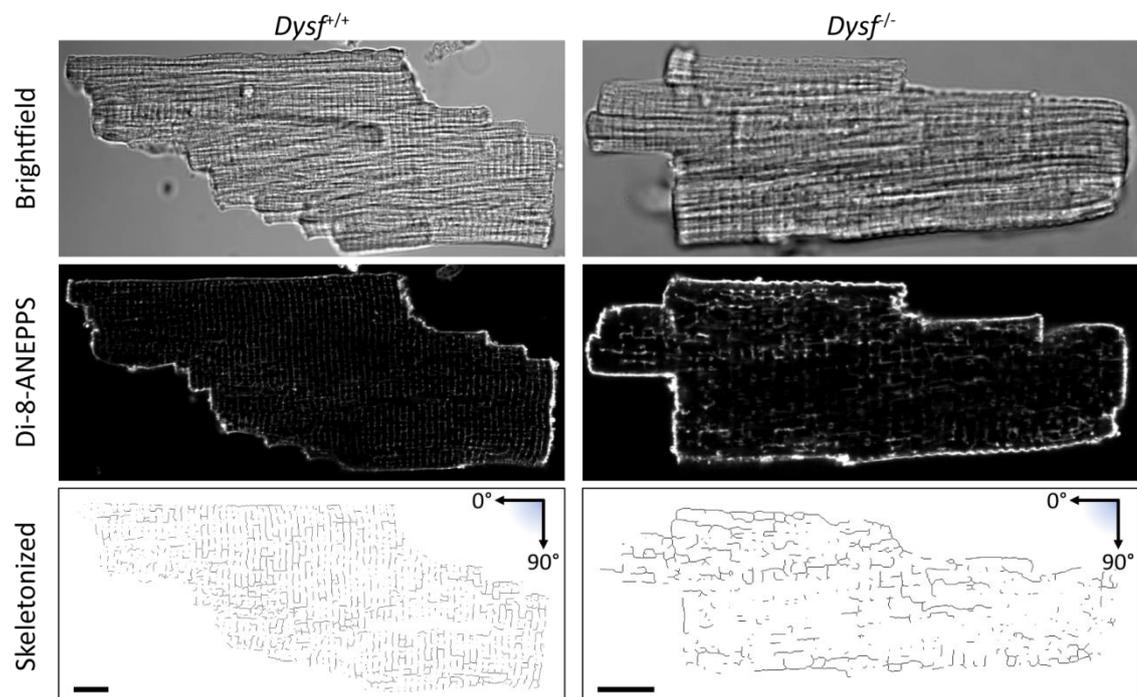

Figure 9 | Altered morphology of tubular membrane network in ventricular cardiomyocytes of dysferlin-deficient mice. Ventricular cardiomyocytes were isolated from control (*Dysf*^{+/+}) and dysferlin-deficient (*Dysf*^{-/-}) mice by Langendorff-perfusion. The membrane system was stained with di-8-ANEPPS for 30 min at RT and cells were imaged by confocal microscopy. Using the software ImageJ, the confocal image signal was skeletonized for subsequent detailed analysis of membrane structures. Representative brightfield, di-8-ANEPPS and skeletonized images are depicted. Scale bars 10 μ m.

The fluorescent signal of the dye was visualized by confocal microscopy (**Figure 9**, middle). Di-8-ANEPPS stains the sarcolemma and cytoplasmic membrane structures. The intracellular membranes have a predominantly axial (0°) or transverse (90°) orientation. The images of the di-8-ANEPPS-labeled transverse-axial membrane system reveal an altered morphology in *Dysf*^{-/-}-cardiomyocytes compared to dysferlin-competent cells. In order to be able to quantify the visually noticeable alterations, the images were skeletonized using an ImageJ plugin (**Figure 9**).

4.4.1 Dysferlin loss results in reorientated transverse-axial tubule system in cardiomyocytes

The intracellular membrane system in cardiomyocytes has transversely- and axially-orientated portions which are both important for a proper cell function (Kirk et al., 2003; Ohler et al., 2010). Di-8-ANEPPS-staining of adult dysferlin-deficient and control cardiomyocytes reveals apparent morphological alterations (**Figure 9**). The dimension of morphological changes was assessed by quantifying the amount of structures for each direction (-45° - 134°) based on the skeletonized images of di-8-ANEPPS-labeled cells (Wagner et al., 2014) (**Figure 9**). The quantification is depicted as histogram with the amount of structures plotted against the structure direction and reveals a bimodal distribution, both, for *Dysf*^{+/+} and *Dysf*^{-/-} cardiomyocytes (**Figure 10, A**). However, the proportion of structures with transverse ($90^\circ \pm 5^\circ$) or axial ($0^\circ \pm 5^\circ$) orientation is significantly changed in dysferlin-deficient cells compared to controls (**Figure 10, B**). Dysferlin-competent cardiomyocytes have 13.4% axially and 16.0% transversely orientated structures. In dysferlin-deficient cells the distribution is changed to 20.1% and 8.8% axial and transverse orientation, respectively (**Figure 10, C**). Thus, dysferlin-deficiency leads to an extensive shift in directionality of the T-tubules in adult cardiomyocytes.

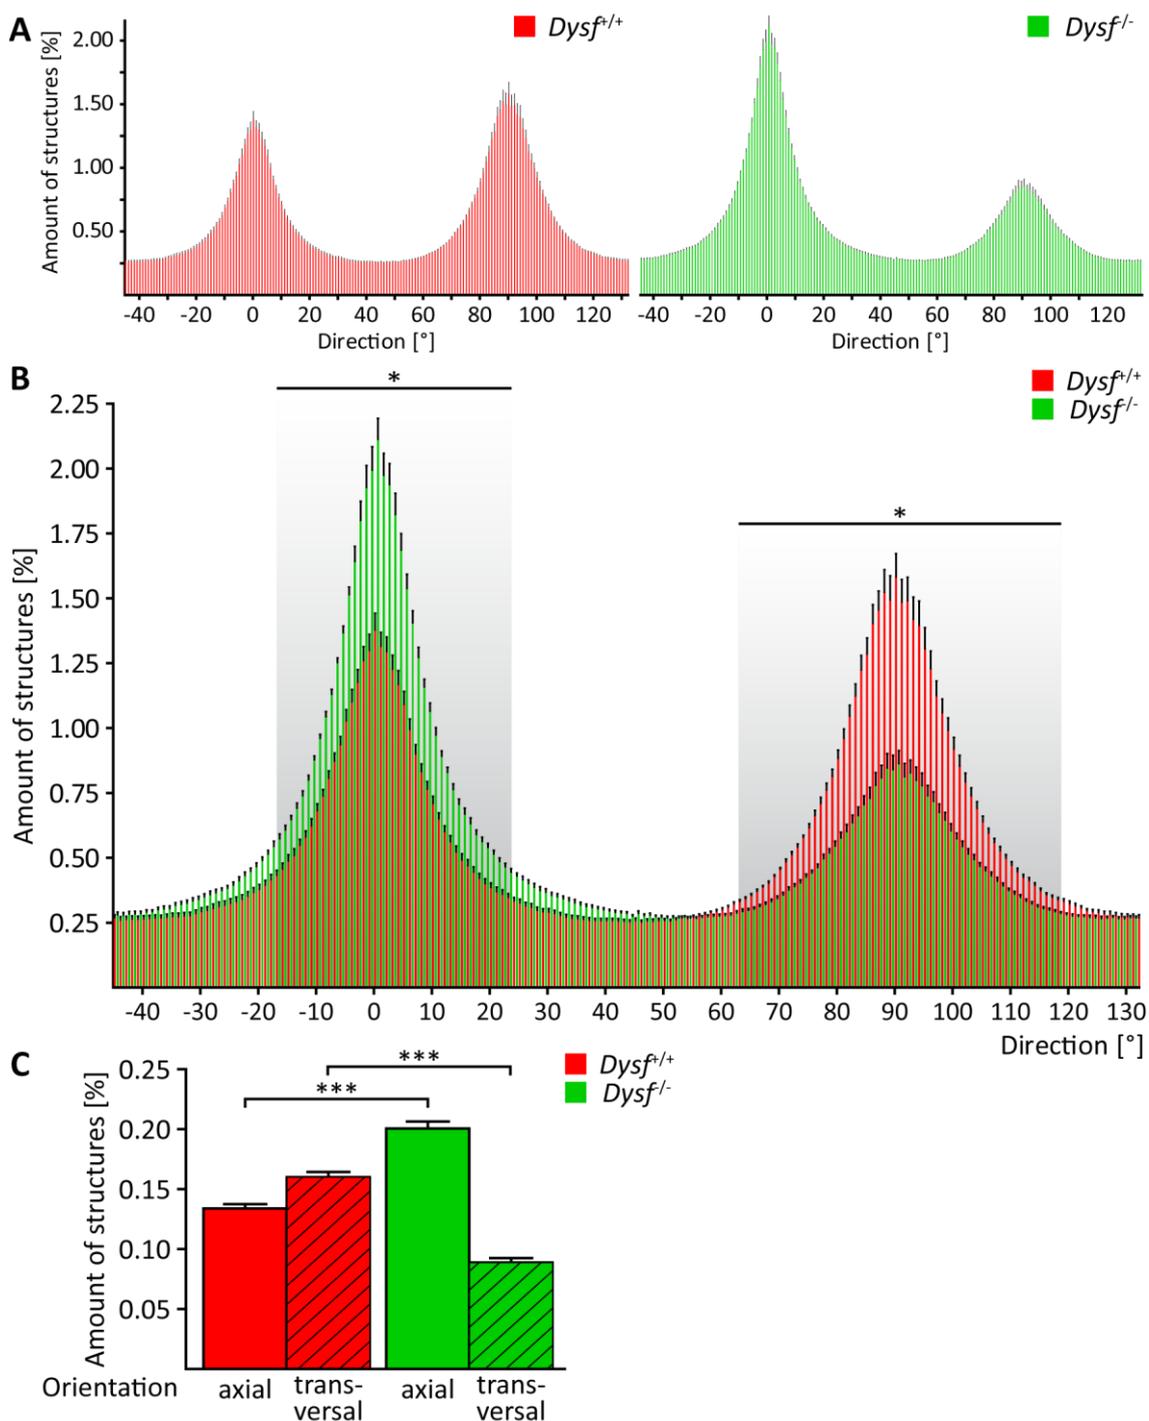

Figure 10 | Altered directionality of transverse-axial tubule system in ventricular cardiomyocytes of dysferlin-deficient mice. (A) Skeletonized images of di-8-ANEPPS-stained dysferlin-competent ($Dysf^{+/+}$) and -deficient ($Dysf^{-/-}$) cardiomyocytes (Figure 9) were used for quantification of structure directionality with ImageJ and depicted as histograms with one bar for each direction. $N=8$ ($Dysf^{+/+}$)/ 5 ($Dysf^{-/-}$) mice, (5-20 cells/mouse). Mean \pm SEM. (B) Histograms for $Dysf^{+/+}$ and $Dysf^{-/-}$ are depicted in one diagram with corresponding $Dysf^{+/+}$ and $Dysf^{-/-}$ bars next to each other. Gray boxes mark area of direction with significant differences between $Dysf^{-/-}$ and $Dysf^{+/+}$ for each bin (16° to 24° , 64° to 118°). $*=P\leq 0.05$ (Two-way ANOVA with repeated measures). (C) Summed amount of structures with axial ($0^\circ \pm 5^\circ$) and transverse ($90^\circ \pm 5^\circ$) orientation. Mean \pm SEM. $***=P\leq 0.001$.

4.4.2 Structural parameters of skeletonized tubular membranes are changed in dysferlin-deficient cardiomyocytes

To characterize the membrane system of dysferlin-deficient compared to control cardiomyocytes more detailed, structural parameters such as skeleton length, number of structures, number of branches and number of end-point voxels were measured on the basis of the skeletonized di-8-ANEPPS images and normalized to the cell area (Wagner et al., 2014). Furthermore, the average branch length was assessed. The cell area was unchanged. The same is true for the average branch length. Though, the number of structures and the number of branches were decreased, thereby reducing the total skeleton length and the number of end-point voxels. Thus, dysferlin-deficiency leads to a reorganization of the membrane system with redirection and reduction of tubular structures (Figure 11).

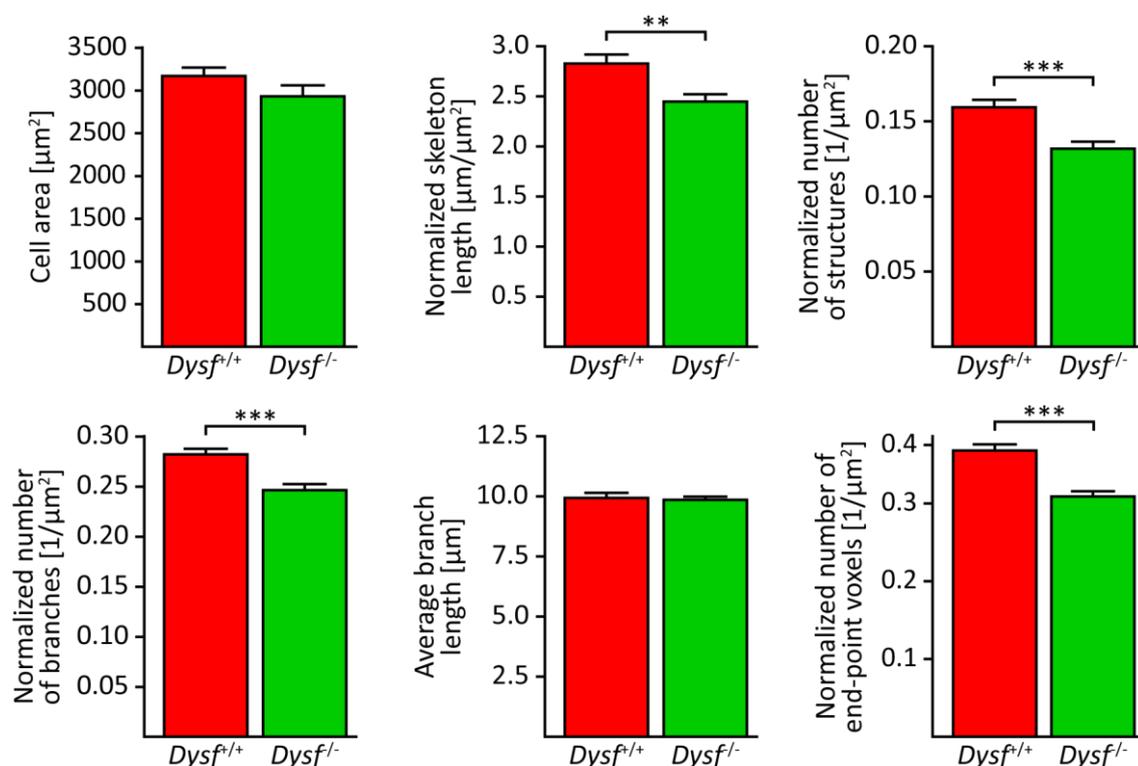

Figure 11 | Altered structural parameters of transverse-axial tubule system in ventricular cardiomyocytes of dysferlin-deficient mice. Skeletonized images of di-8-ANEPPS-stained dysferlin-competent (*Dysf*^{+/+}) and -deficient (*Dysf*^{-/-}) cardiomyocytes (Figure 9) were analyzed with the Analyze Skeleton (2D/3D) plugin of ImageJ. The following parameters were used to characterize the skeletonized transverse-axial tubule system: Cell area, normalized skeleton length, normalized number of structures, normalized number of branches, average branch length, normalized number of end-point voxels. Skeleton length, number of structures, number of branches and number of end-point voxels were normalized to the cell area. N=8 (*Dysf*^{+/+})/5 (*Dysf*^{-/-}) mice, (5-20 cells/mouse) +/- SEM. **= $P \leq 0.01$, ***= $P \leq 0.001$ (Student's t-test).

4.5 Dysferlin gets inserted into the ER

To understand the pathomechanisms underlying dysferlin-deficient muscular dystrophy and to find therapeutic intervention targets it is important to know the route of dysferlin through the cell. Until now, little is known about the fate of the protein after its synthesis. Because of its single C-terminal transmembrane domain dysferlin is counted to the TA proteins, which are inserted into the ER membrane directly after their cytosolic translation. Integration of a protein into the ER can be analyzed by coupling the protein of interest to an opsin tag harboring an N-glycosylation site and detection by western blot. The modification occurring in the lumen of the ER leads to a mobility shift of the protein during electrophoresis of up to 3 kDa (Helenius and Aebi, 2004). Thus, this method is well applicable to relatively small proteins (Figure 12).

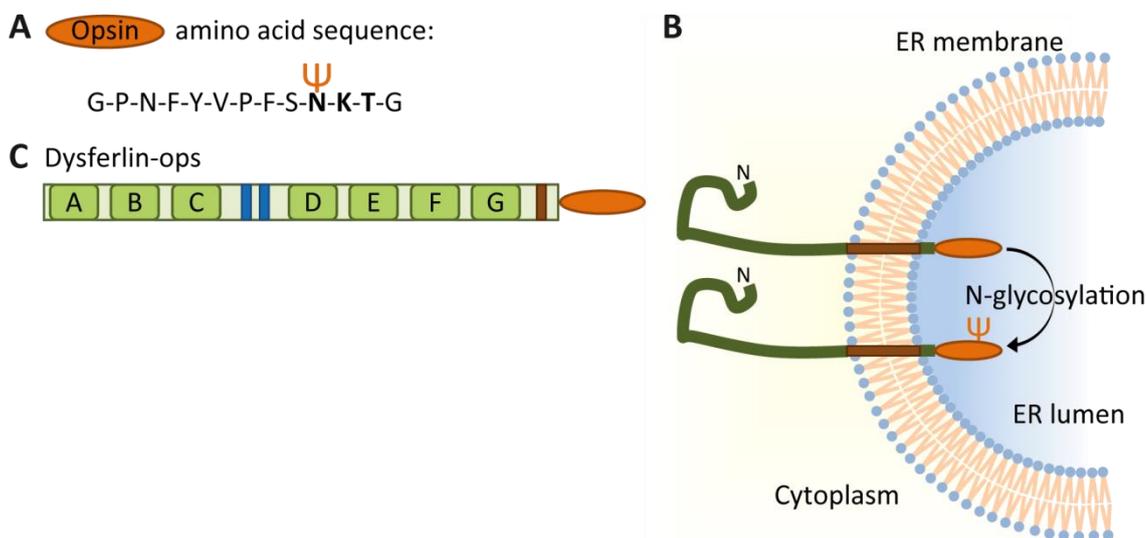

Figure 12 | Use of the glycosylation tag opsin as reporter for protein integration into the ER. (A) Amino acid sequence of the short variant of the glycosylation tag opsin, derived from the bovine rhodopsin, contains one glycosylation site (respective amino acids marked in bold letters, asparagine (N) which can be glycosylated indicated by a fork). (B) Schematic representation of the glycosylation of an opsin-tagged protein inside the ER lumen upon protein integration into the ER. (C) C-terminally opsin-tagged full-length dysferlin (Dysferlin-ops) used for expression in mammalian cells.

Though, dysferlin is a protein of 230 kDa making it unfeasible to detect glycosylation when separating the full-length protein by SDS-PAGE. To overcome this obstacle, we aimed to cleave dysferlin and analyze a considerably smaller peptide with respect to glycosylation. The tool PeptideCutter (http://web.expasy.org/peptide_cutter/) of the bioinformatics resource portal ExPASy was used to search for proteases that specifically cleave the dysferlin protein. The

enzyme thrombin was found to have two recognition sites within the dysferlin protein sequence at positions 187 aa and 1806 aa (**Figure 13, A**). To test, whether the cleavage of dysferlin by thrombin was specific and effective and whether dysferlin gets integrated into the ER membrane, HeLa cells were transfected with constructs encoding untagged or opsin-tagged full-length dysferlin (Dysferlin and dysferlin-ops, respectively). Cell lysates were either nontreated or digested with thrombin and analyzed by SDS-PAGE and western blot (**Figure 13, B**). Untagged dysferlin was detected by anti-dysferlin NCL-Hamlet antibody which recognizes an epitope at 1999 - 2016 aa of the dysferlin protein and dysferlin-ops was detected by anti-opsin antibody (Scheme of antibody recognition sites in **Figure 13, A**). The anti-opsin antibody recognizes a protein at 35 kDa independently of cell type, transfected construct (also untransfected control) or treatment of cells or cell lysates. Therefore, this prominent band is considered as unspecific for the antibody. Full-length dysferlin is detected in all samples at the top of the blot (above the 170 kDa marking). Cleavage of uncoupled dysferlin by thrombin leads to a reduction of full-length dysferlin and to an additional protein band which is detected at approximately 33 kDa. This band represents the C-terminal dysferlin fragment including the C2G and transmembrane domain. Digestion of dysferlin-ops by thrombin also results in the generation of smaller peptides. The two bands that are detected just above the 35 kDa marking also represent the C-terminal fragment of dysferlin. In comparison to the untagged version, they have a reduced electrophoretic mobility due to the opsin tag and therefore are visible at a higher position on the blot. In contrast to uncoupled dysferlin, two well separated bands are detected for dysferlin-ops which might represent a nonglycosylated (lower band) and glycosylated (upper band) peptide. Thus, this result indicates that full-length dysferlin gets inserted into the ER in HeLa cells and thrombin cleavage is a feasible way to make glycosylation of opsin-tagged dysferlin detectable.

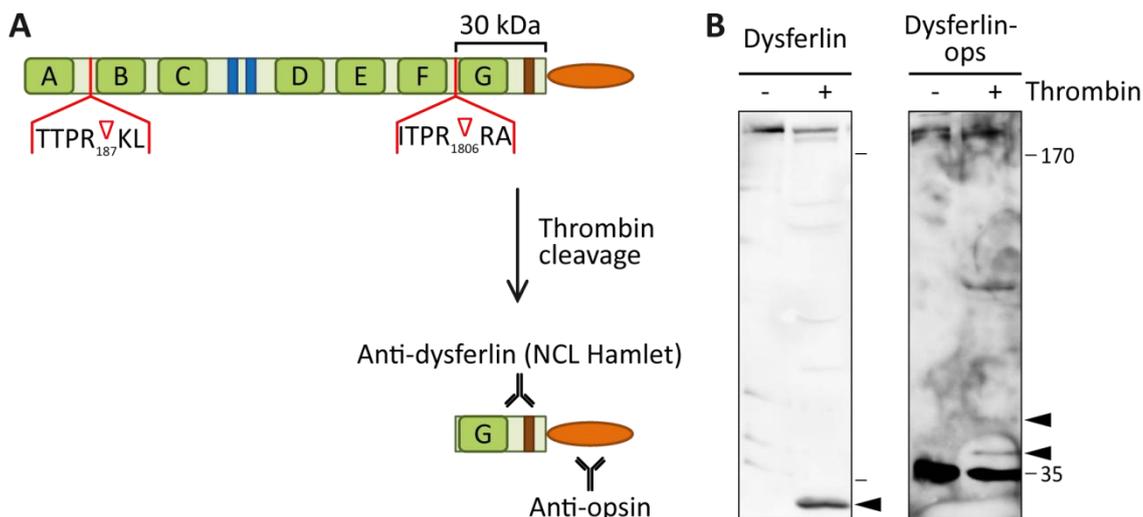

Figure 13 | Site-specific Thrombin cleavage of dysferlin as prerequisite for glycosylation analysis. (A) Thrombin cleavage of full-length opsin-tagged dysferlin at the positions aa 187 and aa 1806 results in a C-terminal peptide of approximately 30 kDa which can be detected either by anti-dysferlin (NCL-Hamlet) or anti-opsin antibody. **(B)** HeLa cells were transfected with dysferlin or dysferlin-ops and harvested 48 h post transfection for western blot analysis. Protein samples of 20 μ g were either nontreated or digested with thrombin for 1 h at 37°C and loaded on SDS-PAGE. Dysferlin was detected by anti-dysferlin (NCL-Hamlet) antibody and dysferlin-ops by anti-opsin antibody. Arrowheads indicate cleaved C-terminal part of dysferlin (left blot) or dysferlin-ops (right blot).

4.5.1 Efficiency of dysferlin insertion into the ER varies between mammalian cell lines

Analysis of opsin-tagged dysferlin expressed in HeLa cells and cleaved with thrombin shows that two bands can be detected by western blot (**Figure 13, B**). To verify that the upper band represents an N-glycosylated form of the lower one, the thrombin digested lysate was additionally treated with the endoglycosidase Endo H which removes N-linked oligosaccharide modifications (Roth et al., 2012). Western blot of Endo H-treated samples shows the disappearance of the upper band and increased level of the lower band compared to the untreated sample (**Figure 14, A**) confirming that the electrophoretic mobility shift is due to glycosylation and that dysferlin is C-terminally inserted into the membrane of the ER in HeLa cells. To answer the question whether dysferlin insertion into the ER is specific for HeLa cells, dysferlin-ops glycosylation was analyzed in the mammalian cell lines HEK293, COS-7 and CHO-K1. A glycosylated form of dysferlin can be detected in all tested cell lines (**Figure 14, A**). However, the level of glycosylated protein compared to the nonglycosylated is not equal. Thus, the proportion of glycosylated dysferlin was calculated by the ratio of glycosylated to total dysferlin-ops protein level (**Figure 14, B**). This analysis reveals that the efficiency of

glycosylation and therewith the integration of dysferlin into the ER differs between cell lines. HeLa cells have the lowest insertion efficiency with 56% of dysferlin being glycosylated. Glycosylation is significantly higher in COS-7 and CHO-K1 cells with a proportion of 77% and 89%, respectively. Glycosylation in HEK293 cells also tends to be higher compared to HeLa cells, but the difference is not significant. The trafficking of dysferlin is of particular interest in muscle cells as mutations in the *DYSF* gene lead to alterations in protein transport and stability causing muscular dystrophy. Therefore, glycosylation of dysferlin-ops was analyzed in the myoblast cell line C2C12. Also in these immature skeletal muscle fibers dysferlin is inserted into the membrane of the ER as shown by western blot (Figure 14, C). Quantification reveals that approximately 80% of dysferlin are glycosylated (Figure 14, D). Thus, using the opsin tag as glycosylation sensor it could be shown that dysferlin is being integrated into the ER with its C-terminus facing the lumen in different cell lines including a muscle cell line and that the efficiency of ER insertion varies in these cell systems.

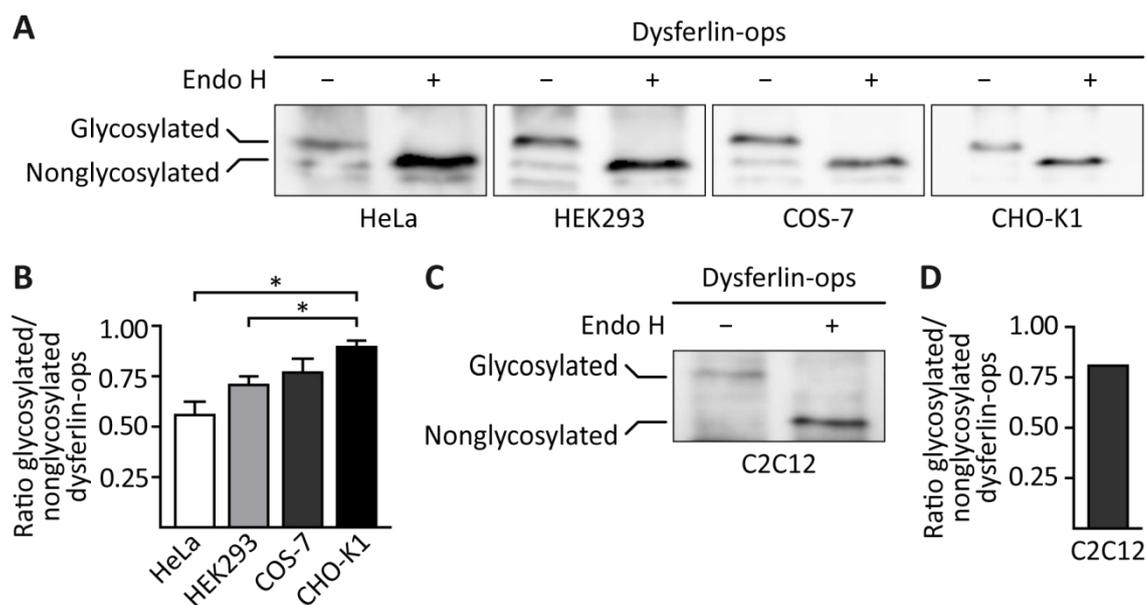

Figure 14 | Differential glycosylation of dysferlin-ops in mammalian cell lines. Glycosylation of dysferlin-opsin in mammalian cells was analyzed via western blot using an anti-opsin antibody. Bands representing glycosylated and nonglycosylated dysferlin-ops are indicated. **(A)** Non-muscle cell lines HeLa, HEK293, COS-7 and CHO-K1 were transfected dysferlin tagged to the glycosylation sensor opsin (dysferlin-ops) and harvested 48 h post transfection. Cell lysates of 30 μ g protein were thrombin-digested for 1 h at 37 $^{\circ}$ C and either nontreated or treated with Endo H for 1 h at 37 $^{\circ}$ C. **(B)** Western blots were analyzed using the software Fiji to calculate the ratio of glycosylated dysferlin-ops relative to total level. $N \geq 4$ +/- SEM, *= $P \leq 0.05$, **= $P \leq 0.01$ (Student's t-test). **(C)** C2C12 myoblasts were transfected with dysferlin-ops and harvested 72 h post transfection. Cell lysates of 65 μ g protein were thrombin-digested for 1 h at 37 $^{\circ}$ C and either nontreated further or treated with Endo H for 1 h at 37 $^{\circ}$ C. **(D)** The ratio of glycosylated dysferlin-ops level in C2C12 myoblasts was analyzed using Fiji software. $N=1$ (preliminary data).

4.5.2 Increased glycosylation of dysferlin mutant L1341P compared to wild-type in HeLa cells

LGMD2B and MM are often caused by missense mutations in the *DYSF* gene. The substitution of a single amino acid in the 2080 aa protein can be sufficient to cause structural changes, mislocalization, instability and degradation, ultimately resulting in loss of functional dysferlin. In this study two missense mutations were characterized which are often found in dysferlinopathy patients: mutation c.2875C>T causes the substitution of arginine to tryptophan at protein position 959 in the C2D domain of the protein (R959W) and c.4022T>C causing the substitution of leucine to proline at protein position 1341 which is in the C2E domain (L1341P) ((Klinge et al., 2010b; Wenzel et al., 2006)). It has been reported that L1341P is prone to aggregation in the ER and autophagic degradation (Fujita et al., 2007).

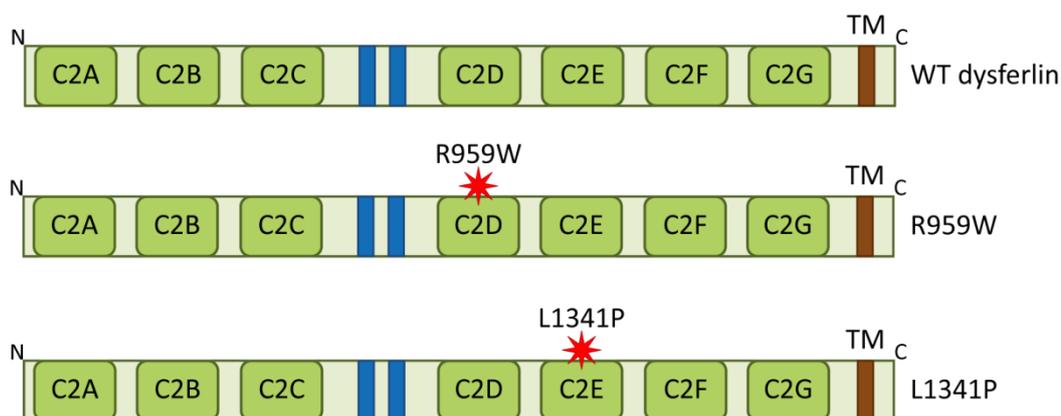

Figure 15 | Protein domain diagram of dysferlin variants. C2 domains are depicted in green (C2), the transmembrane domain is depicted in brown (TM), ferlin domains are depicted in blue. The wild-type dysferlin (WT dysferlin) at the top row. Missense mutations R959W and L1341P are indicated by red stars at the respective protein position.

To analyze whether the insertion of mutant L1341P into the ER membrane is altered in comparison to wild-type dysferlin, HeLa cells were transfected with constructs encoding one or the other dysferlin variant tagged to the glycosylation sensor opsin. Cell lysates were treated with thrombin to obtain a shorter peptide and subsequently either nondigested or digested with the endoglycosidase Endo H. Glycosylation was visualized by western blot (**Figure 16, A**) and proportion of glycosylated protein was calculated by the ratio of glycosylated to total protein level (**Figure 16, B**). This experiment reveals that the proportion of glycosylated protein is about 1.5-fold higher for the dysferlin mutant L1341P compared to wild-type dysferlin indicating that insertion into the ER is more efficient. Additionally, the total protein level of L1341P is higher than the wild-type protein level.

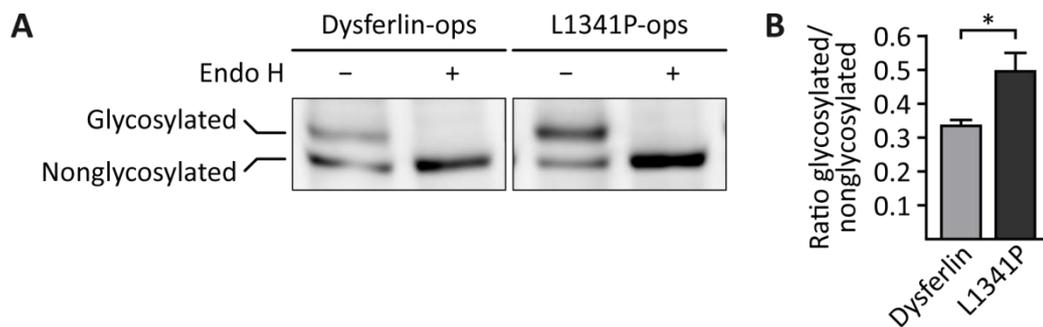

Figure 16 | Increased glycosylation of mutant L1341P compared to wild-type in HeLa cells. Glycosylation of opsin-tagged dysferlin wild-type and mutant dysferlin was analyzed via western blot. **(A)** HeLa cells were transfected with constructs encoding either dysferlin wild-type (Dysferlin-ops) or mutant L1341 (L1341-ops) coupled to the glycosylation sensor opsin and harvested 48 h post transfection. Cell lysates of 30 μ g protein were thrombin-digested for 1 h at 37 °C and either nontreated further or treated with EndoH for 1 h at 37 °C to remove glycosylation modifications. A representative western blot is depicted. **(B)** Western blots were analyzed using the software Fiji to calculate the ratio of glycosylated relative to total dysferlin-ops and L1341P levels. N3 +/- SEM, *= $P \leq 0.05$ (Student's t-test).

4.6 Depletion of the TRC40 pathway component WRB has no effect on the localization or steady-state level of dysferlin

TA proteins have a single transmembrane domain at the very C-terminus causing the requirement of a special post-translational membrane insertion mechanism. One targeting pathway depending on the cytosolic ATPase TRC40 and its ER membrane-located receptor complex consisting of WRB and CAML was found to post-translationally insert a number of tail-anchored proteins into the ER (Favaloro et al., 2008; Pfaff et al., 2016; Stefanovic and Hegde, 2007). The mechanism of ER insertion highly depends on the hydrophobicity of the transmembrane domain. TA proteins with transmembrane domains of high hydrophobicity are preferentially inserted by the TRC40-dependent pathway (Rabu et al., 2008; Stefanovic and Hegde, 2007). On the route to its target membrane the TA protein dysferlin is also inserted into the membrane of the ER (**Figure 13-Figure 15**) and the transmembrane domain has a comparably high hydrophobicity of 70.6 (According to hydropathy scale of (Kyte and Doolittle, 1982). Furthermore, dysferlin is highly expressed at the T-tubule system of developing cardiomyocytes (**Figure 8**). Thus, the effect of TRC40 pathway loss on the expression and localization of dysferlin in ventricular cardiomyocytes was investigated in cooperation with Dr. Jhon Rivera-Monroy and Prof. Blanche Schwappach from the department of Molecular Biology, University Medical Center Göttingen. Cardiomyocytes were isolated by Langendorff-perfusion (Bell et al., 2011), performed by Dr. Jhon Rivera-Monroy) from cardiomyocyte-specific inducible WRB knockout mice two weeks after tamoxifen administration and indirect

4.7 PBA increases steady-state level of dysferlin variants

In this study two mutations were characterized with regard to protein level and a possibility to stabilize the proteins. This would provide information about the pathomechanism of dysferlinopathy and possible targets for the treatment of this disease. Dysferlin variants harboring the two missense mutations R959W and L1341P, located in the C2D and C2E domain, respectively, were analyzed (**Figure 15**). Initially, the expression levels were investigated. HeLa cells were transfected with constructs encoding either wild-type dysferlin or one of the mutant variants and cell lysates were analyzed by western blot. Both mutants show reduced steady-state levels compared to wild-type dysferlin (**Figure 18**). It has been reported that R959W leads to structural changes in the dysferlin protein (Espinoza-Fonseca, 2016) and L1341P is prone to aggregation in the ER and autophagic degradation (Fujita et al., 2007). This might explain the reduced steady-state levels of mutated dysferlin. Small molecules, which have the ability to shield hydrophobic regions of misfolded proteins and thereby reduce protein aggregation, may be called hydrophobic chaperones (Cortez and Sim, 2014). The short chain aromatic fatty acid 4-phenylbutyrate (PBA) is converted *in vivo* into phenylacetate by β -oxidation and this metabolic intermediate is degraded by conjugation to the amino acid glutamine and eliminated via the urinary system (Brusilow, 1991). Due to its metabolic pathway, PBA functions as an “ammonia scavenger” (Iannitti and Palmieri, 2011) and is therefore approved by the FDA for the clinical treatment of children with urea cycle disorders (<https://www.fda.gov/default.htm>). Additionally, PBA acts as histone deacetylase inhibitor and protein chaperone. It modulates cellular gene expression and reduces ER stress as well as the unfolded protein response leading to reduced ER-stress induced apoptosis (Iannitti and Palmieri, 2011). Due to its versatile functions, PBA is currently under investigation for the treatment of several disorders, such as cystic fibrosis (Lim et al., 2004; Rubenstein et al., 1997), neurodegenerative diseases like Alzheimer’s disease (Bondulich et al., 2016; Cuadrado-Tejedor et al., 2011), myocardial ischemia (Takatori et al., 2017), cancer (Carducci et al., 2001) and many others (Braun and Schweizer, 2017; Cao et al., 2016; Collins et al., 1995; Khan et al., 2017; Liu et al., 2016).

PBA is a regulator of cellular proteostasis and was therefore used in this study to test whether it is a suitable therapeutic for the treatment of dysferlinopathy by ameliorating the reduced protein level of dysferlin mutants. Transfected HeLa cells were treated with PBA for 24 h and cell lysates were analyzed by western blot. PBA treatment leads to a significant increase of steady-state level for wild-type and R959W. Also, the protein level of mutant L1341P tends to be higher upon chaperone addition (**Figure 18**). The protein level of mutant R959W upon PBA

treatment is 1.5-fold of the wild-type level without PBA. Thus, PBA has the potency to increase reduced steady-state levels of dysferlin mutants and also the level of wild-type dysferlin.

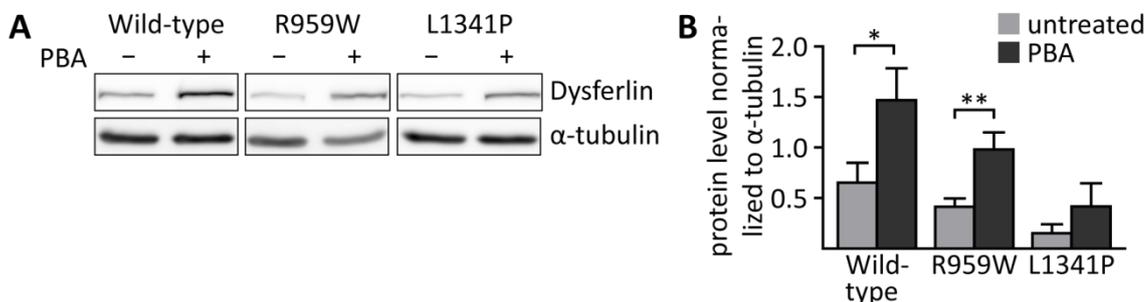

Figure 18 | Increased steady-state level of dysferlin WT and mutants R959W and L1341P upon PBA treatment. (A) Representative immunoblots of lysates from HeLa cells transfected with dysferlin wild-type or missense mutants R959W and L1341P and either nontreated or treated with the chemical chaperone PBA at 5 mM for 24 h. Dysferlin was detected by anti-dysferlin (NCL-Hamlet), anti- α -tubulin served as loading control. (B) Densitometric quantification of western blot. Dysferlin level was normalized to α -tubulin. N=3-8. Mean \pm SEM. *= $P \leq 0.05$, **= $P \leq 0.01$ (Student's t-test).

4.8 No effect of PBA on tubulation properties of wild-type dysferlin in HeLa cells

Heterologous expression of wild-type dysferlin in non-muscle cells leads to the generation of membrane tubules which were shown to have similarities to T-tubules of muscle cell with regard to structure and lipid composition (Hofhuis et al., 2017). Previous work of our group suggests that the ability of dysferlin to form membrane tubules is a central function of the protein during development and maintenance of the T-tubule system. As previously reported by our group, wild-type dysferlin expressed in non-muscle cells does neither colocalize with the Golgi apparatus, nor with the ER (Hofhuis et al., 2017) as shown by immunostaining of EGFP-dysferlin transfected cells for giantin and PDI as Golgi and ER marker, respectively (Figure 19, A and B, top). To analyze whether the increased steady-state level upon PBA treatment leads to a distinct localization of dysferlin, transfected cells were incubated with PBA for 24 h and subsequently used for indirect immunofluorescence. No change in expression or localization of wild-type dysferlin is detectable by epifluorescence microscopy of dysferlin-transfected and immunostained cells (Figure 19, A and B, bottom).

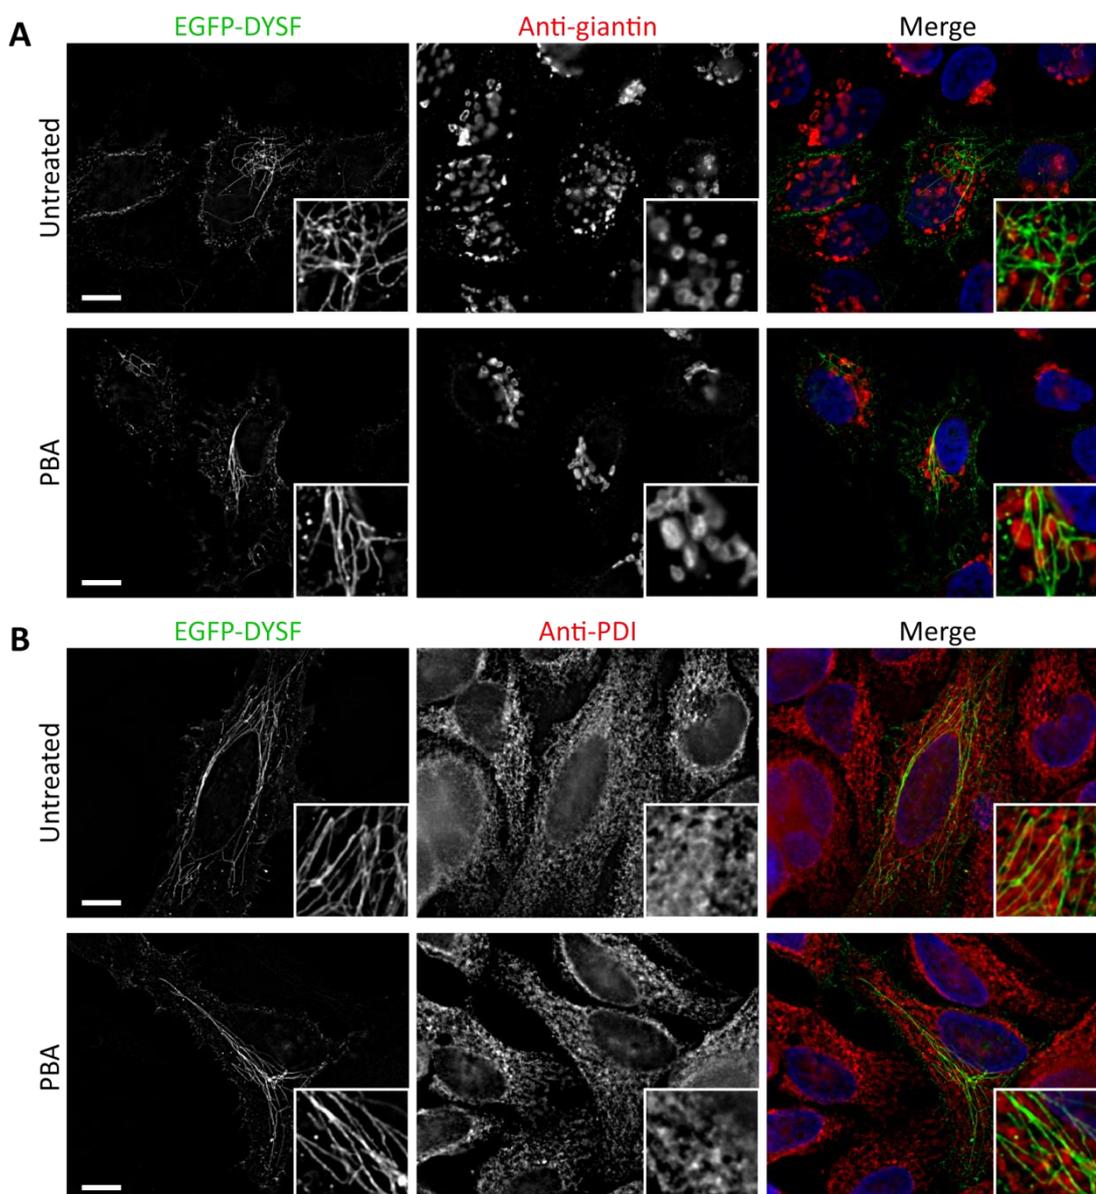

Figure 19 | Wild-type dysferlin does neither colocalize with Golgi marker giantin, nor with ER marker PDI. Representative immunofluorescence images of HeLa cells transfected with EGFP-tagged wild-type dysferlin (EGFP-DYSF) and either nontreated or treated with the chemical chaperone PBA at 5 mM for 24 h. **(A)** The Golgi network was immunolabeled with an antibody against giantin (red). **(B)** The ER was immunolabeled with an antibody against PDI (red). Nuclei are stained with DAPI (blue). Cells were analyzed by epifluorescence microscopy and z-stacks were deconvoluted. Scale bars 10 μ m.

PBA ameliorates the tubulation deficiency of dysferlin mutant R959W, but has no effect on L1341P in HeLa cells

When assuming that deformation of membranes into tubular structures is the main function of dysferlin in muscle cells, the tubulation property of dysferlin variants in non-muscle cells can be used as read-out for proper dysferlin function. Localization to cellular organelles and tubulation property of dysferlin mutants R959W and L1341P were analyzed in HeLa cells. In

contrast to wild-type dysferlin, heterologous expression of R959W does not lead to the *de novo* synthesis of tubular membranes (**Figure 20**, A and B, top). R959W does not localize with ER marker PDI (**Figure 20**, B, top) but shows strong overlap with Golgi marker giantin (**Figure 20**, A, top). More detailed comparison of R959W- and giantin-labeled structures reveals that they do not completely overlap, but are rather strongly associated with each other. Assuming that a certain minimal protein level of full-length dysferlin is necessary for its tubulation function, the absence of R959W-induced membrane tubules might be explained by its reduced steady-state level due to protein instability caused by the amino acid substitution (**Figure 18**). Thus, the effect of PBA on localization of mutant R959W was investigated to analyze whether the increased protein level correlates with tubulation. PBA treatment leads to the generation R959W-labeled membrane tubules as reported for wild-type dysferlin in a proportion of transfected HeLa cells. The tubular structures do neither colocalizes with the Golgi apparatus, nor with the ER (**Figure 20**).

The dysferlin mutant L1341P also has no tubulation ability in untreated HeLa cells (**Figure 21**, A and B, top). The mutated protein localizes to the ER as shown by strong overlap with the PDI signal (**Figure 21**, B, top) and reported previously (Fujita et al., 2007). Colocalization with the Golgi apparatus is not detectable by epifluorescence microscopy (**Figure 21**, A, top). Treatment of L1341P-transfected HeLa cells had no effect on the expression or localization of the mutant in immunofluorescence and did not lead to induced membrane tubulation (**Figure 21**, A and B, bottom).

Heterologous expression of dysferlin mutants R959W and L1341P shows that none of the mutants have tubulation properties, but rather associate with the cellular organelles Golgi and ER, respectively. PBA ameliorates the tubulation deficiency of Golgi-associated R959W, but not of ER-localized L1341P in HeLa cells.

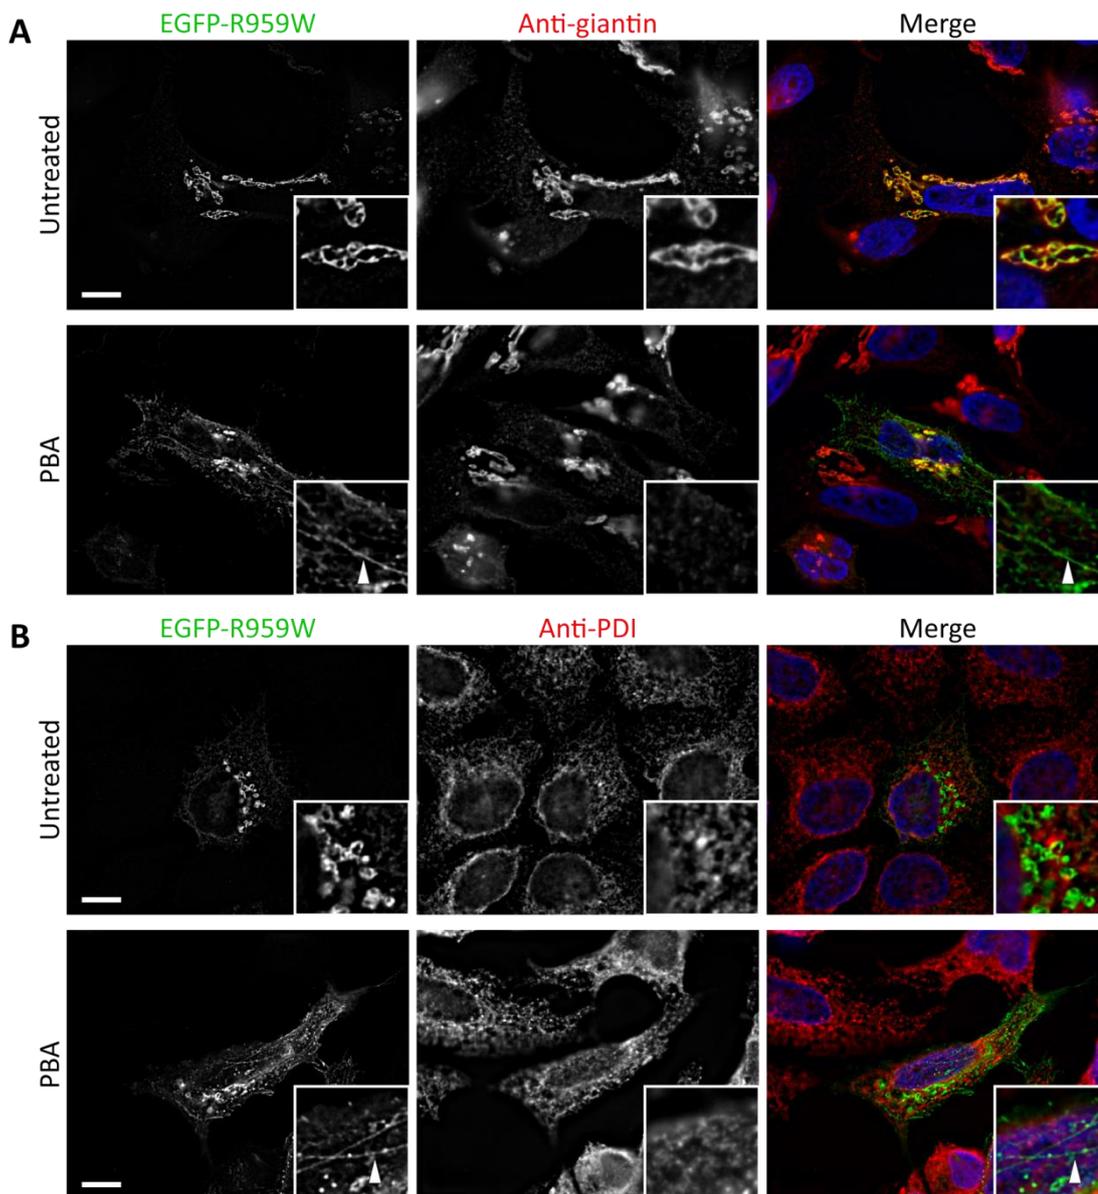

Figure 20 | Dysferlin mutant R959W colocalizes with giantin and PBA rescues tubulation deficiency of R959W mutant. Representative immunofluorescence images of HeLa cells transfected with the EGFP-tagged dysferlin missense mutant R959W (EGFP-R959W) and either nontreated or treated with the chemical chaperone PBA at 5 mM for 24 h. **(A)** The Golgi network was immunolabeled with an antibody against giantin (red). **(B)** The ER was immunolabeled with an antibody against PDI (red). Nuclei are stained with DAPI (blue). Cells were analyzed by epifluorescence microscopy and z-stacks were deconvoluted. Scale bars 10 μ m.

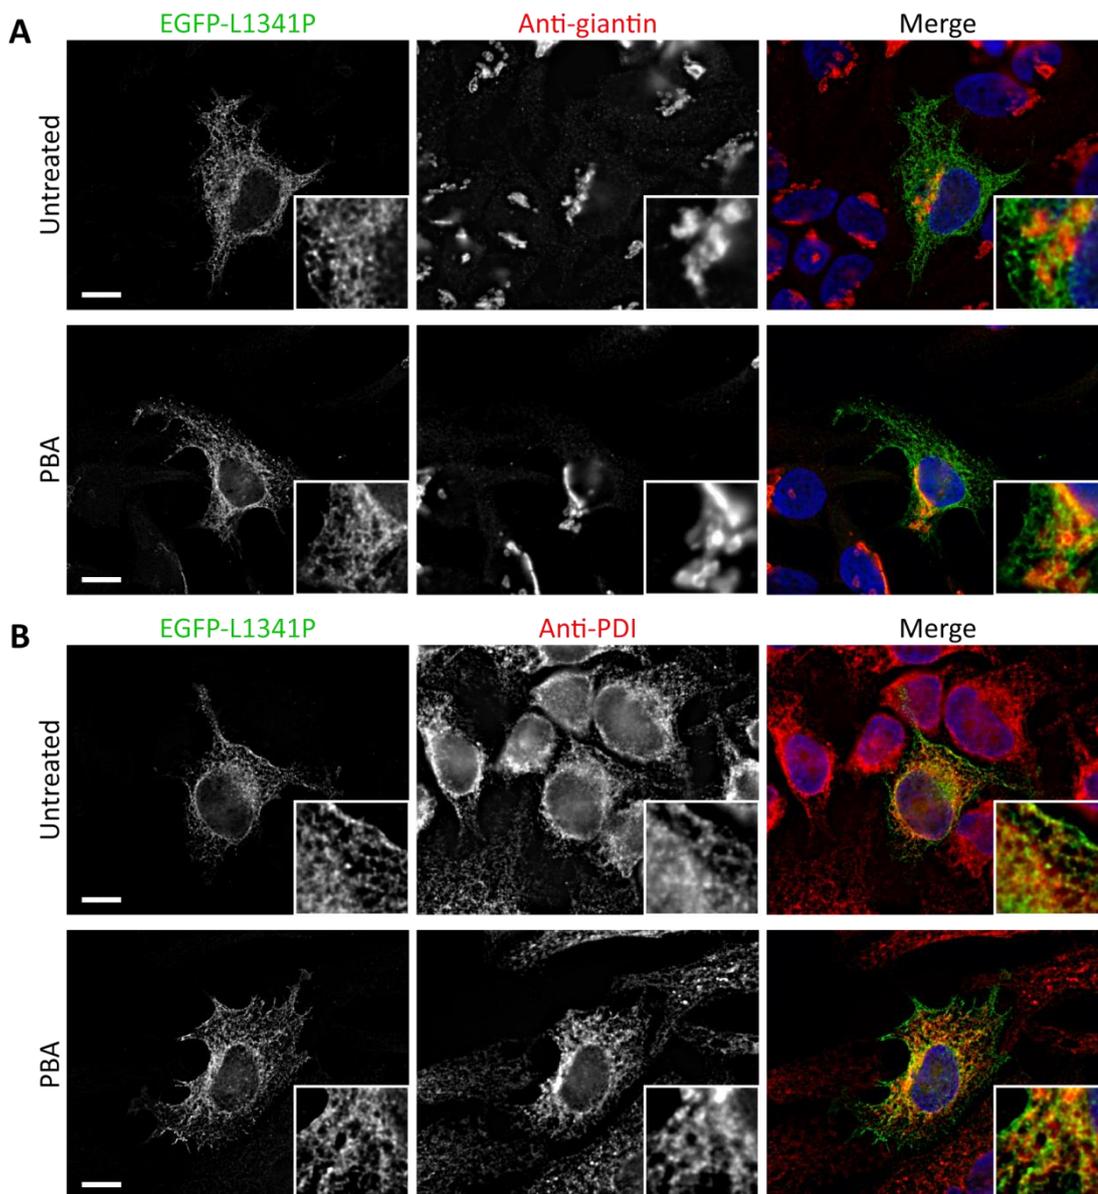

Figure 21 | Dysferlin mutant L1341P partially colocalizes with the ER marker PDI. Representative immunofluorescence images of HeLa cells transfected with the EGFP-tagged dysferlin missense mutant L1341P (EGFP-L1341P) and either nontreated or treated with the chemical chaperone PBA at 5 mM for 24 h. **(A)** The Golgi network was immunolabeled with an antibody against giantin (red). **(B)** The ER was immunolabeled with an antibody against PDI (red). Nuclei are stained with DAPI (blue). Cells were analyzed by epifluorescence microscopy and z-stacks were deconvoluted. Scale bars 10 μ m.

4.9 Dysferlin mutant R959W closely associates with the Golgi marker giantin in C2C12 myoblasts

To get further insight into the pathomechanism of dysferlinopathy caused by missense mutations, the localization of dysferlin mutant R959W was investigated in differentiated C2C12 myoblasts, a model system for T-tubule development in skeletal muscle cells. Therefore, C2C12 myoblasts were transfected with either EGFP-tagged wild-type or mutant dysferlin and differentiated for 5 days in culture. Differentiated myotubes were used for indirect immunofluorescence to label the Golgi by staining the marker giantin. As previously reported, wild-type dysferlin labels predominantly tubular structures with longitudinal orientation, representing the maturing T-tubule system (Hofhuis et al., 2017). EGFP-dysferlin does not show overlap with the giantin signal but in several regions of the cells dysferlin-labeled tubules are in close contact and seem to entangle giantin-labeled Golgi sheets (**Figure 22, A**). Heterologously expressed dysferlin mutant R959W does not localize to the longitudinal membrane structures of the developing T-tubule system. Like in HeLa cells, R959W shows partial overlap with giantin-labeled portions of the Golgi apparatus (**Figure 21, B**). As the overlap is not complete, this speaks rather for a close association of R959W- and giantin-tagged cellular components than for the immediate molecular proximity.

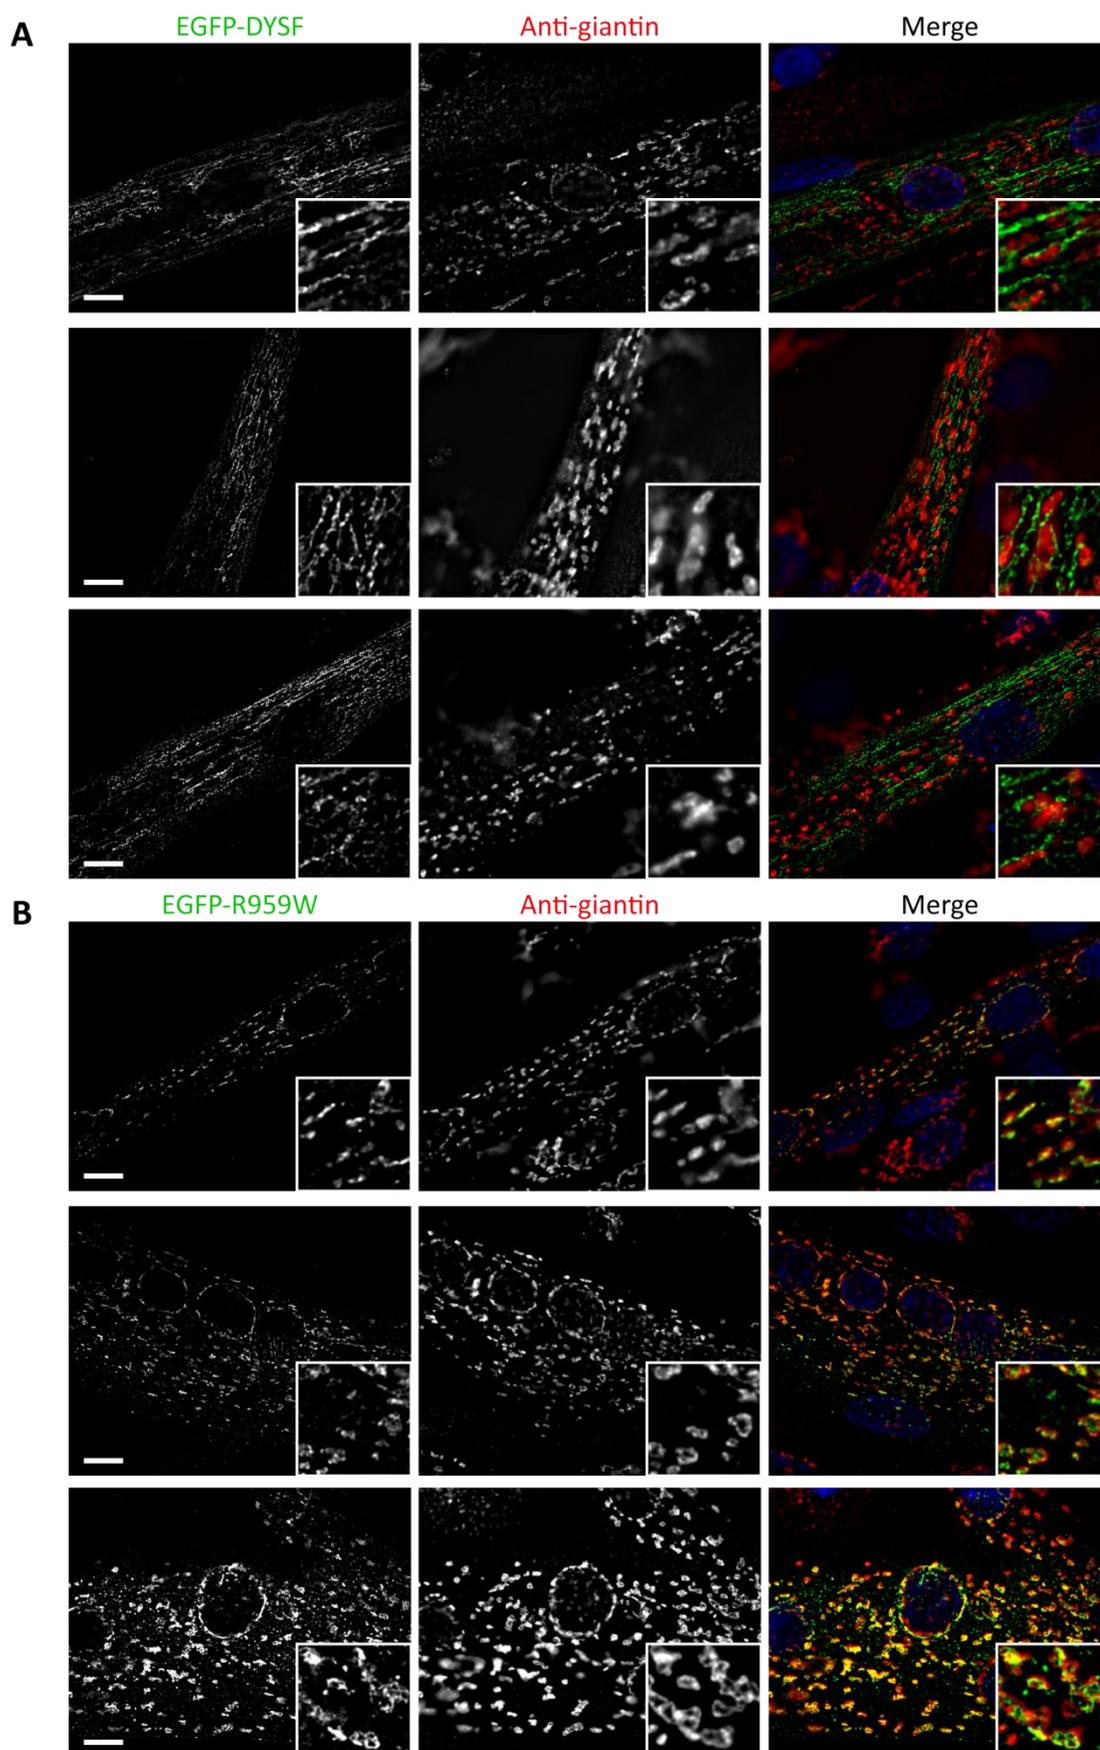

Figure 22 | While wild-type dysferlin localizes to the T-tubule system, mutant R959W closely associates with giantin in C2C12 cells. Representative immunofluorescence images of C2C12 myotubes

transfected with either EGFP-tagged wild-type dysferlin (EGFP-DYSF, **(A)**) or the missense mutant R959W (EGFP-R959W, **(B)**). The Golgi network was immunolabeled with an antibody against giantin (red). Nuclei are stained with DAPI (blue). Cells were analyzed by epifluorescence microscopy and z-stacks were deconvoluted. Scale bars 10 μ m.

4.10 Readthrough of *DYSF* patient nonsense codons can be differentially induced by G418

Dysferlinopathy is caused by mutations in the *DYSF* gene. 80 different mutations are known in at least three unrelated patients (UMD-DYSF mutations database, http://www.umd.be/DYSF/W_DYSF/mutation.html). In 25% of the patients disease is caused by mutations leading to the generation of a stop codon and consequently to premature termination of translation (**Figure 23**).

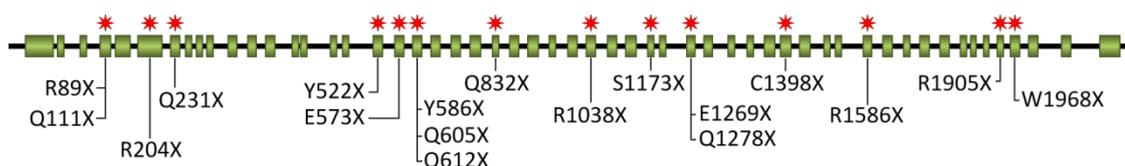

Figure 23 | Spectrum of nonsense mutations in the *DYSF* gene. Figure shows the positions of all known mutations leading to the generation of a premature stop codon (nonsense mutation) in the human *DYSF* gene in at least three unrelated index patients (information extracted from UMD-DYSF mutations database, http://www.umd.be/DYSF/W_DYSF/mutation.html) and the affected amino acids of the dysferlin protein.

One therapeutic approach for the treatment of genetic diseases caused by premature stop codons is the application of aminoglycosides, their derivatives or other small molecules which are able to induce translational readthrough of premature stop codons leading to production of the full-length protein. Gentamicin and G418 are aminoglycosides investigated as readthrough inducers, e.g. for the treatment of Duchenne muscular dystrophy (Barton-Davis et al., 1999; Loufrani et al., 2004). However, these substances have a narrow therapeutic window and they are nephro- and ototoxic. Therefore, the application of these aminoglycosides should be carefully evaluated. The therapeutic efficacy varies strongly from patient to patient and currently no prediction about whether and to which extent readthrough will be induced can be made prior to treatment. Our group has established a very sensitive dual reporter assay for analyzing readthrough of a given SCC (stop codon + 10 bp upstream

and downstream) by flow cytometric analysis of cells transfected with a SCC-encoding construct (Hofhuis et al., 2017b).

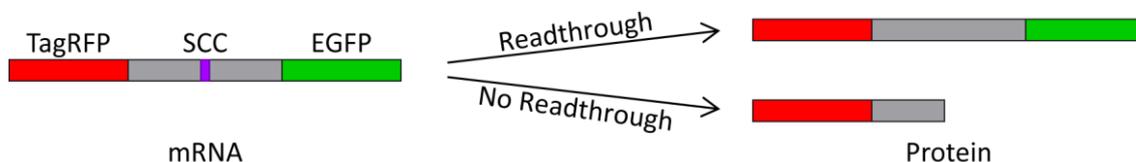

Figure 24 | Schematic representation of dual reporter for readthrough analysis in mammalian cells. A construct consisting of the stop codon (violet) of interest and its adjacent nucleotides (Stop codon context, SCC) surrounded by genes encoding TagRFP and EGFP up- and downstream of the SCC, respectively is transfected into mammalian cells. Following flow cytometric acquisition of the fluorescent signal, the extent of readthrough at the respective stop codon is calculated as EGFP over TagRFP fluorescence ratio.

Readthrough extent is influenced only by the stop codon itself (UGA having the highest readthrough propensity) and the nucleotides surrounding the stop codon (Schueren et al., 2014; Tate et al., 1996). The dual reporter assay was used to investigate the basal (without induction) and G418-induced readthrough of the 18 known nonsense codons in the *DYSF* gene. Therefore, the SCCs (**Table 14**) were cloned into a mammalian expression construct with an N-terminal TagRFP sequence as internal expression control and a C-terminal EGFP sequence as readthrough sensor (Performed by Corinna Dickel and Marco Schmidt). HeLa cells were transfected and subsequently either nontreated or incubated with G418 for 18 h. Cells were analyzed 24 h after transfection by two channel fluorescence flow cytometry for the expression of TagRFP and EGFP. Readthrough was calculated as green over red fluorescence ratio and normalized to a 100% readthrough control (no stop codon between TagRFP and EGFP coding sequences).

Table 14 | *DYSF* nonsense mutations

Amino acid position	cDNA position	SCC

The basal translational readthrough of *DYSF* nonsense SCCs is less than 1%, ranging from 0.29% (R204X) to 0.87% (E1278X) (**Figure 25**). Treatment with G418 leads to significant readthrough induction for all tested SCCs. Readthrough of induced SCCs ranges from 1.46% (E832X) to 10.40% (W1968X), thus, readthrough level differs by up to 7-fold. The readthrough level upon induction does not correlate with the basal level. If the readthrough level is equivalent to the proportion of translated full-length protein, the results suggest that without induction less than 1% of protein is produced but induction with G418 increases amount of full-length protein to up to 10.4% (W1968X).

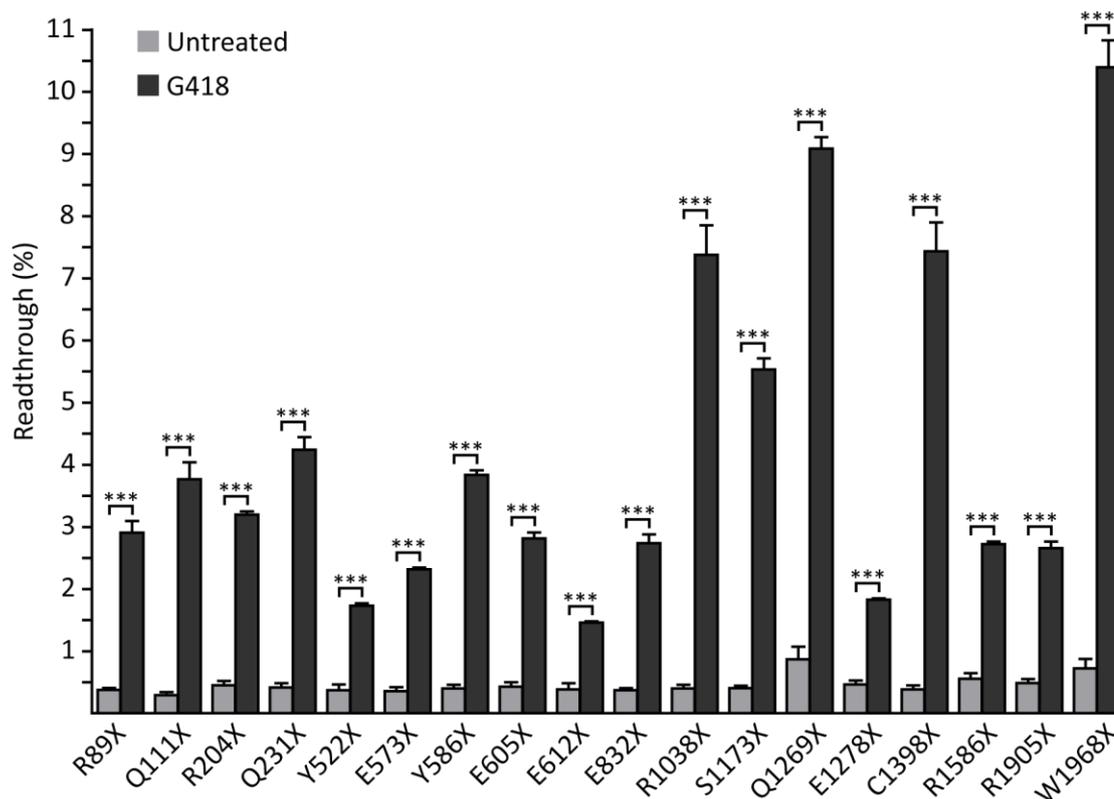

Figure 25 | Differential readthrough induction efficiency of *DYSF* SCCs by G418. HeLa cells were transfected with the dual fluorescence reporter construct encoding SCCs of the known nonsense mutations in the human *DYSF* gene or a construct with no stop codon between the fluorescence tags (100% readthrough control) (cloned by Corinna Dickel and Marco Schmidt). 6 h after transfection, cells were either nontreated or treated with G418 (100 μ g/mL) for another 18 h. Reporter fluorescence was analyzed 24 h post transfection by flow cytometry. Following gating according to FSC/SSC and green/red fluorescence, readthrough was calculated as EGFP over TagRFP fluorescence ratio normalized to the 100% readthrough control. N=3. Mean \pm SEM. ***=P \leq 0.001 (Student's t-test).

5 Discussion

Dysferlin is a protein which is mainly expressed in skeletal and heart muscle. For a long time, it has mainly been implicated in membrane repair (Bansal and Campbell, 2004; Cai et al., 2009; Lek et al., 2013). In recent years, accumulating evidence uncovered an additional and fundamental role for dysferlin. Dysferlin leads to the generation of elongated membranes upon heterologous expression in non-muscle cells or incubation with liposomes. These tubules are characterized by biochemical and morphological similarities with the muscular tubule system leading to the hypothesis that the tubulation capacity of dysferlin mirrors the primary cellular function of the protein, namely the formation of the T-tubule system in skeletal muscle (Hofhuis et al., 2017).

5.1 Dysferlin and BIN1 function at different subcompartments of the tubule system during development

The BAR domain protein BIN1 is an established key player during biogenesis of the tubule system (Hong et al., 2014, 2010; Lee et al., 2002). It is found early at the membrane of the developing tubule system and regulates recruitment and clustering of EC coupling proteins L-type Ca^{2+} channel and RyR at the functional units of the muscle cells (Fu et al., 2016; Hong et al., 2014, 2010; Lee et al., 2002). One of BIN1's molecular functions was determined by heterologous expression in non-muscle cells and incubation of recombinant BIN1 with liposomes (Lee et al., 2002). In these systems, the generation of membrane tubules was observed. The tubules are analogous to those observed in dysferlin-induced tubulation with partial colocalization when expressed in one system. Still, also differences comparing BIN1- and dysferlin-induced tubules were observed. BIN1-induced tubules are longer and more branched than those induced by dysferlin. In contrast to BIN1, dysferlin induces membrane tubulation in a dynamin 2-independent manner. These differences indicate that the mechanism underlying membrane tubulation differs between BIN1 and dysferlin (Hofhuis et al., 2017). To follow up on the difference between those two T-tubule proteins, their endogenous localization was studied in C2C12 myotubes in the frame of this study. In culture differentiated C2C12 cells resemble differentiation of skeletal myofibers and biogenesis of the T-tubule system. Dysferlin and BIN1 show partial colocalization in this system. Though, BIN1 and dysferlin also label different structures with dysferlin localizing to central tubules and BIN1 labeling tubules in proximity to the plasma membrane. Thus, dysferlin and BIN1 localize to different subcompartments of the developing T-tubule system indicating that they might have

distinct specialized roles for the formation of the tubule system. During embryonic development and initial phases of tubule biogenesis, $Ca_v1.1$, the L-type Ca^{2+} channel in skeletal muscles, is localized at the sarcolemma before translocating to the tubule membrane in later stages (Romey et al., 1989). BIN1 is strongly associated with the L-type Ca^{2+} channel during development. In cardiomyocytes, BIN1 recruits $Ca_v1.2$ molecules, which are transported on polymerizing microtubules, arising from the Golgi, to the membrane of the tubule system and clusters them compactly in membrane microdomains (Hong et al., 2010). The BIN1-mediated recruitment and anchoring of Ca^{2+} channels to the tubule membrane might also take place in skeletal muscle. This idea is supported by the observation that BIN1 is at the sarcolemma and proximate tubule structures, which is the site of $Ca_v1.1$ accumulation during early tubule biogenesis. Dysferlin, on the other hand, localizes to tubule membranes in C2C12 myotubes which are more in the center of the cell. In adult myofibers, dysferlin also localizes to the T-tubule system (Kerr et al., 2013). Upon plasma membrane rupture, dysferlin-containing vesicles quickly accumulate at lesion sites and fuse with each other and with the plasma membrane to repair the membrane lesion (Lek et al., 2013; Redpath et al., 2014). Due to the incorporation of dysferlin in both, T-tubule membrane and repair vesicle membrane, it is suggestive that the T-tubule system represents the membrane reservoir that is provided to seal membrane ruptures. In this scenario, dysferlin-containing vesicles might be very quickly pinched off from the preexisting membrane tubule by an endocytosis-like mechanism and translocate to the site of membrane lesion. The possibility that the membrane reservoir, needed for lesion repair, originates from the plasma membrane is less conceivable as this process would require more steps of membrane modulation. Initially, membrane buds would have to be formed prior to pinching off and translocating to the lesion site, making this mechanism unfeasible for fast sarcolemma repair. Thus, the membranes needed for membrane lesion repair might arise from the T-tubules with dysferlin orchestrating the process of membrane modulation. The differentiation of myofibers is a very dynamic process with numerous membrane rearrangement events. The localization of dysferlin at central tubules inside the myofiber indicates that the protein has a role in dynamic membrane remodeling during membrane repair, but also development and maturation of the T-tubule system. The differential localization of endogenous dysferlin and BIN1 during T-tubule biogenesis and possible specific functions that are associated with their cellular localization might explain the distinct pathologies arising from deficiency of either BIN1 or dysferlin.

5.2 Early developmental abnormalities of the T-tubule system in patient myoblasts due to dysferlin loss

Dysferlinopathy is characterized by progressive weakening and wasting of the skeletal muscle. Histologically, muscles show typical signs of dystrophy including loss of muscle fibers, increased fiber size variation, and accumulation of connective and fat tissue. These phenotypes are secondary to defects in cellular functions and need to be investigated to understand the pathophysiology of dysferlin-deficient muscular dystrophy. The identification of primary molecular and cellular alterations is not simple, because many patients remain undiagnosed or maldiagnosed for several years after onset of symptoms (Harris et al., 2016). At the time point of correct diagnosis, muscular dystrophy is fairly advanced. Thus, primary alterations of the skeletal muscle cannot easily be determined. Animal models of muscular dystrophy are therefore required in order to investigate the pathophysiology of dysferlin-deficiency. The adult skeletal muscle T-tubule system of dysferlin-deficient mice shows dramatic rearrangements with dilated, irregularly shaped and longitudinally orientated tubules (Klinge et al., 2010a). Also during regeneration after notexin-induced muscle damage in a mouse model of dysferlin-deficiency, the T-tubule system is abnormally formed tubules are vacuolated (Hofhuis et al., 2017). As dysferlin plays a role during the biogenesis of the T-tubule system (Hofhuis et al., 2017), the present study aimed to analyze the effect of dysferlin-deficiency in a human model of early T-tubule development. The membrane system in a considerable proportion of patient myotubes is massively altered as assessed by membrane staining with the dye DiI_{C16}(3). Instead of single tubules and vesicles as in control cells, dense bundles of longitudinal tubules in perinuclear regions were observed in dysferlin-deficient myotubes. This result shows that dysferlin is not only necessary for membrane repair and maintenance of T-tubules in adult myofibers, but the protein is essential during a very early stage of myofiber differentiation for proper biogenesis of the tubular network.

Previous work of our group has identified a strong association between the phospholipid PI(4,5)P₂ and dysferlin. Heterologous expression of dysferlin in non-muscle cells leads to formation of membrane tubules. PI(4,5)P₂ is recruited to these dysferlin-containing tubules indicating that they share similarities with the T-tubule system of muscle cells, which are enriched in PI(4,5)P₂ (Hofhuis et al., 2017; Milting et al., 1994). Additionally, the existence of PI(4,5)P₂ and binding of dysferlin to PI(4,5)P₂ is a prerequisite for dysferlin's tubulation capacity. Thus, the function of dysferlin is highly dependent on PI(4,5)P₂. As dysferlin is located at the plasma and T-tubule membrane system in myofibers and strongly associates with

PI(4,5)P₂, dysferlin-deficiency might also lead to a reduced level of PI(4,5)P₂ in membranes that usually contain dysferlin. PI(4,5)P₂ is an important mediator of cellular signaling and trafficking (Hofgaard et al., 2008; Itoh and Takenawa, 2004; Suh and Hille, 2005; Sun et al., 2013; Takenawa et al., 1999). Among others, it anchors the growing plus-ends of microtubules at the plasma membrane (Golub and Caroni, 2005). It has been shown that dysferlin interacts with α -tubulin and dysferlin-induced tubules depend on the microtubule system (Azakir et al., 2010; Hofhuis et al., 2017). Thus, the accumulation of membrane tubules in perinuclear bundles upon loss of dysferlin might be explained by the disability of the plasma membrane to anchor the microtubule-associated developing T-tubule system, which is deficient in dysferlin and probably therefore contains lower amount of PI(4,5)P₂.

5.3 Dysferlin is also a key player of cardiac tubule system biogenesis

The implication of dysferlin in the development of the T-tubule system in skeletal muscle is based on the following findings: Dysferlin localizes to the developing and regenerating T-tubule system in skeletal muscle (Hofhuis et al., 2017; Klinge et al., 2010a). Furthermore, the T-tubule system has an abnormal morphology upon dysferlin-deficiency (Klinge et al., 2010a). The results of this study show that the formation of the membrane system is disturbed in in patient myotubes. These observations correspond to the dystrophic symptoms affecting almost exclusively the skeletal muscles of dysferlinopathy patients. In only a few patients a cardiac dysfunction is reported (Kuru et al., 2004; Wenzel et al., 2006, 2007). By contrast, cardiac involvement is more pronounced in some mouse models of dysferlin-deficiency. Without excessive strain, no or only a mild cardiac phenotype is detected, whereas physical stress results in several signs of cardiac dysfunction (Chase et al., 2009; Han et al., 2007; Rubi et al., 2015; Tzeng et al., 2014; Wei et al., 2015; Wenzel et al., 2007). Consequently, a putative role of dysferlin in the development of the cardiac tubule system was hypothesized and addressed in this study. In this study, expression and localization of dysferlin was analyzed in rat cardiomyocytes in the first three weeks of live, the time window when maturation of the cardiac tubule system occurs (Chen et al., 2013). Localization of dysferlin at the developing T-tubule system was assessed by co-staining with the T-tubule marker Ca_v1.2 and appeared to increase over the course of 20 days after birth. Thus, before maturation of the transverse and axial membrane tubules dysferlin and Ca_v1.2 localize to different areas of the cardiomyocyte and co-assemble at membrane tubules during maturation. Cardiac dysferlin protein expression is similar in neonatal rats of P11 and adult rats. In the first three weeks of live, dysferlin protein level increases with a peak at P20 before decreasing again. At this time point the

tubular system is largely mature and transverse and axial tubules are achieving their final structure. Consequently, the expression pattern of dysferlin indicates that the protein is not only involved in the development of skeletal muscle T-tubule system, but also in the maturation of the cardiac TATS.

The highly rearranged TATS in the cardiomyocytes of dysferlin-deficient mice strongly supports the hypothesis that dysferlin also exerts an important function in the heart: The distribution between transverse and axial orientated tubules is shifted to a higher amount of membrane components with axial orientation in dysferlin-deficient cardiomyocytes indicative of a reorientation of the TATS system. Not only transverse tubules get lost upon dysferlin-deficiency, but also the total amount of membrane structures per cell is decreased, reducing the overall tubule length in mice lacking dysferlin. Thus, a disorganized T-tubule system upon deficiency of dysferlin is detected in both, skeletal and heart muscle substantiating the role of dysferlin in the biogenesis of the tubule system in both muscle types.

Reorganization of the cardiac T-tubule system is a characteristic of patients suffering from heart failure and is verified in several animal models of heart failure (Gómez et al., 1997; Heinzl et al., 2008; Louch et al., 2004; Pieske et al., 1999). The rearrangements start very early in cardiac pathology even before the transition to heart failure, a condition when the metabolic demands of the body are insufficiently covered (Chen et al., 2015; Levy et al., 1996; Wei et al., 2010). The TATS of failing cardiomyocytes shows similar features as detected upon dysferlin-deficiency: loss of tubule system components, axialization and dilatation of membrane tubules (Cannell et al., 2006; Pinali et al., 2017; Wei et al., 2010). Thus, dysferlin-deficiency might lead to a phenotype which is comparable to the early subclinical stages of heart failure without affection of heart function under normal conditions. Thereby, the abnormalities of the T-tubule system and resulting molecular changes can be compensated by the cells to prevent effects on a global level. Though, dysferlin-deficient mice have a disturbed cardiac function under physical stress. This indicates that the effects of a destructed cardiac TATS cannot be compensated if the requirements for the heart dramatically increase leading to detectable cardiac dysfunction.

The distinct affection of skeletal and heart muscle upon dysferlin-deficiency might be explained by the structural and molecular differences between these two muscle types. Concretely, the diameter of skeletal muscle T-tubules is 5- to 10-fold smaller than the diameter of cardiac T-tubules (Franzini-Armstrong et al., 1975; Soeller and Cannell, 1999;

Wagner et al., 2012b). The membrane of cardiac tubules is extensively folded into microdomains with low ion diffusion (Hong et al., 2014). Such membrane folding has not been reported for the T-tubule system of skeletal myofibers. Transverse tubules occur in doublets with one tubule between each sarcomeric A- and I-band in skeletal myofibers, whereas only one tubule per sarcomere, which is anchored at the Z-line, is found in cardiomyocytes. Furthermore, cardiomyocytes have an intracellular membrane system composed of transverse and axial tubules forming a complex network (Forbes et al., 1984; Soeller and Cannell, 1999; Sperelakis and Rubio, 1971). Axial membrane tubules are largely missing in skeletal myofibers. In skeletal muscle cells, EC coupling occurs in triads with $\text{Ca}_v1.1$ and RyR1 physically interacting with each other presupposing that the T-tubule and SR membrane are separated by an extremely narrow gap (Ashcroft, 1991; Bezanilla et al., 1972; Boncompagni et al., 2006). In cardiomyocytes, $\text{Ca}_v1.2$ and RyR2 are only functionally coupled as Ca^{2+} release from the SR is induced by Ca^{2+} influx through $\text{Ca}_v1.2$ and not by a conformational change of the channel (DiFranco et al., 2005; Fabiato, 1983; Hong and Shaw, 2017; Ibrahim et al., 2011). Consequently, cardiomyocytes might be more resistant to morphological changes of the tubule system than skeletal muscle cells as they do not depend on a direct association of the $\text{Ca}_v1.2$ with RyR2. This might explain that dysferlin-deficiency causing an abnormal tubule system in both, cardiomyocytes and skeletal myofibers, is mainly leading to clinical pathology of the skeletal and to a much lesser extent of the heart muscle.

5.4 First stop on the route of dysferlin: the Endoplasmic reticulum

To understand the pathomechanism underlying dysferlin-deficient muscular dystrophy and to develop therapeutic targets for this disease, the trafficking route of dysferlin through the myofiber or cardiomyocyte should be elucidated. Until now, very little is known about the transport of dysferlin from its synthesis in the cytoplasm to its target organelle, the plasma and T-tubule membrane. The nature of dysferlin as a TA protein with a highly hydrophobic transmembrane domain suggests that the protein is posttranslationally and chaperone-assisted inserted into the membrane of the ER. This hypothesis was tested using a short peptide, the opsin tag, which is derived from the bovine rhodopsin (Adamus et al., 1991), as a sensor for ER integration. N-glycosylation of a specific arginine inside the recognition site of the opsin tag, which occurs through the activity of glycosyltransferases inside the ER lumen, can be detected by western blot as a mobility shift. As dysferlin has a molecular weight of 230 kDa, a shift due to glycosylation of a single residue inside the opsin tag would not be visible. Specific cleavage of full-length dysferlin by the protease thrombin allows identification of a C-

terminal fragment that is small enough to assess glycosylation on western blot either by anti-dysferlin or anti-opsin antibodies. The coupling of dysferlin to the opsin tag and cleavage by thrombin was subsequently used to analyze insertion of dysferlin into the ER of different mammalian cell lines (HeLa, HEK293, COS-7, CHO-K1, C2C12). Indeed, dysferlin gets C-terminally integrated into the ER in all tested systems suggesting that the ER membrane is the first endomembrane into which dysferlin is inserted after its synthesis in the cytoplasm. Surprisingly, the glycosylation is highly variable between the cell lines with CHO-K1 having the highest and HeLa the lowest amount of modified dysferlin. As glycosylation of dysferlin was also observed in C2C12 cells - a model system for myogenic development – it is possible that the posttranslational integration of dysferlin into the ER in muscle tissue is physiologically important. The variable glycosylation efficiency of dysferlin in different cell lines might be explained by several cellular factors. These include different chaperone proteins or complexes that might be involved in the cotranslational shielding or folding, protein quality control and targeting to the ER membrane (Casson et al., 2016; Hegde and Keenan, 2011; Johnson et al., 2013). The components of the cytoplasmic and ER-membrane resident insertion machinery as well the glycosyltransferases inside the ER might be cell-type adapted (Aebi, 2013; Ellgaard et al., 2016; Johnson et al., 2013). Furthermore, glycosylation extent might be influenced by the duration of ER lumen exposure as some cell types might be more sensitive to ER stress than others resulting in the retention of proteins inside the ER (Oslowski and Urano, 2011; Sano and Reed, 2013). As dysferlin-ops was heterologously overexpressed in the tested cell lines, a certain degree of induced ER stress is plausible. Also, the morphology and the size of the ER is cell type-dependent and might influence the insertion of proteins into the ER.

Patients with the *DYSF* mutation c.4022T>C show clinical symptoms of LGMD2B and partially of cardiomyopathy (Klinge et al., 2010b; Wenzel et al., 2006, 2007). Mutation c.4022T>C in exon 38 is leading to the amino acid change L1341P. The position L1341 is located in the C2E domain and is highly conserved, thus, an amino acid substitution might have dramatic effects on protein structure. Dysferlin L1341P accumulates in the ER of human myofibers and is prone to degradation by the autophagy-lysosome pathway (Fujita et al., 2007). In this study, the ER integration of wild-type and mutant dysferlin was analyzed to uncover possible trafficking defects of the mutant dysferlin. As expected, the proportion of glycosylated L1341P is 1.5-fold higher than glycosylated wild-type dysferlin. The increased amount of glycosylated protein might have different causes. Either, the integration into the ER is more efficient for the mutant than for the wild-type dysferlin. Or, exposure of the L1341P mutant protein to the ER lumen is

prolonged leading to more opportunities for glycosyltransferases to glycosylate the opsin tag. Taking into consideration that the mutant L1341P does not localize to the plasma membrane in myofibers but rather accumulates in the ER (Fujita et al., 2007), the second explanation of increased glycosylation is more plausible. Substitution of leucine to proline at position 1341 probably leads to a conformational change of the dysferlin protein which does not perturb insertion into the ER membrane. Instead, the altered protein structure interferes with dysferlin trafficking possible by inhibiting protein exit from the ER. This leads to loss of dysferlin at the plasma membrane and aggregation of L1341P inside the ER as detected in patient myofibers harboring the respective mutation (Fujita et al., 2007). Consequently, mutations inside conserved regions of dysferlin perturb cellular protein trafficking leading to deficiency of the full-length protein at its target organelle and causing muscular dystrophy.

Dysferlin gets integrated into the membrane of the ER, but mechanistic details of this insertion are currently unknown. In recent years, a pathway has been identified, that mediates insertion of TA proteins into the ER and which is also involved in protein quality control (Favaloro et al., 2010; Payapilly and High, 2014; Rodrigo-Brenni et al., 2014; Stefanovic and Hegde, 2007; Vilardi et al., 2011; Yamamoto and Sakisaka, 2012). The dependence of the TA protein dysferlin on the TRC40/WRB insertion pathway in cardiomyocytes was analyzed in cooperation with Dr. Jhon Rivera-Monroy and Prof. Blanche Schwappach from the department of Molecular Biology, University Medical Center Göttingen. The ER membrane-located receptor component *WRB* was cardiac-specifically deleted in an inducible mouse model. This leads not only to a significant reduction of *WRB* protein level, but also the steady-state levels of other main pathway components, TRC40 and CAML, decrease upon *WRB* gene deletion resulting to complete disruption of the pathway (Rivera-Monroy et al., 2016). Cardiomyocytes were isolated from 8-week old mice and 2 weeks after gene knockout induction by administration of tamoxifen (Performed by Dr. Jhon Rivera-Monroy). Cells were analyzed with regard to dysferlin expression and localization by western blot and indirect immunofluorescence, respectively. Neither the steady-state protein level, nor the localization of dysferlin is affected by disruption of the TRC40/WRB pathway in ventricular cardiomyocytes. These results indicate a probable TRC40/WRB-independent trafficking of dysferlin in cardiomyocytes, although the missing effect on dysferlin upon TRC40/WRB disruption does not exclude that dysferlin might be targeted via this pathway to the ER. Alternative chaperone and insertion pathways have been identified previously, which operate in parallel and to some extent might compensate for the loss of each other (Abell et al., 2007; Ast et al., 2013; Aviram et al., 2016; Rabu et al.,

2008). TA proteins containing a transmembrane domain with comparably high hydrophobicity, like in the case of dysferlin, are suitable candidates for ER insertion via the TRC40/WRB pathway (Rabu et al., 2008). As TRC40/WRB disruption does not lead to a mislocalized or destabilized dysferlin pool, the hydrophobicity is not the only criterion which dictates whether a certain TA is an obligatory client for the TRC40/WRB pathway (Rivera-Monroy et al., 2016). Dysferlin has a very large N-terminal domain upstream of the transmembrane domain incorporating seven C2 domains and several other domains which require proper folding and quality control already during the process of translation. This might be ensured by specialized cytosolic chaperones. BAG6, which is also a component of the cytosolic TRC40 chaperone complex, is additionally involved in quality control. Mislocalized proteins are BAG6-dependently polyubiquitinated by the ubiquitin ligase RNF126 and subsequently degraded by the proteasome (Rodrigo-Brenni et al., 2014). It has been reported that the proteasome is involved in the degradation of wild-type dysferlin (Fujita et al., 2007). Thus, it is conceivable that the BAG6-mediated initiation of proteasomal degradation is one component of the quality control system necessary for proper dysferlin synthesis. In conclusion, dysferlin is C-terminally inserted into the membrane of the ER probably directly after its synthesis and this process does not depend on the TRC40/WRB integration pathway.

5.5 4-Phenylbutyrate as potential therapeutic for the treatment of dysferlinopathy

Dysferlin-deficiency is often associated with dysferlin mislocalization, instability and/or degradation due to mutations in the *DYSF* gene. In this study two missense mutants were analyzed with regard to possible therapeutic intervention. Mutation R959W is located in the C2D domain and is reported to cause structural changes in the dysferlin protein (Espinoza-Fonseca, 2016). Dysferlin harboring the mutation L1341P, which is located in the C2E domain, is prone to aggregation in the ER (Fujita et al., 2007). In this study, the steady-state protein level is decreased for both dysferlin variants compared to wild-type dysferlin. Treatment with PBA leads to an increased levels of wild-type, R959W and L1341P proteins with mutant R959W exceeding the basal wild-type level. Thus, PBA is a potent substance for the amelioration of reduced mutant dysferlin protein level in dysferlinopathy. There are several possible mechanisms by which PBA elevates the protein level of dysferlin variants. One is the general function of PBA as a chaperone (Cortez and Sim, 2014). The hydrophobic chain of PBA might bind to and shield hydrophobic regions of dysferlin variants, thereby facilitating accurate

folding and probably reducing the unfolded protein response which would lead to protein degradation (Lindholm et al., 2017). This could explain the effect that not only mutant dysferlin variants, but also the wild-type dysferlin becomes stabilized. Dysferlin is a large protein making it plausible that folding errors occur also under normal conditions. Thus, PBA may assist in protein folding and thereby increase steady-state levels of dysferlin wild-type and mutants. Recently, the mode of action of PBA as a regulator of proteostasis was addressed by Ma and colleagues (Ma et al., 2017). They hypothesize that PBA affects trafficking from the ER to the Golgi via COPII-coated vesicles. Accordingly, PBA displaces the protein p24 from binding to COPII proteins and thereby reduces stringency of misfolded protein retention inside the ER (Ma et al., 2017). By this mechanism, dysferlin variants, which are partially ER-trapped under basal conditions, would be extruded from the ER by PBA. A distinct line of research has uncovered a role of PBA in inducing the expression of the 70-kDa heat shock protein (Hsp70), which is activated upon ER stress and binds to unfolded or misfolded proteins (Choo-Kang and Zeitlin, 2001). It was suggested that PBA induces Hsp70 expression via activation of elongator protein 2 (ELP2) and signal transducer and activator of transcription-3 (STAT-3). Hsp70 in turn mediates maturation and trafficking of mutated forms of cystic fibrosis transmembrane conductance regulator (CFTR), the cause for cystic fibrosis (Choo-Kang and Zeitlin, 2001; Saud et al., 2011). Thus, stabilization of dysferlin R959W and L1341P steady-state protein level might also be mediated by induction of Hsp70 alleviating the degradation of these mutants. Additionally to a chaperone-mediated elevation of dysferlin protein, the function of PBA as histone deacetylase inhibitor might ameliorate reduced protein level by modulating cellular gene expression.

Several lines of evidence suggest that the deformation of membranes into elongated tubules during biogenesis of the T-tubule system is the primary function of dysferlin in the muscle fiber (Hofhuis et al., 2017). The induction of membrane tubules upon heterologous expression of dysferlin in non-muscle cells is considered as analogous to its physiological function. Thus, the ability to tubulate membranes in non-muscle cells can be used as a read-out for proper dysferlin function (Hofhuis et al., 2017). The dysferlin mutants R959W and L1341P were analyzed with regard to their functionality using this assay. Both mutants are incapable in the generation of membrane tubules when expressed in HeLa cells. R959W is partially colocalizing with the cis-Golgi marker giantin (Linstedt and Hauri, 1993; Puthenveedu and Linstedt, 2001). As the overlap was not complete, it is conceivable that this mutant rather is trapped in the medial or trans Golgi compartment. This localization was confirmed in C2C12 myotubes. As

reported, L1341P is found to be retained in the ER (Fujita et al., 2007). Taking into consideration that both mutants harbor only a single amino acid substitution, which obviously affects protein trafficking, it is plausible that they might be functional when localized at the appropriate cellular position. As steady-state protein level is stabilized by PBA, also the effect on mutant localization was analyzed. Wild-type and L1341P localization is unaffected by PBA treatment. Mutant R595W is mainly localizing to the Golgi compartment, but also the induction of membrane tubules is detectable in a considerable proportion of cells. Consequently, the elevation of R959W steady-state level by PBA-mediated improvement of trafficking leads to some extent to correct localization of mutant dysferlin and partial restoration of its function as membrane modulator. In contrast to R959W, the mutant L1341P does not lead to detectable generation of membrane tubules even upon PBA treatment. This might be explained by the different steady-state levels that are reached by PBA. The level of R959W exceeds the basal level of wild-type dysferlin. These results indicate that even higher amounts of mutant R959W upon PBA compared to nontreated wild-type dysferlin, only partially restore the function of R959W because of structural changes due to the amino acid change. Steady-state levels of L1341P upon PBA treatment are still lower than levels of untreated wild-type dysferlin. Thus, either the improved trafficking for the mutant is not sufficient to restore tubulation in the cell system, or the mutation leads not only to retention inside the ER but also to loss of function. Assuming that dysferlin follows the secretory pathway to traffic from the ER through the Golgi to its target membrane (Azakir et al., 2010), the mutant L1341 gets trapped at an earlier stage of this route than the mutant R959W making it putatively easier for the latter to be extruded by pharmacological intervention. Further investigation is necessary to assess whether PBA might have an ameliorating effect on the functionality of L1341P mutated dysferlin under different conditions or other systems. In conclusion, PBA is a potent pharmacological substance for the restoration of dysferlin function, as shown for the mutant R959W. To determine, whether the functional rescue observed in a cell culture system can be confirmed *in vivo*, the efficiency of PBA treatment in dysferlin-deficient animal models harboring point mutations needs to be investigated regard to progression of muscular dystrophy. PBA is considered as a safe and well-tolerable compound with only mild and reversible adverse effects (Mokhtarani et al., 2013; Perrine et al., 2011). Though, effects on the amino acid homeostasis, caused by the metabolism of PBA, with decreased blood plasma levels of glutamine and branch-chained amino acids valine, leucine, isoleucine, have been reported (Brunetti-Pierri et al., 2011; Burrage et al., 2014; Darmaun et al., 1998; Scaglia et al., 2004). Therefore, a supplementation with glutamine and

branch-chained amino acids was recently recommended for the clinical use of PBA (Holecek et al., 2017). PBA is under investigation for the treatment of several diseases and might also be a potent pharmacological therapeutic for dysferlinopathy. As PBA is already FDA-approved for the treatment of children with urea cycle disorders, it might be feasible to perform clinical trials investigating PBA as treatment for dysferlinopathy in the near future.

5.6 Therapeutic modulation of dysferlin expression by translational readthrough

25% of recurrent mutations in the *DYSF* gene that cause dysferlin-deficiency and the development of muscular dystrophy are mutations leading to the generation of termination codons (UMD-DYSF mutations database, http://www.umd.be/DYSF/W_DYSF/mutation.html). These stop signals cause mRNA instability and nonsense-mediated mRNA decay, or the premature termination of translation resulting in the production of truncated unfunctional proteins that are prone to degradation (Yang et al., 2016). Aminoglycosides can provoke the binding of a near-cognate aminoacyl-tRNA instead of a release factor at premature termination codons (PTCs) by interacting with conserved ribosomal RNA in the ribosomal decoding center (Wimberly et al., 2000). This leads to the incorporation of an amino acid, continuation of translation and synthesis of the full-length protein (Lee and Dougherty, 2012). This approach is approved for the treatment of cystic fibrosis patients and is under investigation for other genetic diseases with premature stop codons, such as Duchenne muscular dystrophy (Barton-Davis et al., 1999; Lee and Dougherty, 2012; Loufrani et al., 2004). The *in vivo* use of aminoglycosides gentamicin and G418 as readthrough inducers is accompanied by severe adverse effects of those drugs. Oto- and nephrotoxicity are the most critical side effects reported (Smyth, 2010). Therefore, a prediction for the treatability of certain PTCs by aminoglycosides would be beneficial for the patients to avoid ineffective readthrough induction and severe side effects. This concept was addressed by the treatment of cystic fibrosis and Duchenne muscular dystrophy (Bidou et al., 2004; Howard et al., 2000; Sermet-Gaudelus et al., 2007). In a systematic analysis, the basal and G418-induced readthrough of the 18 recurrent nonsense codons known in dysferlinopathy patients was assessed in this study. For this purpose, a very sensitive dual reporter expressing TagRFP and EGFP fluorescent protein genes upstream and downstream of an SCC, respectively, was used. Interestingly, a variable level of basal and G418-induced readthrough was detected indicating that at certain SCCs translational readthrough is more likely to occur than at others. Previous

work of our group showed that only the stop codon itself and the adjacent nucleotides have a dominant impact on the basal readthrough propensity (Schueren et al., 2014). The estimation of readthrough propensity for all SCCs of the human genome by an *in silico* regression model lead to the identification of a 6-nucleotide consensus motif for high readthrough tendency: **UGA** CUA (stop codon in bold, positions 1-6, (Schueren et al., 2014). The stop codon UGA is reported to be most leaky with regard to readthrough (Howard et al., 2000; Schueren et al., 2014; Tate et al., 1996). All of the five patient mutations with SCCs yielding the highest induced readthrough levels in our assay (R1038X, S1173X, Q1269X, C1398X, W1968X) harbor the UGA stop codon (table). The high-readthrough consensus motif (Schueren et al., 2014) indicates that a cytosine (C) at position +4 correlates with high basal readthrough, but also the readthrough level achieved by induction with aminoglycosides is positively influenced by this nucleotide at the respective position (Howard et al., 2000; Keeling and Bedwell, 2002; Manuvakhova et al., 2000). Based on their results using a dual reporter assay for the assessment of readthrough induction, Howard and colleagues have graded the four nucleotides at position +4 according to their positive influence on readthrough and showed that C is the most powerful nucleotide following by uracil (U). The five SCCs with the highest induced readthrough in our assay harbor either a C (R1038X, Q1269X, C1398X) or a U (S1173X, W1968X). Therefore, the results obtained for the SCCs of *DYSF* nonsense mutations are in concordance with previously reported data. Schueren et al. suggested that a guanine (G) at position +7 might also contribute to high basal readthrough (Schueren et al., 2014). Interestingly, all of the five SCCs with highest G418-induced readthrough have a C at position +7. Thus, a G at this position may correlate with high readthrough under basal conditions, but when aminoglycosides are bound to the ribosome a C at position +7 of the mRNA may be more beneficial for readthrough induction. Howard and colleagues proposed an inverse correlation between the induced readthrough level and the stringency of translational termination in the absence of aminoglycosides (Howard et al., 2000). This observation was not reflected by this study as no correlation was observed between basal and induced readthrough levels. The results of this study indicate that basal readthrough of a given SCC is positively influenced by a distinct nucleotide composition then readthrough upon induction with aminoglycosides. This hypothesis is supported by the observation that a G at position +7 correlates with high basal readthrough (Schueren et al., 2014), but a C at the same position is located in all of the five SCCs with highest induced readthrough in this study. The results obtained by analysis of *DYSF* nonsense SCCs indicate that the benefit of aminoglycoside treatment would be highly variable depending on the mutation. Thus, the question arises,

whether knowledge of readthrough levels derived from a cell culture system can be translated to the therapeutic success in clinics. The comparison of readthrough induction in a dual reporter assay and the animal model of Duchenne muscular dystrophy by Bidou and colleagues led to the conclusion that results obtained in a cell culture system cannot be transferred into *in vivo* systems (Bidou et al., 2004). The work of Sermet-Gaudelus and colleagues contradicted this conclusion (Sermet-Gaudelus et al., 2007). They analyzed readthrough induction of SCCs from all nonsense mutations found in cystic fibrosis patients by a dual reporter assay and compared these results to the beneficial effects of aminoglycoside treatment of cystic fibrosis patients. The readthrough levels obtained in the reporter assay correlate with the production of the full-length protein in nasal epithelial cells of the treated patients suggesting that a dual reporter assay used in a cell culture system has the potency to predict therapeutic success (Sermet-Gaudelus et al., 2007). Another study analyzed the production of full-length protein in patients treated with aminoglycosides and their initial level of the targeted transcript. Accordingly, patients with high levels of transcript prior to treatment showed better response to readthrough therapy. This indicates that the process of nonsense-mediated mRNA decay and therewith the level of transcript should be considered for each patient (Linde et al., 2007). In conclusion, the sensitive dual reporter assay used in this study to assess basal and G418-induced readthrough of patient SCCs may be suitable as a prediction for the treatability of dysferlinopathy patients with nonsense mutations. According to the obtained results upon G418 treatment, patients harboring the mutations R1038X, S1173X, Q1269X, C1398X, W1968X may be suitable candidates for the treatment with aminoglycosides.

Acknowledgements

An dieser Stelle möchte ich mich ganz herzlich bei all den Menschen bedanken, die mich während meiner Doktorzeit begleitet und unterstützt haben, und die an der Entstehung dieser Arbeit beteiligt waren:

Zunächst möchte ich mich bei Prof. Dr. Jutta Gärtner für die Aufnahme in das Team der Klinik für Kinder- und Jugendmedizin bedanken. Ich bin sehr froh, dass Sie mir ermöglicht haben dieses Projekt in den exzellent ausgestatteten Laboren Ihrer Abteilung durchzuführen. Vielen Dank, dass Sie mich während der Promotionszeit begleitet haben.

Besonders möchte ich mich bei PD Dr. Lars Klinge und PD Dr. Sven Thoms für das spannende und herausfordernde Promotionsthema, und die Aufnahme in eure Arbeitsgruppe bedanken. Danke für das stetige Interesse an meiner Arbeit, für die wunderbare Betreuung und die konstruktive Kritik, die es ermöglicht hat mich weiterzuentwickeln. Danke für eure Unterstützung, ganz besonders in der Schreibphase.

Prof. Dr. Wolfgang Brück und Prof. Dr. Hubertus Jarry möchte ich für die wissenschaftliche Betreuung während der Promotionszeit und die Übernahme der damit verbundenen Aufgaben herzlich danken.

Außerdem möchte ich mich bei Dr. Ira Milosevic, Prof. Dr. Steven Johnsen und Prof. Dr. Blanche Schwappach für die Bereitschaft an der Teilnahme meines Prüfungsausschusses danken.

Ein ganz herzlicher Dank gilt Prof. Dr. Gerd Hunsmann für Ihr großes Interesse und für Ihr Vertrauen in meine Arbeit. Die finanzielle Unterstützung durch Ihre Stiftung hat die Durchführung dieses Projekts erst ermöglicht. Außerdem möchte ich mich bei der Eva Luise und Horst Köhler Stiftung für Menschen mit Seltenen Erkrankungen und dem Sonderforschungsbereich 1002 für die finanzielle Unterstützung bedanken.

Ein weiterer Dank gilt unseren Kooperationspartnern für das Teilen Eurer Expertise, Eures Equipments und Eurer Manpower:

Prof. Dr. Viacheslav Nikolaev und Tobias Goldak für die Isolation von ventrikulären Rattenkardiomyozyten im Rahmen der Dysferlin-Expressionsanalyse.

Prof. Dr. Niels Voigt, Dr. Cristina Molina, Ines Müller und Funsho Fakuade für die Isolation und Untersuchung von ventrikulären Kardiomyozyten aus Dysferlin-defizienten und -kompetenten Mäusen.

Prof. Dr. Blanche Schwappach und Dr. Jhon Rivera-Monroy für Euer großartiges Engagement zur Untersuchung des Traffickings von Dysferlin.

Dr. Eva Wagner für Deine Unterstützung und Deinen Rat bei der Untersuchung des T-Tubulussystems in Kardiomyozyten.

Weiterhin möchte ich mich bei Corinna Dickel und Marco Schmidt für die Klonierung der Reporterkonstrukte bedanken.

Vielen Dank auch an Marc Ziegenbein für Deine Hilfe bei der Isolation von Rattenherzen und deine große Geduld bei der Durchführung der Western Blots.

Dr. Gertrude Bunt und dem MOLCI-Team möchte ich für die Einarbeitung und die technische Unterstützung beim Mikroskopieren danken.

Ein großer Dank geht an Dr. Erik Meskauskas, Dr. Werner Albig und Heike Wolfram für die organisatorische Hilfe und Beantwortung meiner vielen Fragen zur Promotion.

Ich möchte mich auch bei PD Dr. Ralph Krätzner für die Koordination aller Laborangelegenheiten und Deine Ratschläge bedanken.

Ein besonders herzlicher Dank gilt Irmgard Ciorny für Deine langjährige Erfahrung und exzellente Unterstützung im Labor. Danke, dass du mich in meiner Promotionszeit begleitet hast.

Ich möchte mich ganz herzlich bei allen Mitgliedern des Labors bedanken. Ihr habt mich super aufgenommen und eine tolle Arbeitsatmosphäre geschaffen. Danke für jedes gegossene Gel, jede PCR, jeden Puffer, jedes Zellensplitten. Danke für die schönen Mittagsrunden, Kaffeepausen und die vielen Nikoläuse und Ostereier, die mich mehrmals im Jahr erfreut haben.

Ein großes Dankeschön geht auch an Anke, weil Du Dich kümmerst, wo du nur kannst. Danke für deine ehrliche und liebevolle Art.

Ein Dankeschön gilt dem Megaoffice: Rosemol George, Julia Hofhuis, Karina Kaczmarek-Hájek, Kristina Lang, Thomas Weber, Susann Weißbach, Maria Wiese, Annika Wolf. Ein besseres Arbeitsumfeld hätte ich mir nicht vorstellen können. Ihr seid nicht nur Kollegen, sondern auch mit der Zeit Freunde geworden. Danke für Euer geballtes Wissen, die Yogaeinheiten, die mentale Unterstützung durch Stuhlkreise und Eure Ermutigungen. Ganz besonders möchte ich mich bei Julia bedanken. Danke, dass ich in deine Fußstapfen treten konnte und du mich immer unterstützt hast.

Danke an meine Freunde außerhalb des Labors für Euren offenen Ohren, die langen Gespräche über die Arbeit und Privates und eure Unterstützung während der ganzen Zeit.

Schließlich gilt meine unbeschreiblich große Dankbarkeit meiner Familie, insbesondere meinen Eltern, und meinem Mann Andrej. Danke für Eure grenzenlose Liebe, Euren Glauben in mich und Eure Geduld. Ohne Euch wäre diese Arbeit nicht zustande gekommen. Я вас люблю.

Curriculum vitae

Personal details

Name Kristina Bersch, née Gamper
Address Division of Neuropediatrics
Department of Pediatric and Adolescent Medicine
University Medical Center Göttingen
Robert-Koch Straße 40
37075 Göttingen, Germany
Phone +49-551-39-13652
Email kristina.bersch@med.uni-goettingen.de
Date of birth 30.01.1990

Education

10/2013-present **Ph.D. program Molecular Medicine**
Department of Pediatric and Adolescent Medicine
University Medical Center Göttingen
Dissertation: Dysferlin in skeletal and heart muscle: from trafficking to therapy

10/2012-04/2014 **Master program Molecular Medicine**
Georg-August-University, Göttingen
Fast-Track
Thesis: Mechanism of dysferlin-induced membrane tubulation
Grade: 1.3

10/2009-09/2012 **Bachelor program Molekulare Medizin**
Georg-August-University, Göttingen
Thesis: Characterization of the putative tumor suppressor Cyld as Plk1 and Cep192-interacting protein
Grade: 1.5

07/2009 High School Degree Abitur
Gymnasium Johanneum, Lüneburg
Grade: 1.6

Publications

Hofhuis, J., **Bersch, K.**, Büssenschütt, R., Drzymalski, M., Liebetanz, D., Nikolaev, V.O., Wagner, S., Maier, L.S., Gärtner, J., Klinge, L., et al. (2017). Dysferlin mediates membrane tubulation and links T-tubule biogenesis to muscular dystrophy. *J Cell Sci* jcs.198861.
