Acknowledgements

I would like to thank my supervisor Prof. Mikael Simons for giving me the opportunity to join his group and supporting me during my PhD.

I also thank, Prof. Alexander Fluegel and Prof. Holger Reichardt, the members of my thesis committee for their helpful advice during my PhD.

I appreciate the funding and educational support by the Max Planck Society, SFB transregio 43, the Göttingen Graduate School for Neurosciences, Biophysics, and Molecular Biosciences (GGNB) and the Georg-August University.

I am grateful to Prof. Uwe-Karsten Hanisch's group (Hana and Nasrin) for teaching me their techniques and being so friendly to share their knowledge with me.

I also appreciate all the help from our collaborator: Alexander Fluegel and his nice PhD student, Tanja Litke

I am really thankful to Jennifer Schindler, Steffi Thiel, Nadine Jagaschewskie, and Olivia Schulze, in the animal house for taking care of my mice line so carefully that I could do all my *in vivo* experiments without any problem during my PhD

I also should thank to Dr. Ursula Fünfschilling, and Mr. Rainer Libal in animal house for teaching me how to work with mice and helping me in different situations.

I would like to mention the colleagues and friends in AG Simons, for the warm and friendly working atmosphere and also for their help and fruitful advice during my PhD: Giselheid Schulz, Lena Steshenko, Dirk Fitzner, Nicolas Snaidero, Aniket Ghosh, Mostafa Bakhti, Sebastian Schmitt, Shweta Aggarwal, Tina Kling, Schanila Nawaz, Nils Halbsgut, Ulrich weikert, Marie-Theres Weil, Maryam Khojasteh, Caroline Velte, Ludovico Cantuti, Sebastian Timmler, Jan-Georg

I specially appreciate all the support and friendship from Caro, Tina, Maryam, Mostafa, and Natalia.

My Mother for her love, great support, and patience to encourage me for improving my life and education.

Alejandro, my dear, for sharing very nice moments with me and for his help and patience during last year.

My best friends in Iran, for not forgetting me and always staying in touch with me to support me emotionally in every situation, and I specially would like to thank my best best friends ever, Zizi and Hiva in Canada, for taking care of me emotionally, giving me the strong confidence to be able to deal with all my problems during all these years.

Abstract

During development oligodendrocytes in the central nervous system (CNS) produce large amount of membrane to generate myelin which wraps around the axons. The synthesis, maintenance and turnover of such enormous amounts of myelin membranes are crucial for the maintenance of functional nerves. How molecules within the numerous layers of tightly compacted membrane get access to the degradation system for myelin turnover is not well known. In this work, we observed that microglia are in contact with myelin via their processes, and myelin fragments, generated due to myelin breakdown, are engulfed by these cells at 18 and 24 months of age. We could show that microglia are actively engaged in clearing away degenerated myelin in normal aging.

To investigate the connection between myelin breakdown and phenotypic changes in microglia, demyelinating mouse models were analysed. The results showed that microglia in these mice specifically develop large amount of lysosomal inclusions that include internalized myelin components.

In general, such inclusions are typically observed in aged post-mitotic cells and are called aging pigment or lipofuscin.

To test whether impairing the lysosomal system is sufficient to induce an aging phenotype, we generated mice in which the lysosomal degradation pathway was specifically blocked in microglia. This was achieved by deleting the gene encoding Rab7 which is essential for maturation of lysosomes. In these mice, aged microglia with large inclusions was induced already when the mice were 10 weeks old. Already at 5 months of age the clearance function impaired and the number of extracellular myelin fragments increased. Using Rab7 KO mice we confirmed the role of microglia cells in clearing myelin in normal aging, and also induced a phenotype related to aging.

These findings indicate that myelin breakdown can lead to lysosomal inclusion and impairs the clearance function of microglia.

Since the clearance function is important for the cell function to fight against aging, our results may have important implication for multiple sclerosis and neurodegenerative disease associated with protein aggregation such as Alzheimer's disease.

Chapter 1

Introduction

1.1 Microglia

1.1.1 Microglia origin and development

Microglia are resident phagocytic cells in the central nervous system (CNS) which form 5-20% of the total glial cell population (non-neuronal cells) (Lawson, Perry *et al.* 1990; Perry 1998). Microglia originate from myeloid progenitors in the yolk sac before embryonic day 8; they migrate and proliferate in the parenchyma during development. (Alliot, Godin *et al.* 1999; Ginhoux, Greter *et al.* 2010; Ginhoux, Lim *et al.* 2013; Prinz and Priller 2014). Microglia are long-lived cells and their population is maintained in the CNS by self-renewing in physiological condition during adulthood (Lawson, Perry *et al.* 1992; Ajami, Bennett *et al.* 2007).

1.1.2 Microglia phenotype in central nervous system

In normal conditions, microglia are in their ramified shape with long and highly branched processes. In this stage, the cells are considered to be in the “resting” state when they express macrophage-specific molecules like Iba1 (ionized calcium-binding adapter molecule 1), F4/80 and CX3CR1 (CX3C chemokine receptor 1 or Fractalkine receptor) (Kettenmann, Hanisch *et al.* 2011; Prinz, Priller *et al.* 2011). During injury due to the loss of brain homeostasis, microglia become activated and change their morphology to an amoeboid form with retracted and less complex processes. In addition, their gene expression profile changes and pro-inflammatory cytokines like TNF- α (Tumor necrosis factor alpha), IL-1 β (Interleukin 1 beta), and IL-6 (Interleukin 6) as well as activation markers such as MHCII (major histocompatibility complex II), Fc γ RII (Fc gamma receptor II), and iNOS (inducible Nitric Oxide Synthase) are expressed (Kettenmann, Hanisch *et al.* 2011).

1.1.3 Microglia function in central nervous system

Microglia cells have a variety of functions including surveillance, pruning, phagocytic and inflammatory activities which are important for the maintenance of CNS homeostasis during

1 | Introduction

development, adulthood, and aging in healthy and injured brain (Perry, Nicoll *et al.* 2010; Ginhoux, Lim *et al.* 2013; Perry and Teeling 2013; Gomez-Nicola and Perry 2015).

1.1.3.1 Microglia in normal brain

The classical view about microglia was that when they are in their resting state with the ramified morphology, they shut down most of their functions. However, using *in vivo* two photon imaging in the neocortex it has been shown that the cells are highly motile in this stage, actively scanning the environment in the healthy CNS (Nimmerjahn, Kirchhoff *et al.* 2005). Based on this finding, microglia are thought to actively survey the CNS using their processes and phagocytic activity to remove damaged tissues, cells and toxic substances even in the so-called “resting” state (Tremblay, Stevens *et al.* 2011; Gomez-Nicola and Perry 2015). However, beside surveillance function, microglia have additional functions such as contributing to brain plasticity and maintaining the integrity of the CNS (Lourbopoulos, Erturk *et al.* 2015). For example, by secreting cytokines and neurotrophic factors such as BDNF (Brain-derived neurotrophic factor), microglia cells increase plasticity of synapses which are related to learning and memory (Parkhurst, Yang *et al.* 2013). Furthermore, live imaging of fluorescent-labeled neurons and microglia has shown that microglia are in contact with synapses in the steady-state condition, and their contact increases when neurons are more active suggesting that microglia cells are important for neuronal circuitry and connectivity (Wake, Moorhouse *et al.* 2009). Using electron microscopy and two-photon *in vivo* imaging in the primary visual cortex, it was shown that microglia play a role in the remodeling of synaptic structures. Microglia processes are in contact with axon terminal and dendritic spine, where the synapses are located, to modify the structure of synapses by remodeling the extracellular environment. In addition, synaptic elements have been detected inside microglia in normal condition suggesting that these cells are part of the degradation system for elimination of synaptic components (Wake, Moorhouse *et al.* 2009; Tremblay, Lowery *et al.* 2010; Tremblay and Majewska 2011; Salter and Beggs 2014). Moreover, *in vitro* studies have shown that exosomes or extracellular microvesicles derived from oligodendrocyte membranes are exclusively internalized by microglia. In addition, when the purified exosomes were injected in the mouse brain they were engulfed by microglia suggesting that microglia may be responsible for the degradation of oligodendroglial membrane (Fitzner, Schnaars *et al.* 2011). Different functions of microglia in healthy brain are shown in figure 1.1.

Figure 1.1 Functional states of microglia in the healthy brain. Phagocytic cells remove apoptotic neurons and tissue debris, this function is important for high turnover of cell population and consequently for maintaining the CNS integrity. Microglia are also important for removing extra synapses by pruning axon terminal. Furthermore, microglia modulate neuronal activity at the level of synapses. Diego Gomez-Nicola, and V. Hugh Perry, *Neuroscientist* 2014; 1073858414530512. Copyright by SAGE Publications.

1.1.3.2 Microglia in the diseased brain

Microglia have been considered as the brain immune cells contributing in the first line of defense in acute lesions and against microbes by clearing off damaged tissues and cells. These cells are involved in brain injuries and disorders via their phagocytic activity and neuroinflammatory responses (Banati 2003; Nimmerjahn, Kirchhoff *et al.* 2005; Kettenmann, Hanisch *et al.* 2011). However, it is notable that due to the limits for distinguishing resident microglia from infiltrating cells it has not been easy to identify the exclusive role of microglia in disease condition. Now, an increasing number of studies indicate that the function of short-lived peripheral macrophages and long-lived resident microglia are distinguishable (Butovsky, Jedrychowski *et al.* 2014; Evans, Barkauskas *et al.* 2014; Prinz and Priller 2014). For example, in demyelinating model such as EAE (Experimental autoimmune encephalomyelitis), resident microglia are thought to be protective by clearing off the debris whereas infiltrating macrophages appear to cause demyelination due to proinflammatory responses (Yamasaki, Lu *et al.* 2014). The expression profile of activated microglia, including proinflammatory

1 | Introduction

and anti-inflammatory cytokines and other mediators varies depending on the insult in unhealthy brain. The functionality of activated cells can be beneficial or detrimental (Gomes-Leal 2012; Heneka, Kummer *et al.* 2014; Perry and Holmes 2014). Neuroinflammatory responses are the main reaction of activated microglia in the pathology of most neurodegenerative diseases. For instance, microglia-mediated neuroinflammation causes formation of neurofibrillary tangles, pathological hallmark of the Alzheimer's disease (AD). Moreover, microglial immune responses, such as IL-1 β expression, are suggested to be sufficient for tau pathology. (Kosik, Joachim *et al.* 1986; Iqbal, Grundke-Iqbal *et al.* 1989; Iqbal, Alonso Adel *et al.* 2005; Bhaskar, Konerth *et al.* 2010; Heneka, Kummer *et al.* 2014). On the other hand, microglia cells remove extracellular β -amyloid accumulated in AD brain (Lee and Landreth 2010). It has been studied that TLR4- (Toll-like receptor 4) and TNF-mediated activation of microglia are involved in the loss of dopaminergic neurons in the mid brain of Parkinson's disease models. (McCoy, Ruhn *et al.* 2008; Noelker, Morel *et al.* 2013).

1.1.4 Microglia in aging

Considering the fact that microglia reside in the CNS during lifetime of an animal, they are susceptible to aging (Ajami, Bennett *et al.* 2007; Mildner, Schmidt *et al.* 2007). Therefore, an increasing number of studies focus on the anatomical, morphological, physiological, and molecular changes that microglia undergo in normal aging (Conde and Streit 2006; Wong 2013).

1.1.4.1 Aging phenotype of microglia

It has been suggested that the functionality of microglia decline during aging (Streit and Xue 2010). To keep the overall function, microglia are able to proliferate regionally. Therefore, in aging the density of microglia cells in different region of CNS increases (Mouton, Long *et al.* 2002; Damani, Zhao *et al.* 2011; Tremblay, Zettel *et al.* 2012). However, the reason for the increase in the number of cells during aging is not clear. (Wong 2013). In addition, the distribution of microglia in aged brain is regionally different (Santos, Calvente *et al.* 2008; Damani, Zhao *et al.* 2011; Tremblay, Zettel *et al.* 2012). In aging, the morphology of microglia also changes; their processes are shorter and show less complexity so that the surface area of the cells decreases (Sierra, Gottfried-Blackmore *et al.* 2007; Damani, Zhao *et al.* 2011; Tremblay, Zettel *et al.* 2012). In addition, the morphology of microglia in aged human brain is considered to be dystrophic in which the processes are segmented and de-ramified showing large swellings (spheroid) at the end. Notably, the dystrophic changes in microglia are not comparable to the morphological changes that occur during microglial activation in injury (Streit, Sammons *et al.* 2004).

1.1.4.2 Basal activation state of microglia in aging

The phenotype of aged microglia is similar to activated cells; for example, they show hypertrophy and retracted processes (Sheng, Mrak *et al.* 1998; Miller and Streit 2007). In addition, activation markers such as MHCII, CD11b, and OX6 are up-regulated in aged microglia (Ogura, Ogawa *et al.* 1994; Frank, Barrientos *et al.* 2006; Ziv, Ron *et al.* 2006). Increased level of inflammatory cytokines such as IL1 β , TNF- α , IL-6 is also typical of aged microglia (Sheng, Mrak *et al.* 1998; Sierra, Gottfried-Blackmore *et al.* 2007; Njie, Boelen *et al.* 2012). The increased activated basal state of microglia in healthy aging can explain the susceptibility of aged CNS to neurodegenerative diseases (Medzhitov 2008).

1.1.4.3 The functionality of microglia in aging

Regarding age-related changes in the morphology and activation state of microglia it is reasonable to connect these alterations to possible changes in their normal tasks during aging. The dystrophic cells in aged human brain showed a decline in their neuroprotective function (Streit and Xue 2009). Furthermore, it has been found that microglia in aged brain cannot manage their role in synaptic plasticity as efficient as young cells because they are in less contact with synapse and axon terminal (Wong 2013). In fact, this deficiency can be due to declined dynamic motility of aged microglial processes (Damani, Zhao *et al.* 2011). Aged microglia are still able to migrate toward the injured site through parenchyma but at a lower rate compared to young cells (Damani, Zhao *et al.* 2011). Interestingly when they proliferate, their number does not return to the original level, and their activation state persist long term after recovery (Ajami, Bennett *et al.* 2007). In other words, microglia in aged brain represent an enhanced priming state so that, in unhealthy brain, they are more responsive, and their reaction is more sustained (Sparkman, Martin *et al.* 2005; Conde and Streit 2006; Sierra, Gottfried-Blackmore *et al.* 2007; Sandhir, Onyszchuk *et al.* 2008; Wasserman, Yang *et al.* 2008; Norden and Godbout 2013). The age-related priming of microglia results from dysregulated balance between signals which induce activation ("On" signals) and signals that adjust the maintenance or reversibility of responses to the basal state ("Of" signals) (van Rossum and Hanisch 2004; Biber, Neumann *et al.* 2007; Wong 2013). For example, while the expression of TLR1, 4, 5, 7 and CD14 is up-regulated in aging, the level of "Of" signals such as CX3CR1 and CD200 is lower (Frank, Barrientos *et al.* 2006; Letiembre, Hao *et al.* 2007; Bachstetter, Morganti *et al.* 2011).

1 | Introduction

1.1.4.4 Why microglia become aged?

Aged microglia have shorter telomeres in comparison with young cells; therefore, their ability for proliferation is limited (Flanary, Sammons *et al.* 2007). In addition, the production of telomerase, an enzyme for extending the length of telomeres, in aged cells is low. Consequently, telomeres cannot be elongated in again after injury-induced replication (Flanary and Streit 2005). Replication senescence appears to be induced in aged microglia due to shortening of telomeres. Furthermore, an increased level of mitochondria DNA (mtDNA) has been detected in aged microglia and the respiratory chain is thought to be dysfunctional so that reactive oxygen species (ROS) are over-produced and accumulate within the cells (Corral-Debrinski, Horton *et al.* 1992; Lin, Simon *et al.* 2002). It has been suggested that the accumulation of ROS may result in elevated microglial activation during aging because ROS is important for modulation of pro-inflammatory cytokine production which is regulated by NF- κ B-(Nuclear factor kappa-light-chain-enhancer of activated B cells) mediated transcription (Toledano and Leonard 1991; Nakanishi, Hayashi *et al.* 2011). Moreover, since microglia are long-lived cells and their physiological activities are sustained with time, the biological components accumulate within these cells. These accumulations affect the phenotype of the cells including morphology and activation state (Ma, Coon *et al.* 2013; Wong 2013).

1.1.4.4.1 Lysosomal storage; Lipofuscin

Lipofuscin is an indigestible polymeric compound which is formed in non-dividing cells such as neurons, retinal pigment epithelial cells (RPE) as well as microglia due to the accumulation of biological molecules and waste material with time (Essner and Novikoff 1960; Terman and Brunk 1998; Brunk and Terman 2002). Lipofuscin is yellowish-brown with autofluorescent feature; it includes various fluorophores that can be detected across a broad spectrum (Terman and Brunk 1998; Gray and Woulfe 2005). Lipofuscin formation is considered as lysosomal storage which is the main characteristic of aging phenotype since the amount of that increases with age (Strehler, Mark *et al.* 1959; Hohn and Grune 2013).

Lipofuscin has been detected as lysosomal inclusions in microglia in the aged brain. (Peinado, Quesada *et al.* 1998; Sierra, Gottfried-Blackmore *et al.* 2007; Tremblay, Zettel *et al.* 2012). However, lipofuscin formation is well-known in RPE cells. Lipofuscin in RPE cells is mainly derived from photoreceptor outer segments (POS) in the retina (Feeney-Burns and Eldred 1983). In physiological condition, regularly, RPE cells phagocytose POS (photoreceptor outer segments) in a large amounts (Bok 1993; Strauss 2005). Digestion of this huge amount of photoreceptors is a big challenge for the lysosomal system of the cells (Feeney-Burns and Eldred 1983). On the other hand, with time, the end products of oxidized low-density lipoproteins and lipid peroxidation, which are produced during

1.1 Microglia

normal cell metabolism, are stored within lysosomes. These metabolites reduce the degradation of internalized POS. Therefore, POS-derived components accumulate within the cells and facilitate the formation of lipofuscin (Finnemann, Leung *et al.* 2002; Kaemmerer, Schutt *et al.* 2007; Kaarniranta, Sinha *et al.* 2013). In general, it has been shown that the formation of lipofuscin is mainly due to the oxidative stress in the lysosomes. Under normal conditions, the internalized materials in the lysosomes become oxidized because of iron-catalyzed peroxidation occurring inside the lysosome. Consequently, they become resistant to enzymatic activity of lysosome and then indigestible. Then these undegradable components accumulate in the form of lipofuscin with time when the cells no longer divide (Terman and Brunk 1998; Boulton, Rozanowska *et al.* 2004; Terman, Kurz *et al.* 2010; Kaarniranta, Sinha *et al.* 2013). Regarding the importance of oxidative reactions for the daily life of cell, and the fact that a small amount of lipofuscin is also formed in young cells; therefore, oxidative reaction should be considered as age-independent inducer of lipofuscin formation. Age-related increase in autophagocytosis, decline in lysosomal activity, and decrease in exocytosis are noticed as age-dependent enhancer of lipofuscin (Terman and Brunk 1998).

The accumulation of lipofuscin in the cells contributes to a decline in cell function (Neufeld 1991; Brunk and Terman 2002). For example, proteosomal activity is inhibited by loading cells with lipofuscin *in vitro* (Sitte, Huber *et al.* 2000). In addition, due to high amount of iron in lipofuscin the cells become more susceptible to oxidative stress which is mainly iron-mediated (Terman, Abrahamsson *et al.* 1999). The accumulation of damaged mitochondria has been detected within lipofuscin-loaded cells in lysosomal storage diseases. (March, Wurzelmann *et al.* 1995). Furthermore, lipofuscin accumulation in RPE cells cause the most common age-associated visual disorder, known as age-related macular degeneration (Katz 2002; Wolf 2003; Sparrow and Boulton 2005); also, it can be a risk factor for the age-related diseases such as Alzheimer's and Parkinson disease (Adamec, Mohan *et al.* 2000; Brunk and Terman 2002; Wolf 2003; Sparrow and Boulton 2005).

1.2 Myelin

1.2.1 Myelin structure

Myelin is composed of tightly wrapped membranes around axons and is produced by oligodendrocytes in the CNS (Bunge, Bunge *et al.* 1962). Wrapped myelin membranes along the length of axons are regularly spaced; this space, which is myelin free, is called node of Ranvier. In fact, the compacted structure of myelin is important for the fast and saltatory conduction of electric signals from one node to the next. The myelinated area between two nodes is called internode, at each edge of internode, paranodes are located which are considered as the main region for the

1 | Introduction

contact between axon and myelinating oligodendrocyte. The region between paranode and internode is called juxtaparanode (Pfeiffer, Warrington *et al.* 1993(Baumann and Pham-Dinh 2001). Myelin sheath is composed of compacted and non-compacted areas. Compacted myelin is referred to closely packed membrane along the internode between inner and outer tongue with a thin cytoplasm. Non-compacted myelin includes paranodes, contains more cytoplasm and is important for transport of metabolites to the compacted area during myelin biogenesis (Quarles 1999; Snaidero, Mobius *et al.* 2014)

1.2.2 Myelin composition

While most plasma membranes are composed of 50% proteins and 50% lipids in dry weight, 73-81% of the total dry weight of myelin membrane is formed by lipids (Pfeiffer, Warrington *et al.* 1993; Chrast, Saher *et al.* 2011). About 27% of myelin lipids are glycosphingolipids including Galactosylceramide as well as sulfatide, and almost 16% are plasmalogens (Aggarwal, Yurlova *et al.* 2011). In addition, cholesterol is the most abundant lipid in myelin (Baumann and Pham-Dinh 2001). Myelin basic protein (MBP) and proteolipid protein (PLP) account for the majority of myelin proteins (Campagnoni and Macklin 1988). These two proteins are mainly enriched in compacted myelin (Bakhti, Aggarwal *et al.* 2014) while Neurofascin 155 and Tag1 (transient axonal glycoprotein-1) are typical proteins of paranodes and juxtaparanodes. Myelin oligodendrocyte glycoprotein (MOG), myelin-associated glycoprotein (MAG), myelin-associated oligodendrocytic basic protein (MOBP), and 2', 3'-Cyclic-nucleotide 3'-phosphodiesterase (CNPase) compose the remaining part of myelin protein content. CNPase and MAG are found in non-compacted myelin while MOBP is included in compact myelin (Poliak and Peles 2003; Salzer 2003).

1.2.3 Myelination in the CNS

During development oligodendrocyte produce a huge amount of myelin membrane. One cell can form $20 \times 10^5 \mu\text{m}^2$ surface area of myelin (Pfeiffer, Warrington *et al.* 1993); in addition, oligodendrocytes can myelinate several axons at once. In the cortex and corpus callosum one cell can produce between 30 and 80 internodes ranging from 20 to 200 μm in length with up to 60 different lamellae on several thin axons. On the other hand, larger axons are myelinated with longer internodes (1500 μm) and thicker myelin sheath with 150 layers (Matthews and Duncan 1971; Murray and Blakemore 1980; Hildebrand, Remahl *et al.* 1993). Oligodendrocytes are considered as the most efficient membrane producers. In human, during the first year of age, the majority of the axons become myelinated, but in some cortical areas myelination still occurs during adulthood

(Fields 2008). Myelination in mice starts at birth and it is completed in most areas at postnatal day 60 (Baumann and Pham-Dinh 2001).

1.2.4 Myelin turnover

Membrane components of myelin need to be replaced continuously to maintain myelin integrity and, consequently, nerve conductance in the CNS. Myelination is an intensive ongoing process by oligodendrocytes in development and also later during adulthood (Watkins, Emery *et al.* 2008; Young, Psachoulia *et al.* 2013; Nave and Werner 2014), removal of modified toxic components or myelin disposal, produced or accumulated during this process, is considered as a part of myelin turnover. In general, myelin components have slow turnover rate. Using stable isotope-labeling and mass spectrometry (MS) the half-replacement time of myelin lipids was measured according to incorporation rate of newly synthesized molecules in adult mice. The results showed that cholesterol with 359 days half-life is the most stable lipid in the myelin sheath. Ganglioside GM1, cerebroside, phosphatidylethanolamine, and phosphatidylcholine have a half-life of 102 days, 94 days, 25 days and 20 days, respectively (Ando, Tanaka *et al.* 2003). Furthermore, using pulse-chase labeling and mass spectrometry in rats, some proteins of myelin sheaths including MBP, PLP, MOG and Nef3 (Neurofilament 3) were found in the list of long-lived proteome (Toyama, Savas *et al.* 2013).

It is notable that turnover rate of myelin components can be age-related. For example, cerebroside and GM1 were replaced with a slightly higher rate in aged mice compared to young and adult animals (Ando, Tanaka *et al.* 2003).

1.2.5 Myelin plasticity

The concept of myelin plasticity implies that newly differentiated oligodendrocytes are added to the CNS due to the continuous division and differentiation of oligodendrocyte precursor cells (OPCs) from development to the adulthood. (Dimou, Simon *et al.* 2008; Rivers, Young *et al.* 2008; Kang, Fukaya *et al.* 2010; Zhu, Whittemore *et al.* 2011; Wang and Young 2014). The newly synthesized myelin sheaths by adult-born oligodendrocytes are suggested to be incorporated into the pre-existing myelin sheath through myelin sheath replacement or myelin remodeling; or they can be used for *de novo* myelination of previously naked axons (Wang and Young 2014) (Figure 1.2). Furthermore, it has been shown that in comparison to oligodendrocytes in development, adult-born oligodendrocytes in the brain of P60 mice generate more and shorter internodes throughout the

1 | Introduction

axon (Young, Psachoulia *et al.* 2013) and the length of internodes is even more reduced in aging in the spinal cord of 14 and 21 months old mice (Lasiene, Matsui *et al.* 2009) In fact, it has been suggested that generation of short internodes is an indication of *de novo* myelination as it happens during remyelination after myelin degeneration (Gledhill and McDonald 1977). In addition, the cell cycle time of OPCs (NG2 expressing cells) increases with age; therefore, the proliferation rate of OPCs in aging is low. (Lasiene, Matsui *et al.* 2009; Psachoulia, Jamen *et al.* 2009; Clarke, Young *et al.* 2012; Young, Psachoulia *et al.* 2013). However, some studies have shown that the number of new oligodendrocytes (CC1 positive cells) increases in aged mice and also monkeys (Sandell and Peters 2002; Lasiene, Matsui *et al.* 2009).

Figure 1.2 Potential types of myelin plasticity in the CNS in adulthood.

1.2.6 Myelin in aging

Age-related changes in myelin structure have been mostly studied by Peters *et al.* in rhesus monkeys (Sandell and Peters 2001; Peters and Kemper 2012). Myelin alterations during aging, which are considered as degeneration of myelin membrane structure, cause changes in conduction of electric signals between neural networks (Peters and Kemper 2012). Therefore, these changes can be the main reason for cognitive decline. The most common age-dependent defect in myelin is that myelin layers break at the major dense line (formed by apposition of cytoplasmic faces at the edges of the sheet, enclosing cytoplasm within a loop (Quarles 1999)) so that an area with a dense cytoplasm containing lysosomes, vacuoles, and inclusions is formed. Another effect of aging is the formation of

balloons in the myelin sheath. The size of these balloons varies from 1-10 micron; the large ones, basically, interfere with the loading of new formed myelin membrane in the preexisting membrane. It has been shown that in aging myelin formation is continuous which results in myelin redundancy and also the formation of thick sheath with several circuitous splits (Peters 2002; Peters 2007). Over 25 years of age in monkeys there is a decrease in the number of nerve fibers. Moreover, due to the degeneration of axons in the nerve fibers some empty myelin sheaths are detected in the primary visual cortex of a 13-year-old monkey (Sandell and Peters 2001; Peters 2002; Peters 2007).

1.3 Demyelinating animal models

1.3.1 Cuprizone mouse model

1.3.1.1 Cuprizone-induced demyelination

Cuprizone (bis-cyclohexanone-oxaldihydrazone) is a copper chelator. The administration of cuprizone in mice induce copper deficiency preferentially in oligodendrocytes and consequently demyelination. (Kesterson and Carlton 1971; Pattison and Jebbett 1971; Blakemore 1972). Copper is important for the functionality of mitochondrial enzymes including copper-zinc superoxide dismutase and ceruloplasmin (Walshe 1995). Therefore, it has been hypothesized that due to cuprizone-induced copper deficiency, mitochondrial function and consequently energy metabolism in oligodendrocytes is disturbed and cell death is induced (Komoly, Jeyasingham *et al.* 1987; Matsushima and Morell 2001). However, why only oligodendrocytes are susceptible is not well known. It has been thought that due to production of massive amount of myelin, these cells are metabolically active and have an high energy requirement (Matsushima and Morell 2001). Feeding the mice with 0.2% w/w cuprizone in the food for 3-4 weeks induce demyelination mainly in corpus callosum, 5 weeks after cuprizone diet more than 90% of axons are affected. Interestingly, 6 weeks after treatment 50% of axons become remyelinated, and by removing cuprizone, remyelination occurs continuously (Matsushima and Morell 2001; Merkler, Boretius *et al.* 2005). On the other hand, increasing the duration of cuprizone treatment to 10-12 weeks causes ongoing demyelination so that a few myelinated axons are detected (Hoffmann, Lindner *et al.* 2008).

1.3.1.2 Immunopathology of cuprizone mouse model

The blood-brain barrier in cuprizone model is not breached; therefore, there are only little macrophages in the CNS during demyelination course. (Matsushima and Morell 2001; McMahon, Suzuki *et al.* 2002). 3 weeks after cuprizone treatment, when the demyelination is active, a significant number of microglia are observed mainly in corpus callosum. During 4-6 weeks of cuprizone exposure the number of activated cells increases (Hiremath, Saito *et al.* 1998). Beside possible infiltration of monocytes from periphery, it has been suggested that resident microglia from the other regions of the brain migrate to the lesion or they are locally proliferated (Matsushima and Morell 2001). Microglia in cuprizone-induced demyelination remove myelin debris (Smith 1999). Due to intact blood-brain barrier and minimal infiltration of peripheral immune cells, cuprizone mouse model has been considered as a suitable model to study the role of resident microglia during de/remyelination.

1.3.2 Shiverer mouse

Shiverer mutant mouse was first observed in the F38 generation of Swiss Vancouver stock by Biddle *et al.* (1973). Shiverer is an autosomal mouse mutation of MBP; there is no compact myelin in the CNS of the mouse carrying this mutation. While the normal MBP gene (32 kb) has 7 exons, 5 are deleted in shiverer mice and only the first two exons remain (Roach, Takahashi *et al.* 1985). Generalized tremors, seizures, and a short life span (50-100 days) are the main characteristics of this mutant (Chernoff 1981). Dysmyelination in these mice is not due to oligodendrocyte cell death, and no infiltration of macrophages has been reported (Bird, Farrell *et al.* 1978). The form of axoglial junctions in the shiverer CNS is not normally oriented because of fine tubular processes of oligodendrocytes around the axon. In addition, the number of these junctions increases (Rosenbluth 1981). Furthermore, the major dense line, which is normally established by cytoplasmic leaflet of the oligodendrocyte membrane in myelin is absent in the mutant mice (Privat, Jacque *et al.* 1979).

1.3.3 PLP overexpressing transgenic mice, a model for Pelizaeus-Merzbacher disease

Duplication of X-linked *plp1* gene (proteolipid protein gene 1) which results in overexpression of PLP protein is the most common cause of Pelizaeus-Merzbacher disease (PMD), a fatal leukodystrophy without therapeutic options (Seitelberger 1995). PLP overexpressing transgenic (*PLP1 tg*) mice is the mouse model of this disease (PMD mice). The main function of PLP is to maintain the integrity of

1.4 Endocytic pathway

myelin structure(Duncan, Hammang et al. 1987). PLP overexpressing transgenic mouse is considered as a non-immune mediated demyelination model in which dysmyelination starts at the optic nerve and spread into the brain within several months (Edgar, McCulloch *et al.* 2010) Oligodendrocyte death and axonal degeneration are other characteristics of this mouse model (Anderson, Schneider *et al.* 1998).

1.3.3.1 Microglia activation in PLP overexpressing transgenic mice

Activated microglia are found in white and gray matter very early on the 7th postnatal day, and by the third postnatal week microglia cells are endogenously reproduced. Microglia produce a high level of TNF- α and IL-6 in this stage; in addition, CC chemokines ligands and receptors including CCL3, 4, 8, CCR1 and 6, and also CXCL9 and 10 are up-regulated. Since activated microglia are found when the myelination has not started even in normal condition, it has been then suggested that myelin degradation does not trigger microglia activation in *plp1 tg* mice. Overexpression of PLP, but not myelin abnormalities, is thought to be the reason for the primary immune activation.

In PLP overexpressing transgenic mice, microglia-induced inflammation is considered to be important for axonal lost and disease progress (Bradl, Bauer *et al.* 1999; Tatar, Appikarla *et al.* 2010). In addition, short and thick processes are the common morphological features of activated microglia cells that are detectable in both white and gray matter when the mice are at 21 days of age. However, these changes are not seen in all microglia; for example, in the striatum and corpus callosum the processes are longer as they are in normal condition (Tatar, Appikarla *et al.* 2010).

1.4 Endocytic pathway

1.4.1 Endosome biogenesis

Lysosomes are catabolic compartment in eukaryotic cells, important for degradation of internalized materials and also components which are processed by autophagy (Kornfeld and Mellman 1989; Funato, Beron *et al.* 1997). Many different proteins are involved in endocytic trafficking regulating endosome maturation, movement, fission, and fusion. Small molecular weight G-proteins called Rab GTPase play a major role in endocytic pathway (Zerial and McBride 2001). These proteins belong to the Ras suprfamily of GTPases, they are located in the cytosolic part of intracellular membranes, and regulate different steps in membrane traffic pathways by switching between active (GTP-bound) and inactive (GDP-bound) forms. In this context, Rab proteins facilitate vesicle motility, tethering, and

1 | Introduction

fusion (Stenmark and Olkkonen 2001; Pfeffer and Aivazian 2004; Gurkan, Lapp *et al.* 2005). 11 and 60 Rab proteins have been identified in yeast and human, respectively (Pereira-Leal and Seabra 2001). Rab4a, Rab5a, Rab5b, Rab5c, Rab11, Rab18, Rab22, and Rab25 are localized in the early endosomal compartments (Bucci, Parton *et al.* 1992; Lutcke, Parton *et al.* 1994). Rab7 and Rab9 are found in the late endosomal compartments (Chavrier, Parton *et al.* 1990; Lombardi, Soldati *et al.* 1993). Rab5 is responsible for the formation of early endosome by regulating the fusion of endocytic vesicles (Hutagalung and Novick 2011). When cargo is trafficked through endocytic compartments, Rab5 is replaced by Rab7; this switch between Rab5 and 7 mediates transformation of early to late endosome (Rink, Ghigo *et al.* 2005; Vonderheit and Helenius 2005).

1.4.2 Lysosome biogenesis, Role of Rab7

Rab7 is involved in endocytic trafficking, specifically, in trafficking of early and late endosome; Rab7 regulates the movement of cargo out of early endosomes to late endosome (Chavrier, Parton *et al.* 1990; Vitelli, Santillo *et al.* 1997; Vonderheit and Helenius 2005). Rab7 has also been found to be required for the fusion between late endosome and lysosome. Its function is also important for cargo transfer from late endosome to lysosome (Bucci, Thomsen *et al.* 2000; Vanlandingham and Ceresa 2009). Moreover, by expressing Enhanced Green Fluorescent Protein (EGFP)-tagged wild type Rab7 and also using dominant-negative mutant proteins it has been shown that Rab7 is required for the biogenesis and maintenance of lysosomal structure. In the absence of Rab7, the lysosomes cannot be aggregated around the nucleus so that they are diffused throughout the cytoplasm. Therefore, it has been suggested that Rab7 might regulate the movement of vesicles along the cytoskeleton by engaging motor proteins such as myosin I, kinesin, and dynein to facilitate the aggregation of lysosomes around the nucleus. In addition, Rab7 controls the fusion of late endocytic compartments by regulating tight membrane interactions. Furthermore, acidification of lysosomes, which is necessary for the activity of hydrolases, the main lysosomal enzymes, (Mellman, Fuchs *et al.* 1986) is disturbed in the absence of Rab7. In conclusion, Rab7 is required for function of late endocytic structures including endosomes and lysosomes in the perinuclear region (Bucci, Thomsen *et al.* 2000) (Fig 1.3).

1.5 Question and hypothesis of the project

Figure 1.3 Rab proteins involved in endocytic pathway. Rab5 mediates the fusion of early endosomes, and the exchange between Rab5 and Rab7 leads to the transformation of early endosome to the late compartment. Rab7 is involved in downstream endocytic pathway, required for cargo transfer from early endosome to late endosome as well as for the fusion between late endosome and lysosome. Cargo transfer from endosomes to the Golgi complex is also carried out by Rab proteins, such as Rab9. Reprint from Wikipedia, Created by Matthew R G Russell, license: CC BY-SA 3.0.

1.5 Question and hypothesis of the project

The main question of our project was how myelin molecules that are trapped within the numerous layers of tightly compacted membrane get access to the degradation system for myelin turnover. We hypothesized that myelin fragments which are formed by shedding myelin sheath in the extracellular space may be engulfed by microglia cell. Furthermore, we asked how the possible interaction of microglia with myelin affects the cell function with time. We hypothesized that overloading lysosomes with myelin components might induce senescence phenotype in microglia.

Chapter 2

Materials and Methods

2.1 Materials

2.1.1 Antibodies

Primary antibodies:

Table 2. 1 Primary antibodies list

Targen antigen	Host species	Clone	Dilution	Company
Iba1	Rabbit	-	1:1000	Wako
MBP	Mouse	SMI94	1:1000	Covance
MBP	Rabbit	-	1:500	Dako
Mac2 (Galectin 3)	Rat	M3/38	1:200	Biologend
MHCII	Rat	M5/114.15.2	1:200	eBioscience
LAMP1	Rat	1D48	1:200	Santa Cruz Biotechnology
CR3/Mac1/CD11b	Rat	-	1:200	Bio-Rad
Mac3	Rat	M3/84	1:200	BD Pharmingen
CD45	Rat	-	1:200	Bio-Rad
Fcγ RII/III/ CD16/32	Rat	2.4G2	1:200	BD Pharmingen

Secondary antibodies:

All biotinylated secondary antibodies (IgG) for DAB staining were purchased from Vector Laboratories. Fluorescence secondary antibodies including Alexa Fluor 488, 555, 647, Cy3 and Cy5 were purchased from Dianova and Invitrogen. Streptavidin-conjugated Alexa Fluor 488 was from Invitrogen. Anti-mouse and anti-rabbit horse radish peroxidase (HRP)-conjugated secondary antibodies used for Western blot were from Dianova.

2.1.2 Commercial kits

Table 2.2 List of commercial kits

Kit	Application	Company
Spin Tissue Midi Kit	DNA extraction for genotyping	Invitex
NucleoSpin RNA XS	total RNA isolation	Macherey-Nagel GmbH & Co.KG
Neural Tissue Dissociation Kits	Microglia isolation	Miltenyi Biotec

2.1.3 Primers

All the primers were synthesized by ACGT Lab, DNA core facility at Max Planck Institute for Experimental Medicine, they are listed as following:

Table 2.3 list of primers

Primer ID	Sequence	description
25174	5'-CAC GGG GGA GGC AGA GGG TTT-3'	Fwd for E2A Cre; Neo
25175	5'-GCG GAG CAC GGG CCA CAT TTC-3'	Rev for E2A Cre; Neo
26230	5'-AGATGACGTAGTTTTCGCGCTT-3'	Fwd for Ella promotor
17411	5'-TCCGGTTATTCAACTTGAC-3'	Rev for ParvCRE

2.1.5 Solutions and Media

In this study some solutions or media were commercially available, and some were manually prepared as described below:

Table 2.5 Commercial components and media

Media	Copmany
DMEM for Primary cell culture	Gibco/Invitrogen
Fetal Calf Serum (FCS)	PAA
GlutaMAX™-I supplement	Gibco/Invitrogen
Penicillin/Streptomycin (Pen/Strep) 100	Gibco/Invitrogen
Protease inhibitors cocktail	Sigma
1X PBS	Gibco/Invitrogen
1X HBSS	Gibco/Invitrogen
Power SYBR Green PCR master mix (2X)	Invitrogen
Trypsin	Invitrogen

10X PBS (phosphate buffered saline):

80 g NaCl

2 g KCl

18.05 g Na₂HPO₄ · 2H₂O

2.4 g KH₂PO₄

Dissolved in 1 L distilled H₂O. PH was adjusted to 7.4.

2.1.6 Mouse lines

The following mouse lines were used and analyzed in this study:

Table 2.6 List of mouse line

Strain name	source
Rab7 ^{flox/flox}	Aimee Edinger, Department of Cell & Developmental Biology University of California, Irvine
CX3CR1 ^{CreERT2}	Dr. Steffen Jung, Department of Immunology, Weizmann Institute of Science
tdTomato reporter	The Jackson Laboratory, Stock Number: 007905
Ella Cre (E2A Cre)	The Jackson Laboratory, Stock number: 003724
Shiverer	----
Rac1 ^{flox/flox}	The Jackson Laboratory, Stock number: 005550
Plp1-overexpressing transgenic mice	Klaus-Armin Nave, Department of Neurogenetics, Max Planck Institute of Experimental Medicine, Göttingen, Germany.
CX3CR1 ^{GFP/+}	Klaus-Armin Nave, Department of Neurogenetics, Max Planck Institute of Experimental Medicine, Göttingen, Germany.

2.2 Methods

2.2.1 Generation and characterization of conditional Rab7 KO mice

2.2.1.1 Generation and breeding of mutant mice

In order to block lysosomal degradation system in microglia, we took advantage of Cre-lox recombination system and the following strategy was performed. A mouse line carrying Rab7 allele flanked by loxP sites (Rab7^{flox/flox}, from Dr. Aimee Edinger, Department of Cell & Developmental Biology University of California, Irvine), and the mice carrying a tamoxifen inducible Cre recombinase (Cre-ERT2) in CX3CR1 locus (from Dr. Steffen Jung, Department of Immunology, Weizmann Institute of Science) were used. In the latter mouse line the expression of Cre recombinase is derived by CX3CR1 promoter which is specifically expressed in microglia. In these mice the Cre-ERT2 along with a loxP-flanked neomycin resistance cassette replaces CX3CR1 exon 2 (Fig 2.1). For details of targeting and deleted region in the CX3CR1 locus see (Jung, Aliberti *et al.* 2000). To remove the Neomycin resistance cassette from CX3CR1^{CreERT2-neo} locus through Cre-mediated excision, the mice carrying Cre ERT2-Neo were crossed to Ella-Cre (E2A Cre) mouse line which expresses Cre recombinase from

oozyte stage onwards, and in all cell types (Deleter-Cre) (The Jackson Laboratory, B6.FVB-Tg(Ella-cre) C5379Lmgd/J, Stock number: 003724). In the obtained chimeric mice ($CX3CR1^{+/CreERT2-neo}$; $Ella^{+/Cre}$), due to Cre recombination mediated by Ella-Cre, the floxed neomycin cassette was excised but not with 100% efficiency. Therefore, removal of neo cassette was confirmed by doing a PCR using following primer pair, 5'-CACGGGGGAGGCAGAGGGTTT-3'; 5'-GCG GAGCACGGGCCACATTTTC-3' which results in amplification of a 500 bp fragment indicative of $CX3CR1^{+/CreERT2}$ locus without neo cassette, and a 1800 bp product specific for $CX3CR1^{+/CreERT2}$ locus with neo cassette. To remove Ella-Cre locus from the chimeric mice with excised neo cassette, these mice were mated with C57BL/6J wild type mice. PCR reactions were done using two set of primers as follows: sense Ella promoter (P1): 5'-AGATGACGTAGTTTTGCGCTT-3'; antisense Cre (P2): 5'-TCCGTTATTCAACTTGAC-3', and P3: 5'-TATCTTCTATATCTTCAGGCGC-3'; P4: 5'-GTGAACGAACCTGGTCGAAATCAG-3'. The combination of P1 and P2 amplified a 387bp product specific for $Ella^{Cre}$ locus, and the mix of P3 and P4 produced a 223bp fragment for $CX3CR1^{CreERT2}$ locus. In this step, we got $CX3CR1^{+/CreERT2}$ mice.

To obtain double transgenic mice ($CX3CR1^{+/CreERT2}$; $Rab7^{floxed/floxed}$) two sets of breeding was arranged with $CX3CR1^{+/CreERT2}$ and $Rab7^{floxed/floxed}$ mice. For genotyping the offspring of these breeding sets two distinct PCR reactions using the combination of P3 and P4 and the following primer pair were done: wild type $Rab7$ allele: 5'-CTCACTCACTCCTAAATGG-3'; Floxed $Rab7$ allele: 5'-TTAGGCTGTATGTATGTGC-3'. PCR products amplified by the latter primer pair were a 550 bp band specific for wild-type $Rab7$ and a 580 bp band representing floxed $Rab7$ allele (2 Lox: floxed allele without the Neo cassette).

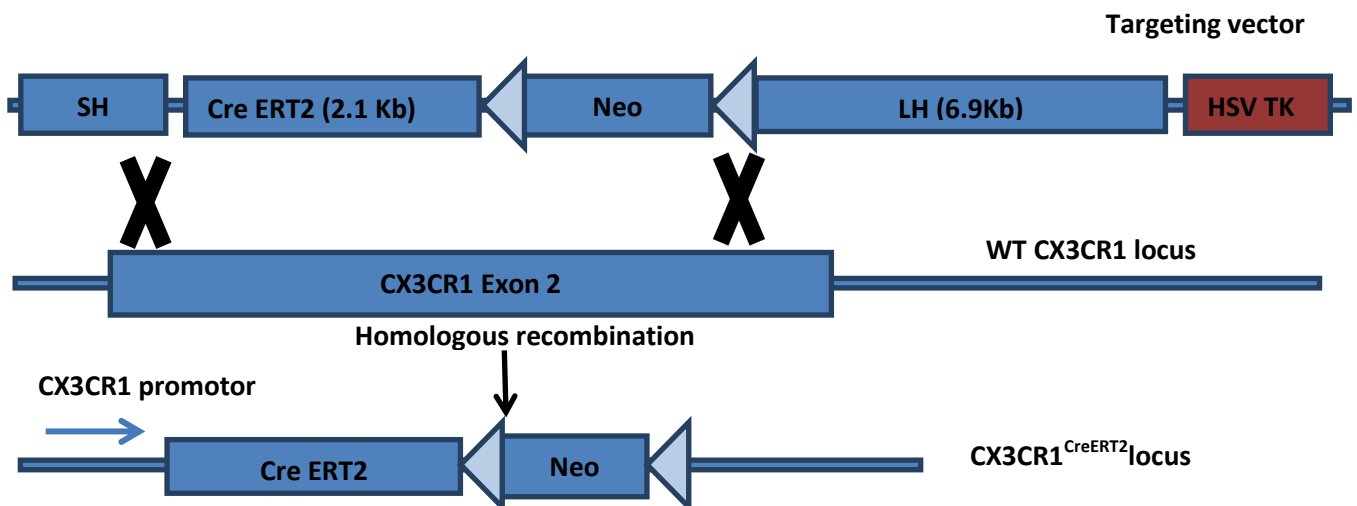

Figure 2.1 Targeted disruption of the CX3CR1 locus in mouse

2.2.1.2 Tamoxifen induction of conditional deletion of Rab7 gene

Double transgenic mice (CX3CR1^{+ / CreERT2} ; Rab7^{flox/flox}) were injected with tamoxifen at 3 weeks of age ,as described below, to induce conditional deletion of Rab7 in microglia of these mice and obtain conditional Rab7 knockout mice. Control mice of the same genotype received corn oil vehicle only.

Tamoxifen preparation and administration

The animal treatment with tamoxifen was approved in advance by the Lower Saxony state authorities (“Niedersächsisches Landesamt für Verbraucherschutz und Lebensmittelsicherheit”; Postfach 39 49; 26029 Oldenburg). The Approval ID is: 33.14.-42502-04-117/09. Tamoxifen (Sigma T5648) was freshly prepared the day before injection. It was dissolved in filter-sterilized corn oil to make solution of 10 mg/ml. The solution was protected from light, and placed on the roller mixer to be dissolved over night at 37°C. Tamoxifen was administrated via intraperitoneal injection once every 24 hours for a total of 5 consecutive days. The injection dose was determined by weight, using approximately 75mg tamoxifen/kg body weight. For adult mice, a standard dose of 100µl tamoxifen/corn oil solution was effective to induce cre recombinase activity.

2.2.1.3 Detection of Cre recombinase activity using reporter mice

To test the activity of Cre recombinase in microglia, CX3CR1^{+ / CreERT2} ; Rab7^{flox/flox} mice were crossed to reporter mice carrying tdTomato gene which is located downstream of a loxP-flanked STOP cassette. The offspring of this breeding, CX3CR1^{+ / CreERT2} ; Rab7^{flox/+} ; tdTomato⁺, was injected with Tamoxifen at 3 weeks of age as the same procedure described previously to drive the translocation of Cre recombinase to the nucleus, where it is able to delete the floxed STOP cassette, and result in tdTomato expression. One week after Tamoxifen injection the expression of tdTomato gene in microglia was confirmed by immunohistochemistry.

2.2.1.4 Cre recombinase-mediated deletion of Rab7 gene in microglia

To confirm deletion of Rab7 gene mediated by CX3CR1-driven expression of Cre recombinase, one and six weeks after Tamoxifen injection microglia cells from double transgenic mice (CX3CR1^{+ / CreERT2} ; Rab7^{flox/flox}) were isolated as will be explained in section 2.2.6.1. The total RNA was isolated from

cells; cDNA was synthesized, and Rab7 gene expression was quantified using real-time PCR as will be described later.

2.2.1.5 Genotyping

The genomic DNA was extracted from the lysate of a small piece of mouse tail using the Invitex Spin Tissue Kit according to the manufacturer's instruction. The DNA was eluted in 100µl elution buffer, and the concentration of DNA was defined by measuring the absorbance of double stranded DNA at 260nm with a BioPhotometer plus spectrophotometer (Eppendorf). 0.1-1µg of DNA was amplified by GoTaq DNA polymerase (Promega, Mannheim, Germany).

PCR master mix for a 25 µl reaction was prepared as following:

15.35µl milli Q H₂O

5µl 5X Taq buffer

0.5 µl dNTPs (10mM, stock)

0.5-1µl MgCl₂ (25mM, stock) (The final concentration depends on the primers)

1µl forward primer (10pmol/µl, stock)

1µl reverse primer (10pmol/µl, stock)

0.15µl Taq DNA Polymerase (5 units/µl)

1µl DNA (0.1-1 µg)

The PCR was performed using a T3000 Thermocycler Kombi (Biometra) as following:

Step	Temperature (°C)	Time	Number of cycles
Initial denature	94	3 minutes	1
Denature	94	45 Seconds	
Annealing	Depending on the primers	45 Seconds	30-35
Extension	72	1 minute	
Final extension	72	5 minutes	1

Agarose gel electrophoresis

1% Agarose gel in 1X TAE buffer containing 1X SYBR safe DNA gel stain (10000X, stock, Invitrogen) was prepared. Electrophoresis was done in the Chambers assembled by the Feinmechanik Service Department at the Max Planck Institute for Experimental Medicine containing 1 X TAE buffer. The PCR products were visualized by transillumination using Intas Gel Documentation System (Intas Science Imaging Instruments GmbH).

10X TAE (1 L):

48.4 g Tris base

11.4 mL Acetic acid

20.0 mL 0.5 M EDTA

Adjust to 1 L with ddH₂O, pH 8.5

2.2.1.6 Real-time quantitative PCR

RNA Isolation

Total RNA was extracted from isolated microglia using the Nucleospin RAN XS kit according to the manufacturer's instruction, the concentration was obtained by measuring the absorbance of RNA at 260nm using a BioPhotometer plus spectrophotometer (Eppendorf).

Reverse transcription

Reverse Transcription of RNA into cDNA was performed using SuperScript[®] III First-Strand Synthesis System. The RNA/Primer mixture is as following:

Component	Amount
0.2µg total RNA	n µl
50µM oligo (dT)	1µl
10mM dNTP mix	1µl
DEPC-treated water	To 10µl

Methods

The mixture was incubated at 65°C for 5 minutes then placed on ice at least for one minute. Meanwhile, cDNA Synthesis Mix was prepared as following:

Component	Amount
10X RT buffer	2 μ l
25mM MgCl ₂	4 μ l
0.1M DTT	2 μ l
RNaseOUT (40 U/ μ l)	1 μ l
SuperScript III RT (200U/ μ l)	1 μ l

Afterwards, 10 μ l of cDNA Synthesis Mix was added to RNA/Primer mixture, incubated at 50°C for 50 minutes, the reaction was terminated at 85°C for 5 minutes, chilled on ice. The residual RNA was digested by Ribonuclease H for 20 minutes at 37°C. cDNA was stored at -20°C for further use.

Real-time quantitative PCR

Expression levels of Rab7 in microglia isolated from adult mouse brain were measured by relative reverse transcriptase quantitative real-time PCR (RT-qPCR). The primers were designed with NCBI Primer Blast software. For each condition triplicates were used. The expression of the target gene was measured in relation to internal levels of GAPDH and 18srRNA as reference genes. The quantitative PCR was performed using SYBR Green PCR Master Mix according to manufacturer's protocols. The relative change in gene expression was analyzed by Δ Ct method, and normalized to the control samples.

Master mix composition:

Component	Amount
2X SYBR Green Master Mix	5 μ l
Primer-Forward (50pmol/ μ l)	0.2 μ l
Primer-Reverse (50pmol/ μ l)	0.2 μ l
Nuclease-free H ₂ O	1 μ l

2 | Materials and Methods

Following adding 4 microliter of cDNA (20ng), 6µl of master mix was added into the each well of 96-well plate. PCR was done in a light cycler 480.

2.2.2 Histology

2.2.2.1 Perfusion and tissue preparation

Animals were anesthetized by intraperitoneal injection of 14% chloral hydrate, perfused transcardially with 4% paraformaldehyde (PFA) using a MPII mini peristaltic pump (flow rate: 3ml/min). After perfusion, brain tissue was post fixed in 4% PFA overnight. Then the tissue was cryoprotected in 30% sucrose in 1x PBS until when the brain sank (at least one day). The tissue was bound to the specimen block using Tissue-Tek O.C.T, frozen on dry ice, and wrapped in pre-cold aluminum foil. Free floating cryosections (30µm thickness) were obtained in coronal direction using cryostat Leica CM 1900, placed in 48-well plates containing cryopreservative solution (25% ethylenglycol, and 25% glycerol in 1x PBS), and stored at -20°C.

2.2.2.2 Immunohistochemistry

The following antibodies were used for immunohistochemistry:

Primary antibodies: Iba1 (Ionized calcium binding adapter molecule 1) against ramified microglia, Mac2 (Galectin 3) and MHCII (major histocompatibility complex class II), Mac3, CD11b (Complement receptor 3 or Mac1), CD16/32 (Fcγ receptor II/III), CD45 for activated microglia, MBP (Myelin Basic Protein) against myelin, LAMP1 (lysosomal-associated membrane protein 1) for lysosomes (For more details see table 2.1).

Secondary antibodies: For DAB staining we used goat anti rat biotinylated immunoglobulin G (1:200) and for fluorescent staining Alexa Flour 488, 647, and 555-conjugated antibodies were used (1:1000).

Immunohistochemistry with Fluorescence detection

Free floating sections were rinsed with 1x PBS containing 0.2% Tween-20 in 24-well plate. Permeabilization was performed in 0,5% Triton X-100, the incubation time varied from 10 to 30 minutes depending on primary antibody. For blocking endogenous mouse tissue immunoglobulins, fab fragment goat anti mouse IgG (1:100) (dianova) was added for 1 hour at RT. The sections were washed briefly and incubated in 100% blocking solution (2.5% FCS, 2.5% BSA, 2.5% fish gelatin in 1x PBS) for 1 hour at RT. Primary antibodies, diluted in 10% blocking solution, were added and incubated overnight at 4°C. On the following day, after washing the sections with PBS 3 time each 10

minutes, they were incubated in secondary antibodies, diluted in 10% blocking solution, for 1 hour at RT. The sections were washed with PBS, distilled H₂O and mounted using fluorescence mounting medium (Dako) over superfrost plus slides.

Immunohistochemistry with HRP-DAB detection

3,3-diaminobenzidine (DAB) immunohistostaining was performed using VECTASTAIN® ABC Kit standard as following: Free floating cryosections were transferred to a 24-well plate, washed three times with PBS, each time 5 minutes on the shaker. Endogenous peroxidase was blocked with 3% H₂O₂, incubated for 20 minutes at 4°C, and washed out with PBS. Then 100% blocking solution (as before) was added to the sections, incubated for 20 minutes at room temperature (RT). The sections were incubated with primary antibodies, diluted in 10% blocking solution, overnight at 4°C. Afterwards, the sections were washed with PBS, incubated with biotinylated secondary antibodies for 1 hour at RT. After washing with PBS 3 times, each 10 minutes, AB solution containing 20µl reagent A (Avidin DH) and 20µl reagent B (Biotinylated Horseradish Peroxidase H) in 1x PBS was added to the sections and incubated for 30 minutes at RT. Following three washes, (each 5 minutes) staining was developed using 3,3'-diaminobenzidine (DAB) staining kit (Vectastain, Vector Laboratories). The incubation time varied depending on primary antibody. DAB reaction was stopped with distilled water for 5 minutes on the shaker. Then sections were washed with PBS, and placed on super frost plus microscope slides to let them dry for 2-3 days. The sections were rehydrated in decreasing concentrations of ethanol, and finally in water, stained with hematoxylin for 1 minute, and dehydrated using increasing percentages of alcohol, cleared in xylol (Chemie Vertrieb GmbH) and mounted with DePeX.

2.2.3 Lipofuscin autofluorescent reduction

2.2.3.1 Chemical treatment

To reduce lipofuscin autofluorescent in old brain tissues after immunohistochemistry, the sections were removed from PBS, dipped briefly in distilled water, and treated with 10mM CuSO₄ (Fisher Scientific; Pittsburgh, PA) in a buffer containing 50mM ammonium acetate and 100µM EDTA, pH 4.5 for 90 min on a shaker. The sections were washed briefly in distilled water, and transferred to PBS. (Schnell, Staines *et al.* 1999)

2.2.3.2 Dye separation

Autofluorescent of lipofuscin was a significant problem in fluorescent microscopy. Therefore, by means of dye separation tool on Leica SP5 Confocal microscope the autofluorescent was treated as another fluorophore so that it could be removed from the specific signal. An unstained sample as a reference was used then the emission spectrum of lipofuscin was determined using lambda scanning option on Leica SP5 confocal microscope. The obtained spectrum should be saved in spectra database.

To separate lipofuscin spectrum from a labeled sample (either with Alexa Flour 488 or 555) “spectral dye separation tool” was chosen, a region of interest (ROI) was manually drawn, the size of reference region was 10 in voxels. The measured emission spectrum which was displayed in a dialog box was added to spectra database; it was then available in the list under user. Afterwards, in the spectral dye separation dialog, lipofuscin spectrum was selected from the database, and by selecting “All channels” in “rescale box” all channels were rescaled together using the same factor, finally by applying all these factors the image was processed to get an image without crosstalk with lipofuscin spectrum.

2.2.4 Imaging

2.2.4.1 Confocal microscopy

In this study, laser scanning microscopy was used for image acquisition because confocal microscopy provides higher resolution images with less background than conventional light microscopy. Confocal microscopic images were taken using a Leica TCS SP5 AOBS confocal laser scanning setup (Leica Microsystems, Mannheim, Germany).

2.2.4.2 Electron microscopy

The mouse brain was fixed by transcardial perfusion using 4% paraformaldehyde and 2.5% glutaraldehyde in 0.1M phosphate buffer containing 0.5% NaCl. The brain was extracted, post fixed in the same fixative solution overnight. The tissue was sectioned into 200 micron thick vibrotome sections. Rostral and caudal regions of corpus callosum was cut and post-fixed in a solution of 1% osmium tetroxide in 0.1M phosphate buffer (pH 7.4) for 30 minutes at room temperature. Following washing with distilled water the sections were stained with 0.5% uranyl acetate in 70% ethanol for one hour, dehydrated in a serial dilution of ethanol, and cleared in propylene oxide and embedded in Epon, incubated at 60°C for 24 hours. The tissues in Epon blocks was then trimmed and reoriented so

that ultrathin (60nm) cross section of midline corpus callosum could be cut using ultramicrotome. Ultrathin sections were collected on collodion-coated copper grids. The sample area was selected at low magnification of 2500x.

2.2.4.3 In vivo time-lapse imaging

Mice were initially anesthetized by an intraperitoneal (i.p.) injection of a mixture of dorbene (Pfizer), ketamine (Medistar) in 0.9 % NaCl to achieve a dose of 1 mg/kg body weight for dorbene and 100 mg/kg for ketamine. The surgical plane of anesthesia was monitored by paw pinch reflex. Typically, half of the initial dose was injected i.p. every 60 min during imaging session according to the level of anesthesia. The eyes were protected from drying out with Bepanthen (Bayer). The hair of head was shaved with a small animal clipper (Pocket Pro, Wahl). Afterwards, Mice were placed on the custom-build microscope stage and the temperature was maintained at 36-37 °C using a built-in heating block (Telemeter Electronic GmbH, Donauwörth, Germany). Using a rectal temperature probe (Telemeter Electronic GmbH, Donauwörth, Germany) the body temperature was monitored during imaging process. To control the breath of animal, an oxygen stream with the controlled pressure was transferred to a mask which was positioned in front of the snout. The surgery got started with removing the skin on top of skull and cleaning skull so that it became free of hair and connective tissue and dry. Then a custom-built ring is fixed on the skull bone using Durelon™ Carboxylate Luting Cement (3M ESPE). Once the cement is completely dry and stably fixed in the setup, the bone in the center of the ring is thinned using a dental micromotor (FOREDOM® Electric Co.). The ring around the thinned area provides a waterproofed pool around the area of interest for imaging; the ring was filled with 0.9 % NaCl. To acquire the images, a Laser Scanning Microscope 710 from Carl Zeiss equipped with a 20x Plan-APOCHROMAT water immersion objective with a high numeric aperture (NA 0.95) was used. A modelocked Ti: sapphire Chameleon Vision II laser system from Coherent was adjusted to 880 nm wavelength. Excited fluorescence was detected with nondescanned detectors endowed with 525/45-nm and 624/40-nm band-pass filters (Semrock, Inc.). The live imaging was done for 15 minutes.

Image analysis: To quantify the dynamics of the cell process motility, time lapse movies were analyzed with Imaris software as following. A single process of the cells was segmented; a surface was created for the whole area and volume of the process. The surface with the same threshold was applied for the same process in the following images every 32 seconds. Using the surface, the area occupied by the process was measured automatically every recording period of 32 seconds. Two processes of 5 cells were analyzed. Finally, variance between the sizes of process area, which was obtained every 32 seconds, was calculated and compared between different groups.

2.2.5 Image processing and analysis

In this project all the Images were processed and analyzed with Imaris (64x version 7.7.1) and ImageJ 1.41 image processing software.

2.2.5.1 Cell counting

To estimate the number of Iba1 positive cells, confocal stacks (step size: 0.8 μ m) were captured in the z-direction from the whole region of interest with 20X or 40X objectives of a Leica TCS SP5 confocal microscope.

An area in the size of 1mm² in the region of interest was selected, the total number of Iba1 positive cell bodies and as well as the number of Iba1 positive cells with internalized components (such as FITC-Dextran or MBP or lipofuscin) were counted using cell counter plugin in ImageJ. In addition, to confirm the quantification performed by ImageJ, cell counting was done automatically using Imaris software. Briefly, a region of interest was segmented and spots layer was created (radius scale: 8) for each marker (Iba1 and FITC/MBP/LF) in the corresponding channel, using those spots the cells were counted automatically. The colocalized spots were defined in the distance of 0.2 μ m (threshold value).

2.2.5.2 Lipofuscin volume measurement

To measure the size of lipofuscin within microglia, the individual cells were analyzed using Imaris software as following. An area the size of 1mm² in cortical white matter as well as striatum was chosen and confocal z-stacks (step size: 0.8 μ m) were acquired with a Leica TCS SP5 confocal microscope (40x objective). A three dimensional image was generated In Imaris' Surpass view. Then the "surface" option in tool bar was selected, in the third channel (Far red), a region of interest including lipofuscin compartment within a single cell was segmented. The threshold was manually set in a way to carefully cover the whole volume of compartment in the cell by creating a surface. By pressing the end bottom in the software the volume of lipofuscin was automatically calculated, and could be exported as an excel sheet. Normally, 50 single cells were analyzed.

2.2.5.3 Microglia-myelin contact

Confocal z-stacks (step size: 0.8 μ m) were taken in striatum with 40X objective of a Leica TCS SP5 confocal microscope. Then a three dimensional image from the whole area was created using surpass view in Imaris software. To measure the surface area of each microglia cell in contact with myelin, first, a single cell, including cell body and all the processes in total focus, was segmentad then by choosing "spots" option in tool bar and adjusting the appropriate threshold, the whole cell was covered. Second, the whole area labeled with MBP against myelin around the cell of interest was

segmented; by activating the “Surface” item in tool bar a surface was created over that area. Total number of spots (representing cell process or cell body) and also number of close spots to the surface (representing myelin) was calculated using distance threshold 0.4. Finally, using these numbers the percentage of cell area in contact with myelin was calculated.

2.2.6 Isolation of lysosomal inclusions from microglia

Nukina and Ihara in 1985 described a protocol, based on ultracentrifugation and detergent (Sarkosyl) insolubility, to isolate protein aggregations such as tau paired helical filaments from Alzheimer’s disease brain as well as indigestible lysosomal inclusions such as lipofuscin accumulated in aged brain. Therefore, in this project, we used the same protocol to isolate the lysosomal inclusions from microglia cells in aged mice for biochemical analysis. To do that, first we isolated microglia from old mouse brain.

2.2.6.1 Microglia isolation

For optimal dissociation of tissue samples, brain tissue from 12-month-old C57Bl/6 wild type mice was dissociated using a Neural Tissue Dissociation Kit (Papain) (Miltenyi Biotec). Briefly, the mouse was perfused by cold 1x PBS, the brain was taken out and cut into small pieces then the tissue got dissociated using enzyme mix 1 containing papain for 15 minutes at 37°C, and enzyme mix 2 for 10 minutes at 37°C. Afterwards, the tissue was dissociated mechanically by wide and narrow-tipped pipettes until no tissue pieces remained. The suspension was applied to a 40µm cell strainer, and washed twice with Hank’s balanced salt solution (HBSS). To remove myelin, the tissue pellet was resuspended in 37% Percoll (Sigma) and overlaid on 70% Percoll in DMEM containing 2% FCS (Fetal Calf Serum), centrifuged at 500g for 30 minutes with no break. A thick myelin fraction which was formed over 37% percoll gradient was totally removed using vacume pump. A Thin fraction, containing single cell suspension, in the interface between 37% and 70% percoll was then carefully taken out and washed with the medium and MACS rinsing solution (0.5% BSA and 2mM EDTA in PBS 1X). Microglia were then isolated from that single-cell suspension by MACS® Technology. The suspension was incubated with CD11b (Microglia) MicroBeads (Miltenyi Biotec) at 4°C for 15 minutes, after washing with MACS rinsing solution, the pellet was resuspended in 500µl of the same buffer, applied on a MACS column placed in the magnetic field, following three times wash with 500µl MACS buffer, CD11b positive cells (microglia) were then flushed out of the column, centrifuged at 400 x g for 8 minutes at 4°C. The pellet was resuspended in 1ml 1x PBS and washed one more time. The final pellet was flash frozen in liquid nitrogen, and stored at -80°C for future use.

2.2.6.2 Sarkosyl-insoluble fractionation of microglia

The final pellet containing 1.5×10^6 isolated microglia cells of 12-month-old mice was resuspended in PBS, and divided into two portions. One part, called cell lysate, was prepared to be used directly for western blotting later. The other part was used for Sarkosyl-insoluble fractionation, resuspended in 300 μ l 10% sarkosyl and 1 μ l of 10 μ g/ml β -mercaptoethanol and incubated at 4°C for 4 hours on a roller. Afterwards, to separate Sarkosyl-insoluble fraction of the cells, the solution was transferred in Beckman 1.5ml tubes, and centrifuged at 130000 x g for 35 min at 4°C. The pellet was resuspended in 1ml cold 1x TBS (50mM Tris pH 7.6, 150mM NaCl) and, centrifuged again at 130000 x g for 35 min at 4°C. The resulting pellet was washed one more time in cold 1x TBS. the supernatants was removed carefully and the final pellet (Sarkosyl-insoluble fraction, SIF) was flash frozen and stored at -80°C for further use.

To examine the solubility of myelin membrane in Sarkosyl, the same experiment was done with 1.5 μ g pure myelin membrane isolated from 2 months old wild type mice as following.

2.2.6.3 Myelin isolation and purification

The myelin from 8-week-old C57BL/6 mice brains was isolated by sequential centrifugation on discontinuous sucrose gradient according to a protocol previously described (Norton and Poduslo, 1973) with some modifications. The ultracentrifugation was done using SW41 Ti rotor. The brain tissues were homogenized with a Dounce homogenizer in a solution containing 10mM HEPES, 5mM EDTA, 0,3M sucrose, and protease inhibitor. The homogenized tissue was layered on a sucrose gradient composed of 0,32M and 0,85M sucrose prepared in 10mM HEPES, 5mM EDTA. (pH 7,4), centrifuged at 75000g for 30 minutes with low deceleration and acceleration. The crude myelin fraction was removed from interface, resuspended in distilled water, and centrifuged at 75000g for 15 minutes. The pellet was subjected to two rounds of hypo-osmotic shock by resuspension in 10ml ice-cold water, centrifuged at 12000g for 10 minutes. For purification of myelin, the pellet obtained from the last step was dissolved in HEPE/EDTA buffer, and placed over the sucrose gradient; all the centrifugation steps and hypo-osmotic shocks were repeated as before. Eventually, the purified myelin pellet was resuspended in 1ml HEPE/EDTA buffer and stored at -20°C.

2.2.6.4 Western blotting

SDS-PAGE

To detect proteins in isolated sarkosyl-insoluble fraction (lipofuscin), sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) was performed as described previously. (Burnette,1981; Laemmli, 1970Natalia thesis). 12% two-layer gel was prepared with Bio-Rad Mini-PROTEAN 3 casting system as following:

Stacking gel (10 ml)

Component	Amount
30 % Acrylamide/bis-acrylamide	1.3ml
0.5M Tris-HCl pH 6.8	2.5ml
10% SDS	0.1ml
10% ammonium persulfate (APS)	0.05ml
N'N'N'-tetramethylethylene diamine (TEMED)	0.005ml

Resolving gel (12 %) (10ml)

Component	Amount
30 % Acrylamide/bis-acrylamide	4ml
1.5M Tris-HCl pH 8.8	2.5ml
10% SDS	0.1ml
10% ammonium persulfate (APS)	0.05ml
N'N'N'-tetramethylethylene diamine (TEMED)	0.005ml

The resolving gel was poured to 2/3 height of casting system, the remaining part of system was filled with isopropanol to ensure a horizontal interface. After polymerization, isopropanol was removed, the stacking gel was added and a comb was adjusted.

The equal volume of all protein samples were dissolved in protein sample buffer (see below) and boiled at 90°C for 5 min to denature proteins.

2 | Materials and Methods

Protein sample buffer 6X:

SDS	1.2g
Bromophenol blue	6mg
Glycerol	4.7 ml
Tris 0.5M pH 6.8	1.2ml
DTT	0.93g
ddH ₂ O	2.1ml

The gel cassette was adjusted into a clamping frame, placed in the tank filled with PAGE buffer (see below). 15µl of sample was loaded onto the gel and the electrophoresis was performed with 100 voltages.

PAGE buffer

0.25 M Tris base

1.92 M Glycine

1 % SDS

Western Blot

After electrophoresis, western blot was performed to detect MBP in the cell lysate, Sarkosyl-insoluble fraction of microglia cells and pure myelin membrane using a polyclonal MBP antibody. After separation with SDS-PAGE, the proteins were transferred from the gel onto the nitrocellulose membrane using the mini Trans-Blot Module. The gel sandwich in blotting cassette was set up and placed in the tank of the module containing transfer buffer (0.25 M Tris base, 1.92 M glycine, 20 % methanol) and applied with 100 V for 1 hr.

Afterwards, the membrane was washed in PBST (0.1 % Tween 20 in PBS) for 10 min, immersed in 4 % skim milk powder in PBST as a blocking solution for 30 min at RT and then incubated with primary antibody in PBST at 4°C overnight. After washing the membrane 3 times, each 10 min, with PBST, it was incubated with horse radish peroxidase (HRP)-conjugated secondary antibody in PBST for one hour at RT. Then targeted protein was detected with enhanced chemiluminescence method using equal volumes of Luminol enhancer and peroxide solutions (Pierce/Thermo Scientific) covering the membrane at dark. The light emission was detected with X-ray films, which were scanned with a conventional scanner.

2.2.7 In vivo endocytosis assay

Mice were anesthetized intraperitoneally with a solution (0.15ml/25g) containing 4% Rompun™ 2% (xylazine) (Bayer DVM for veterinary professionals) and 12.5% ketamine 10% (Medistar) in 0.9% NaCl, placed into stereotaxic apparatus (Kopf Instruments), and 1.5µg FITC-conjugated Dextran (40kDa; Molecular probes, Eugene, OR, USA) in sterile PBS 1x was injected by a glass capillary microinjector at the following coordinates relative to bregma: 0.3mm anterior, 1.2 mm lateral and 1.2 mm below cortical surface. 7 hours after injection the mice were perfused and the brain tissues were prepared and stained as described before.

2.2.8 Cuprizone treatment

Six weeks after tamoxifen injection, Rab7 conditional knockout mice as well as corresponding control mice were treated with 0.2% cuprizone for four weeks to complete demyelination course in the central nervous system, following that the animals received normal diet for another four weeks to induce remyelination. Some groups were fed with the normal food 5, 11, 19, and 33 weeks after completed remyelination (recovery). Age-matched controls received normal diet without cuprizone throughout the whole experiment.

2.2.9 Ethics Statement

All experiments were approved and conducted in accordance with animal protection laws approved by the Government of Lower Saxony, Germany. The Approval ID is 33.7-42502-04-12/0778. C57BL/6 mice were used for all experiments. They were kept in groups of three in standard plastic cages and maintained in a temperature-controlled environment ($21 \pm 2^\circ\text{C}$) on a 12-h light/dark cycle with food and water available ad libitum.

2.2.10 Statistics

Statistical analysis was done using GraphPad Prism (GraphPad Software, Inc.). To compare two groups, a Student's *t*-test was used. One-way ANOVA was performed for comparison of more than two groups. A *p* value of <0.05 was considered significant in all the tests. All values are represented as mean \pm SD.

chapter 3

Results

In this study we tested the possibility that microglia are involved in normal turnover of myelin during aging.

3.1 Myelin breakdown during normal aging

The brain tissues from 7 and 18 months old mice were prepared for electron microscopy as previously described. Myelin fragments were detected in extracellular space and also inside the cells in the white matter including corpus callosum and cortical white matter. Quantification of the number of extracellular myelin fragments in different age groups showed a significant increase with time.

Figure 3.1 Myelin fragments during normal aging in wild type mice. A) Electron microscopy images from an 18-month-old mouse showing myelin fragments in different positions: **(a)** in the extracellular space, **(b)** inside the cell, **(c)** a myelin fragment tearing away from the axon **(d)** a myelin fragment being engulfed by a cell, and. Scale bar: 2000nm. **B)** Quantification of myelin fragments number in 7 and 18 months old wild type mice. There is an increase with time. Mean value+SD were indicated. ** $p < 0.05$. Student's t-test.

3.2 Microglia are involved in myelin turnover in normal aging

3.2.1 Microglia are in contact with myelin in wild type mice

To visualize microglia and compact myelin in the parenchyma, we used Iba1 and MBP antibodies, respectively, the brain slices of wild type mice at 2, 4, 9, 18, and 24 months of age were used for histological studies to assess the contact of microglia with myelin. Confocal imaging of 18 and 24 months old mice showed that microglia form contact with myelin fragments via their processes.

3.2 Microglia are involved in myelin turnover in normal aging

In addition, we quantified the size of microglia-myelin contact by measuring the cell surface area in contact with myelin using Imaris software as previously described. The size of contact was quantified mainly in striatum where the processes of microglia were more in focus due to less compaction of myelin compared to corpus callosum. The results showed that with age the size of cell area in contact with myelin significantly increased. (Fig. 3.2)

Figure 3.2 Microglia are in contact with myelin in normal aging. Microglial and compact myelin in the striatum of 2, 4, 9, 18, and 24 months mice were labeled using Iba1 (red) and MBP (green) antibodies; confocal images were captured by acquiring Z-stacks. **A)** Confocal image from striatum in 18 months old wild type mice, Scale bar: 30 μ m. **a-c)** the myelin fragments (Labeled with MBP in green) in myelinated areas are detected in close contact with the processes of microglia (Labeled with Iba1 in red). **(d)** and **(e)** 3D reconstruction of a microglia cell in contact with a myelin fragment. Scale bar: 2 μ m. **(C)** Quantification of contact size of microglia with myelin is shown as mean + SEM (n=4). The bigger contact size was detected in 9 months of age in wild type mice. Statistically significant differences are indicated by asterisks (***)p<0.0001). There is no significant difference (n.s) in the contact size between 9 and 18 months old mice (p=0.6).

3.2.2 Myelin fragments are engulfed by microglia

Using immunohistochemistry myelin fragments labeled with MBP were detected at 18 and 24 months of age of wild type mice. These fragments which were mainly observed in cortical white matter and striatum but less in the corpus callosum were found within microglia at the age of 18 and 24 months. (Fig. 3.3)

Figure 3.3 Engulfment of myelin fragments by microglia in normal aging. **A)** Confocal image of the striatum of a 24-month-old mouse. Scale bar: 30 μ m. **(a-e)** A microglia cell with internalized myelin fragment. **(d)** 3D reconstruction showing the myelin fragment inside the cell. Scale bar: 2 μ m. **(e)** 3D reconstruction of the same cell in a rotated position. Scale bar: 1 μ m. **C)** Quantification of the number of cells with internalized myelin fragment. n=3, Mean+SD was reported, *p<0.05. Student's t-test.

3.2.3 Density and lysosomal activity of microglia cells increase in the white matter

Regarding the regional difference in microglia phenotype in the central nervous system in adult mouse (Hart, Wyttenbach *et al.* 2012), we focused on changes in microglia phenotype in white matter in normal aging. We considered the size of lysosomes as an indication of lysosomal activity in microglia. The brain tissues from 2, 4, 7, 9, and 24 months old wild type mice were co-labeled by Iba1 and LAMP1 antibodies; a series of z-stack confocal images within 30 μ m volume of brain slice was acquired and the volume of lysosomes were measured with Imaris software. Enlarged lysosomes were detected in microglia from 7 months of age whereas in 2 and 4 months old mice there was almost no LAMP1 positive microglia. (Fig. 3.4 A and B). Furthermore, variation in size of lysosomes in white matter versus gray matter was analyzed by measuring the volume of lysosomes within microglia in 7, 9, and 24 months old animals. In all groups there was a significant increase in the size of lysosomes in the white matter in comparison to gray matter (Fig. 3.4 C). These results are consistent with previous work that has shown an increase in the number of ED1 positive microglia in corpus callosum with age (Hua, Schindler *et al.* 2012).

We labeled microglia cells with Iba1 using DAB staining in wild type mice at the age of 2, 9, 18, and 24 months old and counted the cells exclusively in corpus callosum (size of area=0.3mm²) of 5 animals in each group. The number of Iba1 positive cells in corpus callosum was significantly higher in

3.2 Microglia are involved in myelin turnover in normal aging

18 and 24-month-old mice compare to 2 and 9 months old (Fig 3.4.D) as shown previously (Mouton, Long *et al.* 2002; Hua, Schindler *et al.* 2012; Poliani, Wang *et al.* 2015)

Figure 3.4 Density and lysosomal size of microglia cells increase in white matter **A)** Visualization of LAMP1 (red) positive microglia (Iba1, green) in wild type mice. Lysosomes are not detectable within microglia in 4 months old mice. Lysosomes are observed in microglia at 7, 9, and 24 months of age. Scale bars: 20µm (overview) and 7µm (zoom in). **B)** Quantification of the number of lysosome positive cells at different age of wild type mice. **C)** Quantification of lysosome size in white matter versus gray matter. The size of lysosomes which were labeled by LAMP1 antibody was quantified by measuring the volume using Imaris software. In 7, 9, and 24 months old wild type mice the volume of lysosomes in white matter compared to gray matter was significantly larger. **D)** Quantification of cell number in corpus callosum of young, middle aged and aged wild type mice showed a significant increase in the number of cells with age. The statistics were done by t-test and one-way ANOVA. *p < 0.05, **p < 0.01, ***p < 0.001. Mean values plus SD were indicated.

3.2.4 Phagocytic activity of microglia in white matter of wild type mice

We analyzed the expression level of galectin 3/Mac2, a galactose binding lectin, which is known to be upregulated in demyelination areas and involved in myelin phagocytosis (Smith 1999; Smith 2001). Mac2 antibody was used in DAB staining for labeling microglia in the stage of phagocytic activity on the brain tissues of 2, 4, 7, 9, 18, and 24 months of age. Surprisingly, Mac2 positive microglia were detected only in aged (18 and 24 months old) mice but not in earlier time points. In addition, in these mice Mac2 positive populations were found mainly in myelinated areas including corpus callosum, anterior commissure, and medial septal nucleus (Fig. 3.5).

Figure 3.5 Detection of galectin 3/Mac2 positive microglial population during normal aging in wild type mice. Histological analysis of brain tissue of 24-month-old wild type mice using DAB staining showing a particular subtype of microglia which are galectin 3/ Mac2 positive and located in myelinated area including corpus callosum (**a**), anterior commissure (**b**) and medial septal nucleus (**c**). These cells were not detected in young and middle aged mice. Scale bars: 500 μ m (overview); 50 μ m (zoom in).

3.3 Cellular phenotypic alterations of microglia with age

An increasing number of studies have shown that with age the functionality of microglia is impaired. Some changes in morphology and phenotype of microglia are listed in table 3.1 (Luo, Ding et al. 2010; Damani, Zhao et al. 2011; Hart, Wyttenbach et al. 2012; Harry 2013; Wong 2013). In this project we studied microglial characteristics in young (2 months old) and aged (18 or 24 months old) wild type mice to test whether myelin uptake by microglia during normal aging drives age-related alterations in the cells.

Table 3. 1 characteristics of aged microglia

Intracellular accumulation of lipofuscin
retracted processes with less branches
Increased activation state
Decreased clearance function
Decrease in motility of processes

3.3.1 lipofuscin granules accumulate within aged microglia

Intracellular lipofuscin accumulation is a hallmark of microglia aging in the retina as well as brain, and studies on retina have shown that the amount of lipofuscin in RPE cells increases with age (Sierra, Gottfried-Blackmore *et al.* 2007; Tremblay, Zettel *et al.* 2012; Wong 2013). In our project we visualized and quantified the amount of lipofuscin within microglia in wild type mice. Images from 30 micron brain slices, labeled with Iba1 using immunohistochemistry, were captured. To visualize lipofuscin we took advantage of autofluorescent feature of lipofuscin. Regarding the broad range of excitation and emission spectra for lipofuscin (excitation: 436-650, emission 450-700nm)(Barden 1980; Dowson 1982; Dowson, Armstrong *et al.* 1982; Sparrow and Duncker 2014), we found that when the brain tissue was excited at 633nm the strongest autofluorescent signals from internalized lipofuscin was generated so that we could capture the images in far red channel (emission wavelength: 650-750nm) and used them for all the analysis. We measured the volume of lipofuscin within microglia using Imaris software. The quantification showed a significant increase in the quantity of lipofuscin with time.

Figure 3.6 visualization and quantification of lipofuscin granules in wild type mouse brain. A) Confocal images from wild type brain tissue shows intracellular lipofuscin (gray) in microglia (red) in 18 months old wild type mouse. Autofluorescent signal from lipofuscin was captured by excitation at 633nm in far red channel. Scale bar: 20μm **B)** Quantification of lipofuscin volume in 2, 9, and 24 months old mice indicates an age-related increase in the amount of lipofuscin. ***P<0.001, one-way ANOVA.

3.3.1.1 The amount of lipofuscin in white and gray matter in aged wild type mice

To test whether intracellular lipofuscin might contain remnants of internalized myelin membrane, we compared the amount of lipofuscin in white matter versus gray matter in 9, 18 and 24 months old wild type mice. Confocal z-stack images in white matter including striatum, corpus callosum and cortical white matter and in cortical gray matter including layer I and II were captured. Then the volume of intracellular lipofuscin in 40 single microglia in both regions was quantified using Imaris software. Three mice were evaluated per age group. In the mice of each group, the size of lipofuscin in white matter was larger as compared to gray matter.

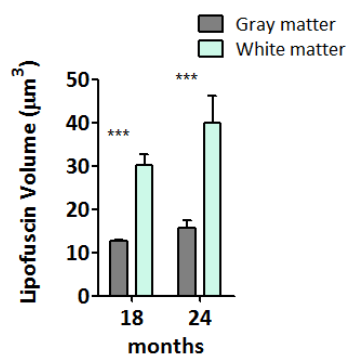

Figure 3.7 Lipofuscin amount in white and gray matter in aged wild type mice. Quantification of lipofuscin amount in white matter versus gray matter indicates a significant increase of lipofuscin in white matter in aged mice. Mean value+SD was reported, ***p<0,001, Student t-test.

3.3.1.2 Detection of myelin fragments within lipofuscin

Given that myelin is engulfed by microglia during normal aging, and that lipofuscin accumulates within microglia with age, we hypothesized that lipofuscin might contain remnants of myelin with time. To test this, brain tissues from 18 months old mice were labeled with Iba1 and MBP. To visualize myelin overlapping with lipofuscin in separated channels we needed to remove autofluorescent signal produced by lipofuscin in green channel where MBP was captured. Therefore, we did dye separation using Leica software as previously described so that lipofuscin signal was exclusively captured in the far red channel. However, due to broad range of emission spectrum of lipofuscin we were not able to eliminate autofluorescent signal of lipofuscin from the red channel (Em: 570-630nm). Therefore, we used this channel for detection of Iba1 signal. Using this strategy we could detect myelin fragments (in green Channel) associated with lipofuscin (in far red channel) within microglia. The volume which was labeled with MBP overlapped with the volume occupied by lipofuscin in the cell. (Fig 3.8 A) We also labeled myelin with green Fluoromyelin (FM) and applied the same strategy as above. 3D reconstruction showed that internalized myelin fragments labeled with FM is partially included in intracellular lipofuscin (Fig 3.8 B). We also quantified the number of cells

3.3 Cellular phenotypic alterations of microglia with age

with internalized myelin within lipofuscin in 18 and 24 months old mice, and found out that the association between myelin and lipofuscin increases with time (Fig 3.8 C).

Figure 3.8 myelin fragments in the cells are associated with intracellular lipofuscin. A) co-labeling of myelin and lipofuscin using MBP antibody (green) and separated autofluorescent signal (Far red) in 18 months old shows overlapping between internalized myelin fragment and intracellular lipofuscin. Scale bar: 2 μ m. **B)** 3D reconstruction of myelin fragments labeled with fluoromyelin and intracellular lipofuscin in 24 months old mouse confirms the association of myelin and lipofuscin. Scale bar: 2 μ m. **C)** Quantification of the number of microglia cells with internalized myelin included within lipofuscin representing an increase with time. * $p < 0,05$. Mean value+SD.

3.3.1.3 Biochemical characterization of lipofuscin contents

To analyze myelin membrane remnants in lipofuscin we isolated and analyzed their content biochemically by Western blotting. For this, we isolated microglia from 12 months old mice (pooled from 8 mice) using neural tissue dissociation kit and MACS technology. The obtained pellet of the pure microglia cells at this stage was divided into two parts. One part used directly for Western blotting to define the amount of intracellular myelin. The other part was incubated in 300 μ l 10% Sarkosyl for four hours at 4 $^{\circ}$ C to separate Sarkosyl-insoluble fraction (SIF). After ultracentrifugation, the final pellet was used for Western blotting to detect modified aggregated MBP in sarkosyl-insoluble fraction of cell lysates. We isolated purified myelin membrane from wild type mice, and extracted it with Sarkosyl to isolate Sarkosyl-insoluble pellet and use for western blotting.

3 | Results

An aggregation of a high-molecular weight (70kDa) fraction of MBP was found in cell lysate. After extraction in Sarkosyl the same fraction of MBP was recovered indicating that internalized MBP forms detergent-insoluble aggregates in microglia. In sarkosyl-insoluble fraction of pure myelin membrane no MBP was detected indicating that MBP is soluble in sarkosyl.(Fig 3.9).

Figure 3.9 Characterization of sarkosyl-insoluble fraction of isolated microglia. Left, Western blot analysis of purified microglia lysates from 12 months old mice shows MBP in the high-molecular weight region; MBP in myelin is shown as a reference in the right lane. Middle, high-molecular weight species of MBP existed in the Sarkosyl-insoluble (SIF) microglia membrane fraction (12 months old mice, 1 out of 5 representative experiments); MBP in myelin is shown as a reference in the right lane. Right, Sarkosyl extraction on purified myelin shows that myelin-associated MBP is Sarkosyl-soluble (Sarkosyl-soluble membrane fraction, SF).

3.3.2 Age-related changes in microglia shape

Iba1 antibody was used to visualize microglia cells in the mouse brain by immunohistochemistry in 30 μ m thick sections. To obtain the whole volume of an individual cell, 40 image stacks were acquired in z direction using confocal microscopy. Images were captured in different regions including corpus callosum, cortical white matter and gray matter. To assess the complexity and length of dendritic arbors of microglia the total area occupied by a single cell was measured by Imaris software as described before. The quantification was done in different region of brain for 40 cells per each mouse. The results showed that microglia in aged wild type mice (15 months old) have significantly smaller cell area than young mice (2 months old). Furthermore, all the cells with less branched processes contain large amount of lipofuscin (Fig 3.10).

3.3 Cellular phenotypic alterations of microglia with age

Figure 3.10 Aged microglia have less branched and shorter processes. A) The confocal images are showing a comparison between dendritic arborization of microglia in aged (24 months old) and young (2 months old) wild type mice. Whereas cell processes are much more branched and longer in 2 months old mice, they are less complex and more retracted in aged microglia. Scale bar: 50 μm . The images show that large lipofuscin granules are detected exclusively in the cells with less branched processes (a and b). **B)** cell area quantification showed a decrease in the size of cell area of microglia in 15 months old compared to 2 months old mice (n=5). Mean values+SEM were indicated; Student's t-test. ***P<0.001.

3.3.3 Less motility of microglia processes in aging brain related to lipofuscin accumulation

It has been shown that microglia processes are less motile in aged brain, (Damani, Zhao *et al.* 2011; Wong 2013) and this may be related to shorter and less branched processes of these cells. We tested whether there is a correlation between accumulation of lipofuscin within microglia and the motility of their branches. To examine this, live imaging of green fluorescent-labeled microglia in CX3CR1^{GFP/+} young (3 months old) and aged (24 months old) mice was done to compare process motility of lipofuscin positive microglia versus cells with no lipofuscin in young mice. In two dimensional maximum-intensity projections of time-lapse recordings for 15 minutes the area occupied by a process was measured every recording period of 32. Variance between the size of process area calculated every 32 seconds in 2 months old mice was 70028,72 while the variance for 24 months old mice was 26839,47. These numbers indicated that the branches of young microglia cells with almost no lipofuscin were more dynamic compared to microglia in old mice which accumulates lipofuscin (blue arrow (Fig 3.11). The calculation was done for 2 processes in 5 cells from each mouse.

Figure 3.11 Dynamics of the motility of microglia processes in old and young mice regarding lipofuscin accumulation. Two dimensional maximum-intensity projections of time-lapse recordings from Green microglia in CX3CR1^{GFP/+} mice for 15 minutes were achieved. 3D Reconstitution of a process of microglia cell showing the variation in area occupied by the process in 3 month and 24 months old mice. The variation was considered every 128 seconds during recording period of 15 minutes. The process of microglia in young mouse shows a higher movement dynamics compared to that in old microglia containing a large amount of lipofuscin (blue arrow). Scale bar, 10µm (overview, 3 months old) and 5µm (overview, 24 months old, and zoom in).

3.3.4 Age-related changes in activation state of microglia

The changes in the basal activation state of aged microglia is shown in previous studies (Rogers, Lubert-Narod *et al.* 1988; Sheng, Mrak *et al.* 1998; Frank, Barrientos *et al.* 2006; Miller and Streit 2007; Wong 2013). Our histological studies showed MHCII positive cells were found in aged mice (18-24 month old) (Fig 3.12). In addition, we found an upregulation of Mac2 (Galectin 3) in aged mouse brain which was mainly restricted to the white matter. While there was no up-regulation of Mac3 during normal aging, the expression of Fcγ receptor II/III (CD16/CD32) and complement receptor 3 (Mac1) was detectable during normal aging, and there was no significant difference in the level of their expression among different age groups. Previous *ex vivo* and *in vitro* studies of aged microglia showed an increased expression of inflammatory cytokines including IL-1β, TNF-α, and IL-6 (Ye and Johnson 1999; Sierra, Gottfried-Blackmore *et al.* 2007; Njie, Boelen *et al.* 2012). However, by performing quantitative PCR for isolated microglia none of these cytokines was detected in aged mice. The reason for our negative finding could be that the expression of these cytokines in physiological condition is so low that cannot be detected *in vivo*.

3.3 Cellular phenotypic alterations of microglia with age

Figure 3.12 Analysis of the activation state of microglia in normal aging. DAB staining was done for brain sections of wild type mouse at the age of 2, 4, 7, 9, 18 and 24 months. Histological studies showed a small population of MHCII positive cells only in aged mouse brain (18-24 months old). The distribution of those cells is not restricted to a certain region of brain, they are found all over the brain. Scale bar: 50µm. CWM: Cortical White Matter, CC: Corpus Callosum, St: Striatum

3.3.5 Clearance function of microglia in aging

We hypothesized that due to age-related accumulation of lipofuscin in aged microglia, clearance function of cells may decline. Therefore, we injected FITC-conjugated Dextran into the brain of wild type mice at the age of 2 and 10 months old. There was a 20% reduction in the number of cells with internalized dextran in middle aged (10 months old) compared to young (2 months old) mice. (Fig 3.13).

Figure 3.13 Clearance function of microglia in normal aging. **A)** Quantification of Dextran positive (Dex+) cell number in 2 and 10 months old wild type mice. 1.5µg FITC-conjugated Dextran was injected in the cortex of brain (n=4) and 7 hours after injection, the mice were analyzed. Number of dextran positive cells in middle aged mice was 20% less than that in young animal. Mean value+SD was indicated. **B)** Confocal image of Dextran injection site in the cortex of brain in 10-month-old mouse showing that Iba1 (red)/lipofuscin (gray) positive cells engulfed Dextran (green). Scale bar: 30 µm (overview) and 5µm (zoom in).

3.4 Enhanced myelin breakdown in demyelinating models and microglia behavior

We speculated that increased myelin breakdown might induce aging-related changes in microglia. Therefore, we used three mouse models of demyelination, PLP overexpressing mice (a model for Pelizaeus-Merzbacher disease, (PMD mice), Cuprizone-induced demyelinating mice, and shiverer mice. In these mice, we analyzed three hallmarks of aging in microglia, lipofuscin formation, activation state, and uptake activity.

3.4.1 Myelin in PMD mice and cuprizone model

We analyzed PMD mice at the age of 2, 7, and 10 months old. These mice rarely survive beyond 10 months of age. Figure 3.14 A shows the rate of demyelination during this time. At the age of 2 months demyelination was not severe; compact myelin was detectable by MBP especially in corpus callosum. However, at later time points (7 and 10 months old) the level of demyelination increased showing myelin breakdown in the white matter.

In addition, we induced demyelination in wild type mice by Cuprizone treatment. In these mice demyelination was detectable mainly in corpus callosum 4 weeks after cuprizone treatment, and following 4 weeks of normal diet remyelination was induced. To distinguish between de and remyelination phase in cuprizone mice we used Fluoromyelin as shown in figure 3.14 B.

Figure 3. 14 An overview of demyelination rate in PMD and cuprizone mice. A) Myelin was labeled with MBP. 2-month-old PMD mice showed normal myelination while in 7 and 10 months old animals, compact myelin could not be completely detectable. Scale bar: 30 μ m. **B)** de- and remyelination phases in cuprizone mouse. The compact myelin was labeled with Fluoromyelin. During demyelination the loss of myelin was detectable mainly in corpus callosum following 4 weeks of cuprizone diet. Completed remyelination was observed 4 weeks after feeding the mice with normal food. Scale bar: 300 μ m.

3.4.2 Microglia in PMD mice and cuprizone model

3.4.2.1 Morphology and activation state

PMD mice

In PMD mice microglia accumulation was observed in corpus callosum and striatum where myelin breakdown was severe. Myelin fragments were detected within microglia with very short and retracted processes (Fig 3.15 A). In addition, DAB staining showed that all the cells were totally activated with high expression of Mac2 and MHCII. Compared to 2 month old mice, the population of activated cells in 7 and 10 months old was bigger (Fig 3.15 B).

Figure 3.15 Morphology and activation state of microglia in PMD mice. A) Confocal images of brain tissues of PMD mice at the age of 10 months old showing myelin phagocytosis by microglia (Iba1, red) with highly retracted branches in areas with myelin breakdown (striatum). Scale bar: 30 μ m (overview) and 5 μ m (zoom in). Quantification of the number of microglia engulfing myelin fragments in PMD mice. Student' t-test, n.s: P=0.2865, One-way ANOVA, **p<0.01, mean values +SD was reported. **B)** At 2 months of age, Mac2 and MHCII positive cells are detected mainly in corpus callosum while these cells are highly populated all over the white matter such as corpus callosum and striatum at 7 and 10 months of age. Scale bar: 500 μ m.

Cuprizone-treated mice

In cuprizone-treated mice the expression of Mac2 and MHCII in microglia was analyzed at different time points as shown in figure 3.16 A. 4 weeks after cuprizone treatment, when the demyelination was induced, a considerable number of MHCII positive cells were detected mainly in striatum and corpus callosum and a large population of Mac2 positive cells was found in the white matter as well. After 4 weeks of normal diet, when remyelination was ongoing, a considerable number of both Mac2

3 | Results

and MHCII positive cells were still detectable. Activation state of microglia cells was analyzed at later time points after completed remyelination (see the timeline diagram in figure 3.16. A, T: Time point). 5 weeks after completed remyelination the expression of Mac2 and MHCII was mainly detectable in the corpus callosum. 11 and 19 weeks after completed remyelination, Mac2 was expressed by a small cell population in corpus callosum and striatum (Fig 3.16 B and D) whereas there was no MHCII positive cells detectable at these time points. (Fig 3.16 C and D) However, a significant number of MHCII reappeared 33 weeks (almost 8 months) after completed remyelination in the commissura anterior (Fig 3.16 C, i) Mac2 positive population was also found in the same region 33 weeks after complete remyelination (Fig 3.16 B, j).

Figure 3.16 Activation state of microglia in Cuprizone mice. A) Timeline diagram for cuprizone mice analysis (T: Time point). **B, C)** Quantification of the expression of MHCII and Mac2 in cuprizone mice after completed remyelination compared to untreated age-matched group. n=4, Mean value+SD was indicated, ***p<0.001. **D)** The expression of Mac2 (**a-e**) and MHCII (**f-h**) in cuprizone mice at different time points. 11 and 19 weeks after remyelination there was no MHCII positive cells detectable. (**i and j**) MHCII and Mac2 positive cells in anterior commissura 33 weeks after completed remyelination. CC: Corpus Callosum, St: Striatum. WPRE: Weeks Post Remyelination. Scale bar: 50µm.

3.4.2.2 Lipofuscin accumulation in microglia in demyelinating models

Next we tested whether the amount of lipofuscin was affected in demyelinating models. Therefore, as described before, lipofuscin was visualized and quantified at different time points in both PMD and cuprizone-treated mice. Compared to age matched wild type mice, there was no significant

3.4..Enhanced myelin breakdown in demyelinating models, microglia behavior

change in the amount of lipofuscin in PMD mice at 2 months of age while it increased drastically at later time points (7 and 10 months old mice) (Fig 3.17 A and B). In cuprizone-treated mice, 5, 11, and 33 weeks after completed remyelination, lipofuscin increased significantly in comparison to age matched untreated mice (Fig 3.17 C).

Shiverer mice: In these mice, a population of unramified microglia with retracted unbranched processes was observed in the corpus callosum at 9 weeks of age. We detected lipofuscin inside those cells (Fig 3.17 E). In comparison with heterozygous shiverer mice, at 25 and 63 days of age there was a significant amount of lipofuscin in microglia in homozygous mice (Fig 3.17 D).

Figure 3.17 Lipofuscin formation and quantification in demyelinating models. **A)** Confocal images from PMD mice showing the development of intracellular lipofuscin (gray) in microglia (red), the size of lipofuscin increases with time. Scale bar: 20µm. Quantification of lipofuscin amount in PMD **(B)** cuprizone-treated **(C)** and shiverer **(D)** mice at different time points. n= 3-4 for each group of study. Mean +SD was indicated, *p <0.05, ***p<0.0001. **E)** Confocal images of microglia in corpus callosum in 9 weeks old shiverer mice. Microglia in this stage has retracted processes and intracellular lipofuscin, and they are aggregated in corpus callosum. Scale bar: 30µm.

3.4.2.3 Detection of myelin fragments within intracellular lipofuscin in cuprizone mice

Previously we found that lipofuscin partially contains myelin fragments in physiological condition when the mice were more than 18 months old (See section 3.3.1.2). To confirm that, we analyzed cuprizone mice at the latest time point (33 weeks after completed remyelination), when microglia have a large amount of lipofuscin compared to untreated mice and were in contact with myelin debris during de- and remyelination. The mice were one year old at this time point. We labeled myelin with Fluoromyelin, microglia with Iba1, and visualized lipofuscin via autofluorescent signal. Using confocal images we could find co-localization of internalized myelin fragments with lipofuscin. In addition, the number of cells with Fluoromyelin-labeled myelin within lipofuscin was significantly higher in treated mice as compared to untreated mice (Fig 3.18 B)

Figure 3.18 Myelin fragments are found within Lipofuscin in microglia in cuprizone mice 33 weeks after completed remyelination. A) Confocal image of lipofuscin (gray) within microglia (Iba1, red) containing myelin fragments (Fluoromyelin, green). Scale bars: 20 μ m (overview) and 2 μ m (zoom in). **(a)** 3-D reconstruction of lipofuscin (gray) including myelin (green) within microglia (red). Scale bar: 1 μ m **B)** Quantification of the number of lipofuscin positive cells that contain myelin. 6 treated and untreated (age-matched) mice were analyzed. Mean+SD was reported, **p<0.01, Student's t-test.

3.4.2.4 Clearance function of microglia in PMD mice

We injected FITC-Dextran into the cortex of 7 months old PMD mice and quantified the number of microglia internalizing FITC-Dextran. Compared to age matched wild type mice, we found 50% reduction in clearance function of microglia in PMD mice (Fig 3.25)

Figure 3.19 Quantification of Dextran uptake by microglia in 7-month-old PMD mice. Dextran-FITC was injected in the cortex of 7 months old PMD and wild type mice, 7 hours after injection the mice were analyzed to measure the percentage of Iba1/Dex positive microglia in the injection site. The number of these cells is significantly lower in PMD mice compared to wild type. Mean value+SD was reported, n=4, *p<0.05

3.5 Genetically induced impairment of lysosomal degradation in microglia

To analyze the effects of lysosomal storage on morphology and functionality of the cells we blocked the lysosomal degradation system specifically in microglia. This was achieved by crossing floxed Rab7 mice to a Tamoxifen inducible CX3CR1 Cre mouse line. Double transgenic mice (CX3CR1^{Cre+/-}; Rab7^{flox/flox}) were injected with Tamoxifen for 5 consecutive days to obtain conditional Rab7 knockout mice (Fig 3.20 A). We started to analyze the conditional knockout mice at different time points after Tamoxifen injection (Fig 3.20 B).

3.5.1 Cre recombinase-mediated deletion of Rab7 gene in conditional Rab7 knockout mice

To evaluate deletion of Rab7 gene induced by Cre recombinase we performed two strategies as following. First, double transgenic mice were crossed to tdTomato reporter mice then CX3CR1^{+ /CreERT2}; Rab7^{flox/+}; tdTomato+ mice were injected with Tamoxifen to induce Cre-mediated expression of tdTomato in microglia. One week after Tamoxifen injection, histological studies showed that more than 95% of microglia in the brain were tdTomato positive, which indicated an efficient activity of cre recombinase in microglia (Fig 3.20 C). Second, one week after tamoxifen injection in CX3CR1^{Cre+/-}; Rab7^{flox/flox} mice, microglia cells were isolated to measure relative expression of Rab7 mRNA in the cells by quantitative real time PCR. The quantification showed a 98% reduction of Rab7 transcript (Fig 3.20 D).

Figure 3.20 Evaluation of Rab7 gene deletion in conditional Rab7 knockout mice. **A)** Strategy for conditional targeting of Rab7 in mice. **B)** Timeline diagram for histoglogical analysis of conditional Rab7 knockout mice. **C)** Confocal image from cortex in $CX3CR1^{+/CreERT2}; Rab7^{fl/+}; tdTomato+$ mice. One week after Tamoxifen injection, microglia were visualized with Iba1 in green and the number of Iba1+/tdTomato+ (red) cells were counted. The quantification showed that tdTomato was expressed in 95% of microglia, Scale bar: 300 μ m. **D)** Relative expression of Rab7 mRNA in microglia one week after Tamoxifen injection in double transgenic mice ($CX3CR1^{Cre+/-}; Rab7^{fl/fl}$). 98% of Rab7 transcript was reduced.

3.5.2 Phenotypic characterization of conditional Rab7 knockout mice

3.5.2.1 Enlarged lysosomes in microglia

Considering the role of Rab7 in maturation of lysosomes, we first investigated the lysosomal morphology of microglia in Rab7 knockout mice. Brain sections were co-labeled with Iba1 (against microglia) and LAMP1 (against lysosomes) using immunohistochemistry. Confocal images were captured to visualize lysosomes in microglia. We started our histological studies one week after Rab7 deletion when we didn't detect any changes in lysosomes within microglia. However, enlarged

3.5 Genetically induced impairment of lysosomal degradation in microglia

lysosomes appeared only 6 weeks after Rab7 deletion when the mice were 10 weeks old (Fig 3.21 A). At this time point there was no detectable lysosomes in microglia of control group. Enlarged lysosomes were detectable in microglia of Rab7 knockout mice at later time points (10, 18, and 26 weeks after Tamoxifen injection) as well. Quantification of the number of LAMP1 positive showed that almost 50% of microglia cells have enlarged lysosomes in conditional Rab7 knockout mice (Fig 3.21 B).

Figure 3.21 Visualization and quantification of LAMP1-positive microglia in conditional Rab7 knockout mice. A) Enlarged lysosomes (labeled with LAMP1 in red) are detectable within microglia (labeled with Iba1 in green) 6 weeks after Tamoxifen injection. Scale bar: 20 μ m. **B)** The percentage of LAMP1-positive microglia cells in the cortical white matter in Rab7 knockout mice 6, 10, 18, and 26 weeks after Rab7 deletion.

3.5.2.2 Myelin fragments inside microglia

To study the interaction between microglia and myelin in conditional Rab7 KO mice, myelin and microglia were labeled with MBP and Iba1, respectively by immunohistochemistry. The labeled brain tissues of KO and control groups were analyzed 6, 10, 18, 26, 34, and 48 weeks after tamoxifen injection to detect myelin phagocytosis by microglia. Myelin fragments were detected inside microglia in KO mice 34 weeks after Tamoxifen injection, when the mice were 9 months old (Fig 3.22 A). In wild type mice internalized myelin was detected only at 18 months of age (Section 3.2.2). The number of cells with internalized myelin components was quantified in 1mm² of white matter including corpus callosum and striatum. 2.78% of microglia cells engulfed myelin. (Fig 3.22 B)

Figure 3.22 myelin phagocytosis by microglia in conditional Rab7 KO mice. **A)** Confocal image representing myelin components (MBP, green) within microglia (Iba1, red) in striatum of a 9-month-old KO mouse (34 weeks after Tamoxifen injection). **B)** Quantification of the percentage of cells engulfing myelin fragments at the same time point. Each group: n=3, Mean+SD was indicated, * $p < 0.05$, Student's t-test.

3.5.2.3 Early accumulation of lipofuscin in microglia

Immunohistological studies showed that a considerable amount of lipofuscin accumulated inside microglia in KO mice at very early time point (6 weeks after Tamoxifen injection) when the mice were only 10 weeks old. Quantification of the volume of lipofuscin 6, 18, 34, and 48 weeks after tamoxifen injection showed a significant increase in the amount of lipofuscin in KO mice in comparison with control group.

Figure 3.23 Lipofuscin in conditional Rab7 KO mice. The volume of lipofuscin in the cells was measured in the callosum and cortical white matter using Imaris software. The amount of lipofuscin in microglia in KO mice is significantly higher than that in control mice at all the time points. Three mice per group were analyzed and mean value plus SD is indicated. *** $p < 0.0001$, Student' t-test.

3.5.2.4 Myelin fragments are associated with lipofuscin within microglia

To search for myelin remnants within lipofuscin, myelin was labeled with MBP and Fluoromyelin. Myelin and lipofuscin were visualized simultaneously using dye separation method with confocal

3.5 Genetically induced impairment of lysosomal degradation in microglia

microscopy as explained before. We found MBP or Fluoromyelin positive lipofuscin granules 34 and 48 weeks after Tamoxifen injection (Fig 3.24).

Figure 3.24 Lipofuscin contains internalized myelin fragments in microglia in Rab7 KO mice. A) 48 weeks after Tamoxifen injection when the mice were 12 months old, myelin fragments (MBP, green) were detected inside microglia (Iba1, red) while they were associated with intracellular lipofuscin (LF, gray). Scale bar: 20 μ m (overview) and 2 μ m (zoom in). **B)** 3-dimensional reconstruction showing Fluoromyelin-labeled myelin fragment (green) within lipofuscin (gray) inside a single microglia cell Scale bar: 2 μ m **C)** Quantification of the number of cells with internalized MBP associated with lipofuscin.

3.5.2.5 Clearance function of microglia in conditional Rab7 KO mice

Due to early accumulation of lipofuscin as well as lysosomal dysfunction in microglia in Rab7 KO mice we assumed that the clearance function of the cells might be impaired. FITC-Dextran was injected into the cortex of KO and control mice 6 and 18 weeks after Tamoxifen injection. Clearance function of microglia in KO mice was significantly reduced only at the later time point (18 weeks after Tamoxifen injection) while there was no significant difference between control and KO mice at earlier time point, 6 weeks after Tamoxifen injection (Fig 3.25)

Figure 3.25 Clearance function of microglia in conditional Rab7 KO mice. Dextran was injected into the cortex 6 and 18 weeks after Tamoxifen injection; 7 hours after injection, the number of Iba1/Dex+ cells was counted. There was no difference in clearance function of cells between KO and control mice 6 weeks after Tamoxifen injection. There was a 50% reduction in the number of Dextran positive microglia in KO mice in comparison to control group at later time point (18 weeks after Tamoxifen injection). n=4, mean+SD, **p value<0.01, n.s: p= 0.3206, Student's t-test.

3.5.2.6 Myelin fragments in conditional Rab7 KO mice

We quantified the number of myelin fragments in electron microscopic images from white matter, mainly corpus callosum, in KO and control mice 48 and 77 weeks after Tamoxifen injection. At both time points there was a significant increase in the number of extracellular myelin fragments (Fig 3.26).

Figure 3.26 Number of myelin fragments increases in conditional Rab7 KO mice. Brain tissues from control and KO mice 48 and 77 weeks after Tamoxifen injection were prepared for conventional electron microscopy. The number of myelin fragments was counted per 1000 axons. The quantification shows that myelin fragments in KO mice are significantly more than control groups at both time points.

3.5.2.7 Microglia morphology in conditional Rab7 KO mice

Microglia were analyzed in Rab7 KO mice morphologically using immunohistochemistry. Compared to control group, microglia in KO mice showed smaller and less complex processes 6 weeks after tamoxifen injection (Fig 3.27 A). In addition, the surface area occupied by microglia processes in KO mice was reduced compared to control mice (Fig 3.27 B). Although the KO mice at this time point were only 10 weeks old, the morphology of microglia was comparable to those of aged microglia.

Figure 3.27 morphological analysis of microglia in Rab7 KO mice. **A)** Confocal image of microglia population in cortical white matter 6 weeks after Tamoxifen injection showing shorter and less branched processes in KO compared to control mice. Scale bar: 30µm. **B)** Quantification shows that cell area of microglia in KO mice is significantly less than cell area in control group. ***p < 0.0001, Mean value+SD.

3.5.2.8 MHCII expression in microglia in conditional Rab7 KO mice

To assess the activation state of microglia in KO mice, using DAB histostaining, we evaluated expression of Mac2, Mac3, MHCII, CR3(CD11b/ Mac1), Fcγ RII/III, at different time points (18, 26, 34, 48 and 77 weeks after Tamoxifen injection). The results showed that there were no Mac3 positive cells in any of the mice, and there was no significant difference in number of CR3 and Fcγ RII/III positive cells between KO and control mice 26, 34, 48, and 77 weeks after Tamoxifen injection. In addition, Mac2 and MHCII were not expressed in both KO and control mice 18, 26, and 34 weeks after Tamoxifen injection. The number of MHCII positive cells in KO mice 48 and 77 weeks after Tamoxifen injection was significantly higher compared to control group.

Figure 3.28 MHCII expression in microglia of Rab7 KO mice. **A)** A few MHCII positive cells were detected in Rab7 KO mice 48 weeks after Tamoxifen injection in cortical gray matter **(a)**, cortical white matter **(b)**, striatum **(c)**, hippocampus **(d)** and corpus callosum **(e)**. Scale bar: 50µm. **B)** Quantification of MHCII positive cell in Rab7 KO and control mice 26, 48, and 77 weeks after Tamoxifen injection showing a significant increase in KO mice at later time points compared to their control group. n=3, Mean plus SD was represented, *p<0.05, n.s: p=0,2221

Chapter 4

Discussion

4.1 Myelin turnover by shedding of myelin fragments into the extracellular space

Myelin is a tightly packed membrane in which the protein and lipid molecules are sandwiched between compacted layers. This special membrane has been considered as one of the most stable membranes. Myelin molecules have little contact with the metabolic pool in the cytoplasm so that they exhibit a low rate of metabolic turnover (O'Brien 1965). Previously, the turnover rate of some myelin lipids and proteins were determined using isotope-labeling and mass spectrometry (MS). Sphingomyelin, gangliosides, cerebroside, and cholesterol were found to have low rate of metabolism. Proteolipid protein (PLP) with the half-life of 20-35 days was reported as metabolically active myelin component (Smith 1968; Fischer and Morell 1974; Ando, Tanaka *et al.* 2003). The incorporation of tyrosine into the myelin proteins using [¹⁴C] tyrosine showed that only 20 % of myelin proteins were replaced within 10 days (Lajtha, Toth *et al.* 1977)

Due to the heterogeneity of myelin structure, the turnover rates of myelin lipids and proteins are heterogeneous. (Smith 1968; D'Monte, Mela *et al.* 1971; Sabri, Bone *et al.* 1974; Poduslo and Braun 1975; Figlewicz and Druce 1976; Lajtha, Toth *et al.* 1977; Singh and Jungalwala 1979). Myelin proteins that have access to the metabolic machinery might have higher turnover rate (Lajtha, Toth *et al.* 1977). Iodination studies showed that MBP is less exposed to the outer surface compared to PLP (Poduslo and Braun 1975). Recently, using pulse-chase labeling and mass spectrometry, myelin proteins such as MBP, PLP, and MOG were reported as long-lived myelin proteins (Toyama, Savas *et al.* 2013).

Long-lived proteins are at increased risk for accumulation within the cells which can be linked to the cellular aging process (Toyama, Savas *et al.* 2013). Therefore, structures like myelin membrane exhibiting long-term protein persistence need to be maintained or remodeled. Studies in human and rodents claimed that myelin is continuously exchanged (Lasiene, Matsui *et al.* 2009; Young, Psachoulia *et al.* 2013; Yeung, Zdunek *et al.* 2014). Studies in human brain suggested that preexisting mature oligodendrocytes are responsible for myelin modulation. Oligodendrocytes in human show a very low rate of turnover. After 9 years of age the number of oligodendrocytes remains stable throughout the rest of the human lifespan. There is no correlation between oligodendrocyte

4 | Discussion

turnover and myelin remodeling that occurs at a high rate in human. However, several observations in the rodents indicate that oligodendrocyte turnover contributes to myelin remodeling (Dimou, Simon *et al.* 2008; Emery 2010; Young, Psachoulia *et al.* 2013). 30% of all oligodendrocytes in the corpus callosum in adult mice are newly differentiated (Rivers, Young *et al.* 2008; Zhu, Whittemore *et al.* 2011). Adult oligodendrocytes are thought to be required for the maintenance of myelin by the replacement or remodeling of preexisting myelin sheaths (Young, Psachoulia *et al.* 2013). For the remodeling of myelin, new myelin segment appears to displace old myelin segments (Wang and Young 2014). Internode retraction and expansion of the node of Ranvier due to disruption of key proteins lead to a transient hypofusion. This mechanism is suggested to play a role in myelin remodeling (Reimer, McQueen *et al.* 2011).

It still remains to be understood how the old segments of myelin sheath are removed from axons. How the molecules that are trapped within closely compacted membranes get access to the degradation system for myelin turnover during long period of time. Using electron microscopy, we detected multilamellar myelin fragments in the intracellular and extracellular space in adult and aged mice. We noticed that a large part of myelin sheath tears away from the axon (Fig 4.1 A). In addition, light microscopic histology in the striatum, interestingly, showed that a part of myelin is pulled by microglia in aged mice (Fig 4.1 B). We propose that myelin fragments can be formed by shedding of myelin sheaths into the extracellular space.

Figure 4. 1 Myelin fragments are formed by shedding of myelin sheaths into the extracellular space
A) Electron microscopic image in the corpus callosum showing myelin tearing away from the axon. **B)** Confocal image in striatum of 18 months old mouse showing a microglia (Iba1, red) pulling a part of myelin (MBP, green) into the extracellular space. The middle image shows the same phenomenon in a rotated position. Scale bar, 5 μ m (left); 4 μ m (middle and right).

4.2 Myelin uptake by microglia

The processes of microglia in their “resting” state *in vivo* are highly motile to survey the microenvironment in the CNS and also to interact with synapses (Nimmerjahn, Kirchhoff *et al.* 2005; Wake, Moorhouse *et al.* 2009). We speculated that resting microglia have also potential functions in myelin turnover in the CNS. Our work showed that microglia processes are in contact with myelin in

physiological condition. The frequency of these contacts and also the surface area in contact with myelin increase with age, starting at least at 9 months of age. In addition, myelin fragments were detected inside microglia cells in striatum as well as cortical white matter at 18 months of age and later. Consistent with previous observations, we found an age-dependent increase in the number of microglia cells in the white matter (Sandell and Peters 2002). Moreover, compared to gray matter, a considerable number of cells expressing Mac2/Galectine 3 were observed in the white matter. Interestingly, this population was detectable only in aged mice. Mac2/Galectine 3 is a galactose-binding lectin which appears to be active in demyelination of peripheral nerves (Saada, Reichert *et al.* 1996). Mac2/Galectine 3 is also known to be upregulated in demyelination areas in EAE, and is expressed by microglia, macrophages that phagocytose myelin (Reichert and Rotshenker 1999; Smith 2001; Rotshenker, Reichert *et al.* 2008; Rotshenker 2009). Additionally, while lysosomes were rarely detectable in young microglia, they appear from 7 months of age on. Also, in both middle aged and aged mice, lysosomes are strikingly larger in the white matter than in gray matter. This finding suggests that the lysosomal system of microglia cells is actively engaged in degradation of myelin. Previous studies have shown an increase in the number of CD68 positive microglia cells which are involved in the engulfment of synaptic elements in the postnatal retinogeniculate system. CD68 is a marker for lysosomes (Schafer, Lehrman *et al.* 2012). Moreover, our results are consistent with previous work that has shown an increase in the number of ED1, a lysosomal marker, positive microglia in corpus callosum with age (Hua, Schindler *et al.* 2012). Altogether, our results indicate that microglia cells are actively involved in the removal of myelin in normal aging.

4.3 Age-related increase in microglia-myelin contact is correlated with higher rate of myelin turnover in aging

Electron microscopic studies have revealed that during aging myelin sheaths undergo some structural alterations that make the membrane unstable and prone to degeneration (Peters 2002). In this context, it has been shown that in aged mice the replacement of some molecules such as cerebroside and GM1 is relatively accelerated and metabolic turnover of myelin is slightly higher (Ando, Tanaka *et al.* 2003). Previous studies on oligodendrocytes in aged brain of monkeys have detected dense inclusions which aggregate in the cell body or develop swellings at the end of processes (Peters 2002). These inclusions are suggested to originate from degenerating myelin membranes and turnover of material in the sheaths. In some oligodendrocytes, the swelling was seen along the length of their processes (LeVine and Torres 1992).

4 | Discussion

To maintain the integrity of myelin, unstable molecules must be removed either from axons or from oligodendrocytes. Accordingly, our studies show that microglia can be responsible for clearing degenerated myelin in aged brain of mice. Our results specifically shows that myelin molecules such as MBP which are trapped within layers of tightly compacted membrane are transferred to microglia by fragmentation of myelin in the extracellular space. The other possibility is that myelin components are outsourced by oligodendrocytes into the extracellular space.

In adulthood, myelin is remodeled or replaced by new myelin sheaths that are produced by adult-born oligodendrocytes (Wang and Young 2014). These cells, intrinsically, generate shorter myelin segments not only in adulthood but also in aging to actively myelinate the axons which have not been myelinated in development (Lasiene, Matsui *et al.* 2009; Young, Psachoulia *et al.* 2013). These studies suggest that myelination continues from development to adulthood as well as aging. Therefore, the old segments from pre-existing myelin sheaths during remodeling of myelin membrane as well as myelin disposal generated due to *de novo* myelination must be removed efficiently for the maintenance of myelinated fibers.

4.4 Internalized myelin contribute to the formation of lysosomal inclusions

The normal functionality of microglia cells is essential for the integrity of the CNS in healthy as well as pathological conditions. During the life span of an animal, microglia cells are targeted with the aging that cause changes in their morphology and functions (Ajami, Bennett *et al.* 2007; Streit and Xue 2010). Therefore, it is important to define the factors which induce age-related alterations in these cells.

Consistent with other studies we could also detect an aging phenotype in microglia in wild type mice. One of the most specific hallmarks of aging in microglia is lipofuscin accumulation, defined as lysosomal inclusions (Sierra, Gottfried-Blackmore *et al.* 2007; Tremblay, Zettel *et al.* 2012). There was an age-related increase in the number and amount of intracellular lipofuscin. It is notable that lipofuscin was not totally absent from cells in young (2 months old) mouse brain, but was detectable only in very small amount. Formation of lipofuscin even in the early time of life is thought to be due to oxidative reactions which are important for the survival of the cell during the lifetime (Terman and Brunk 1998). In middle aged and aged mice, lipofuscin positive microglia cells were found all over the brain. However, interestingly, microglia in the white matter have larger amount of lipofuscin compared to gray matter. In addition, we found that internalized myelin fragments are frequently

associated with lipofuscin. The main reason for lipofuscin formation is thought to be age-related and (reactive oxygen species) ROS-mediated oxidative stress. Endogenous ROS which is mainly derived from mitochondria cause oxidative damage to the internalized material in lysosomes so that they become undegradable and form lipofuscin (Terman and Brunk 1998; Terman, Kurz *et al.* 2010). Therefore, lipofuscin is considered as a mixture of oxidized proteins and lipids (Gray and Woulfe 2005). Myelin proteins and lipids are known to be susceptible to ROS-induced oxidation (Bongarzone, Pasquini *et al.* 1995; Luoma, Kuo *et al.* 2015). This type of oxidation is mainly mediated by iron which increases with age and accumulates within lipofuscin (Brunk 1989; Gray and Woulfe 2005; Wong 2013). Myelin membrane exposure to iron-catalyzed free radical generation system induces protein aggregation and lipoperoxidation (Konat, Gantt *et al.* 1986; Domanska-Janik and Bourre 1990). Altogether, we suggest that myelin components which are engulfed by microglia with time undergo oxidative damage so that accumulate within the cell as a part of lipofuscin.

4.5 Microglial phenotype changes with age

We observed that lipofuscin positive cells have shorter and retracted branches, and are less motile. Other studies have also shown that aged microglia cells in the brain as well as retina have less branched processes, reduced arborization and motility (Sierra, Gottfried-Blackmore *et al.* 2007; Damani, Zhao *et al.* 2011). We found a correlation between the presence of intracellular lipofuscin and ramification as well as motility of their processes. The latter characteristics of microglia are required for the surveillance function. Because of less dynamic and ramified processes of aged microglia, the cellular migration of cells toward a local lesion is not as efficient as in young cells. Consequently, their immune responses may become slower. Moreover, following injury, aged cells represent a delayed dynamics of deactivation; they are not dispersed from the lesion site after a long time (Damani, Zhao *et al.* 2011). Sustained accumulation of activated aged cells avoids the maintenance of tissue homeostasis and may induce chronic neuroinflammation involved in the pathogenesis of age-related neurodegenerative diseases (Medzhitov 2008; Damani, Zhao *et al.* 2011). Furthermore, it is known that the aggregation of undigested materials within the cells leads to deficient clearance function. For example, oxidized lipoprotein-loaded macrophages, known as foamy cells in atherosclerosis, are inefficient in clearance of apoptotic bodies (Schrijvers, De Meyer *et al.* 2007; Ley, Miller *et al.* 2011). We expected that aged microglia with accumulation of lipofuscin, a mixture of oxidized proteins and lipids, also show an impaired clearance function. Following injection of Dextran-FITC in the cortex of young (2-month-old) and middle aged (10-month-old) mice, we could see a reduction in dextran uptake by 10-month-old mice. Consistent with the other studies (Frank,

Barrientos *et al.* 2006). Overall, we suggest that lipofuscin can be considered as a biomarker of senescent and dysfunctional microglia.

4.6 Myelin breakdown leads to lipofuscin formation

In summary, our results show that in aging brain, myelin is fragmented and taken up by microglia where it is partially included within lipofuscin, and that lipofuscin positive cells represent a senescence-type of phenotype. We asked whether there is a casual correlation between myelin uptake by microglia and their aging phenotype. We assumed that overloading the lysosomal system with myelin may induce microglia senescence. Therefore, we analyzed microglia in demyelinating mouse models in which the cells are exposed to large amount of myelin fragments due to enhanced myelin breakdown. Immunohistochemical analysis of dysmyelinating mouse model for Pelizaeus-Merzbacher disease, which overexpress *plp 1* gene (PMD mice), at different age, (2, 7, and 10 months old) showed that the stability of myelin is reduced with time and consequently, myelin sheaths were broken-down. Loss of myelin was accompanied with accumulation of microglia expressing MHCII and Mac2 in the white matter. These observations are in consistent with the studies that characterized these mice previously (Karim, Barrie *et al.* 2007; Edgar, McCulloch *et al.* 2010; Tatar, Appikatla *et al.* 2010). We frequently found myelin fragments within these cells at later time when demyelination was peaking (10 months of age). In addition, by comparing transgenic mice at different age we detected a significant increase in the amount of intracellular lipofuscin with time. There was no difference between PMD and wild type mice at 2 months of age when the myelin was still stable. Compared to age-matched wild type mice there was a striking increase in the quantity of lipofuscin in 7 as well as 10 months old PMD mice in which the stability of myelin sheaths was compromised. The difference between 10 months old PMD mice and wild type was bigger than difference between 7 months old PMD mice and wild type. Altogether, these data showed that the accumulation of lipofuscin overlaps with the level of myelin breakdown in these mice.

Next, we observed that microglia in 7 months old PMD mice have a reduced capacity to clear away dextran particles from the extracellular space. Therefore, considering the high level of myelin fragmentation in these mice we suggest that overwhelming the cells with myelin fragments and consequently, lipofuscin affects their clearance function.

Next to demyelination, PMD mice develop axonal degeneration due to inflammation and oligodendrocyte dysfunction (Anderson, Schneider *et al.* 1998; Edgar, McCulloch *et al.* 2010). Thus, in these mice the formation of inclusions in microglia may results from engulfment of not only myelin

but also axonal elements. Therefore, to avoid the contribution of other factors besides myelin, we used shiverer mice in which there is no sign of axonal change or loss and the pathology is restricted to myelin (Griffiths, Klugmann *et al.* 1998). In these mice, myelin breakdown occurs due to lack of MBP already in development (Roach, Takahashi *et al.* 1985). Previous studies have reported that there is no macrophage infiltration in shiverer mice (Bird, Farrell *et al.* 1978). However, we could detect a massive accumulation of microglia in the corpus callosum in these mice at P25 as well as P63. These cells have a significant amount of lipofuscin indicating that myelin degeneration contributes to its accumulation.

In these models, demyelination or dysmyelination are continuous processes. We asked whether a short-term exposure of myelin to the cells would be also sufficient to enhance aging at a later time. To test this, we induce a singular event of demyelination for 4 weeks by cuprizone treatment of wild type mice, and then induce remyelination by changing cuprizone to the normal diet. According to previous studies (Matsushima and Morell 2001; McMahon, Suzuki *et al.* 2002), microglia remain in their activation state 4-6 weeks after removing cuprizone from the diet. Thus, we started our histological studies 4 weeks after diet change, when remyelination was completed, to differentiate phenotypic changes that might occur as a result of activation from those produced as a consequence of aging. As the main hallmark of aging we quantified the volume of lipofuscin in microglia cells at later time points after completed remyelination. In comparison with the control mice, the amount of lipofuscin increased significantly in cuprizone-treated mice already 5 weeks after completed remyelination and continued to increase 11 and 33 weeks after completed remyelination. In addition, interestingly we could find myelin fragments associated with lipofuscin even 33 weeks after complete remyelination, confirming our previous data that showed the association of internalized myelin with lipofuscin in wild type conditions.

Further investigation of cuprizone mice showed that MHCII and Mac2 were up-regulated in corpus callosum 5 weeks after completed remyelination. These up-regulations were expected as an indication of microglia activation in this time point. Interestingly, while Mac2 positive cells were still detectable 11, 19, and 33 weeks after complete remyelination, MHCII expression went back to the basal level and reappeared only at week 33 after complete remyelination. These data indicate that low grade inflammation which is normally characteristic of microglia senescence occurs earlier when the brain has undergone a single event of widespread demyelination. Moreover, expression of Mac2 at all the time points can be explained regarding its role in myelin phagocytosis during demyelination (Smith 1999; Smith 2001). Notably, at the latest time point in cuprizone mice Mac2 expressing cells were found mainly in anterior commissure, and previously in aged wild type mice we also detected the same population of microglia in the same region of brain. Therefore, we propose that even in

4 | Discussion

normal aging the contact of microglia with myelin fragments, produced due to myelin sheaths breakdown, keeps the cells in a mild activation state that mainly appears as Mac2 expression. Studies on demyelinating models, including PMD, shiverers, and cuprizone mice, suggest that myelin breakdown can accelerate age-related phenotype in microglia cells.

Myelin consists of long-lived proteins (Lajtha, Toth *et al.* 1977; Ando, Tanaka *et al.* 2003; Toyama, Savas *et al.* 2013). Long-lived proteins are thought to have implications for age-dependent deficiency in the cells and tissues. These components are possibly at the risk of damage during a long period of time (Toyama, Savas *et al.* 2013). For example, it was shown that accumulation of damaged crystalline with time cause vision deficiency (Bloemendal, de Jong *et al.* 2004; Wilmarth, Tanner *et al.* 2006). Long-lived scaffold nucleoporins undergo oxidative damage during aging that is associated with defects in nuclear trafficking and the breakdown of the nuclear permeability barrier (D'Angelo, Raices *et al.* 2009). Due to the nature of myelin components, they are thought to be vulnerable to the iron-catalyzed proxidation occurring normally in lysosome for degradation (Bongarzone, Pasquini *et al.* 1995; Luoma, Kuo *et al.* 2015). Therefore, these components become indigestible with time. The constant contact of non-dividing cells such as microglia with myelin cause lysosomal storage which can be linked to deficient clearance function (Schrijvers, De Meyer *et al.* 2007) and possibly age-related features.

4.7 Lysosomal storage induces cellular senescence

We asked how microglia senescence is induced. We could show that when the cells are exposed to myelin fragments or overloaded with them, the amount of intracellular lipofuscin increases and premature aging phenotype is induced. Therefore, we suggested that overloading the lysosomal system with time may influence the functionality of microglia and induce cellular senescence. To test this, we generated conditional Rab7 Knockout mice in which the cargo transport from endosomes to lysosomes is blocked so that a pile of material in degradative compartments accumulates within microglia. In these mice, enlarged lysosomes, as an indication of lysosomal dysfunction, were detectable in the cells only 6 weeks after Tamoxifen injection and not earlier than that although just one week after Tamoxifen injection more than 98% of Rab7 transcript was already deleted. We assumed that at the earlier time point, residual pool of Rab7 protein in the cytosol still can compensate the functionality of lysosomes in the cells. It is notable that the enlarged lysosomes were detectable for 48 weeks after Tamoxifen injection which shows stability of microglia in the CNS (Lawson, Perry *et al.* 1992)

Interestingly, the hallmarks of senescence, including lipofuscin accumulation and shorter and less branched cell processes, were detected in microglia in Rab7 KO mice already when the mice were 10 weeks old. Moreover, regardless the normal aging effect, at later time points, the amount of lipofuscin significantly increased in Rab7 KO mice in comparison with control mice. The clearance function of cells decreased significantly with time. Possibly, due to higher amount of indigestible materials, lysosomes are more exhausted at later time so that the cells are not efficient enough for clearance. These data are comparable with our previous results that showed less clearance activity in aged cells with high amount of lipofuscin, and also with other studies shown that lysosomal storage in phagocytic cells cause a defect in clearance of apoptotic bodies (Schrijvers, De Meyer *et al.* 2007). Due to deficient clearance function of microglia cells in Rab7 KO mice a higher number of extracellular myelin fragments in the white matter was found confirming that microglia cells are responsible for myelin fragments removal in aging.

At the age of one year a few cells expressing MHCII were detected while there was no positive cell in control mice. Altogether, the results show that impairment of lysosomal degradation system induces a pre-mature aging phenotype in microglia. We propose that there is a reciprocal correlation between aging and lysosomal function. While aging factors, mainly oxidative stress, affects the functionality of the lysosomes (Kurz, Terman *et al.* 2008), dysfunctional lysosomes may induce cellular aging.

We found that Rab7 KO mice develop intracellular MBP positive myelin fragments more frequently compared to control group. Furthermore, myelin uptake by microglia in Rab7 KO mice was detected 9 months earlier than in wild type. The internalized myelin fragments were found in association with lipofuscin more abundant in KO mice. Overall, using this mouse model we could confirm our previous results showing that in normal aging myelin fragments are constantly taken up by microglia and partially get trapped within intracellular lipofuscin.

4.8 conclusion

In summary, we suggest that myelin breakdown plays a role in inducing microglia dysfunctionality that occurs in the aging brain. Increasing rate of myelin turnover in demyelinating models as well as in normal aging cause cells to become overloaded with myelin fragments with time, and develop lysosomal storage pathology, which consequently induce aging.

Our results may have important implication for neurodegenerative disease. If constant transfer of myelin fragments may block the lysosomal system and consequently impairs the function of microglia cells in a long term, this may be relevant for diseases associated with protein aggregation.

4 | Discussion

For example, in Alzheimer's disease, it is known that the capacity of microglia to remove β -Amyloid goes down with time.

Our findings may explain why prior traumatic brain injury (TBI) associated with tissue breakdown acts as a risk factor for chronic neurodegenerative diseases. We propose that a long term exposure to myelin debris or neuronal elements cause microglia cells to be overloaded so that they become exhausted and may lose their function to clean brain from more debris.

Furthermore, our results may also be important for the pathophysiology of CNS autoimmune diseases such as multiple sclerosis. In this disease, myelin is known to be the most common target of autoimmune responses (Steinman and Zamvil 2003; Fletcher, Lalor *et al.* 2010). However, according to immunopathology of MS, it is not well understood how myelin antigens reach antigen presenting cells in the CNS to reactivate auto-reactive T cells in the parenchyma (Goverman 2009; Hart, Hintzen *et al.* 2009). We suggest that the permanent circulation of myelin-derived components in the brain parenchyma may predispose myelin towards autoimmune diseases.

Curriculum vitae

1. Personal data

Name: Shima Safaiyan

Date of birth: September 23, 1980

Nationality: Iran

Family status: single

2. Contact information

Address: Cellular neuroscience department, Max Planck Institute for Experimental Medicine,
Hermann Rein Str. 3, 37075, Goettingen, Germany

Email Address: safaiyan@gmail.com

3. Education

Aug. 2011-expected Nov. 2015

PhD, Neuroscience, Georg-August University Goettingen

Dissertation: Role of microglia in myelin turnover

Committee: Prof. Dr. Mikael Simons (Advisor), Prof. Dr. Alexander Fluegel, Prof. Dr. Holger Reichardt.

Sept. 2003-Sept. 2006

M.Sc. Microbiology, Tehran University, Iran

Thesis topic: “Screening and Primary Identification of Native Exopolysaccharide-producing Halophilic Bacteria.”

Chair: Dr. Mohamad Ali Amoozegar

G.P.A: 18.03 out of 20

Sept. 1999 to June 2003

B.Sc. Microbiology, Tehran University, Iran

Thesis topic: The Study of Genetics of Mushrooms and Evaluation of Their Biotechnological Applications.

Chair: Dr. Behboodi (Cytology lab, Department of Cellular Biology, Tehran University)

G.P.A: 16.29 out of 20

4. Employment history**October 2007-February 2011**

Research Associate in Molecular Immunology and Vaccine Research Laboratory, Pasteur Institute of Iran

5- Professional Research Experiences**2008-2011**

Molecular Immunology and Vaccine Research Laboratory, Pasteur Institute of Iran,

Project: The contribution of human neutrophils in development of protective immune responses during in vitro *leishmania major* infection” in collaboration with Karolinska institute, Sweden.

2008-2010

Molecular Immunology and Vaccine Research Laboratory, Pasteur Institute of Iran:

Project: The role of, a certain CpG ODN, in modulation of immune responses of human (normal and patients) PBMCs as well as macrophages infected with *Leishmania major* in vitro.

2007-2008

Molecular Immunology and Vaccine Research Laboratory, Pasteur Institute of Iran

Project: Assessment of NOD2 Gene polymorphism to find SNPs which have a crucial role in manifestation of different clinical outcomes in humans with Cutaneous Leishmaniasis in Mashhad.

2006, Exteremophiles Lab., Department of Microbiology, Tehran University

Proposal: Using the Exopolymers Produced by Halophilic Bacteria to Absorption of Pb^{2+} and Hg^{2+} in polluted environments

Supervisor: Dr. Amoozegar, approved and supported by “National Projects Organization”.

2005, Exteremophiles Lab., Department of Microbiology, Tehran University.

Proposal: Introducing a new medium for culture of exopolysaccharide-producing halophilic bacteria

2001, Tehran University, Study of cloning procedure in animal cells,

Supervisor, Dr. Anis Jafari (Pasteur Institute of Iran, Molecular Biology Dept.)

Pavlou, Athanasios Stergiopoulos, **Shima Safaiyan**, Sandra Völs, Marianne van Cann, Panagiotis K. Politis⁴, Mikael Simons, Benedikt Berninger, Antonio del Sol , Jens C. Schwamborn. (Submitted)

7- Training Course

Real-Time PCR training course at “International workshop on *Leishmania*”. March 1st – 6th, 2008, Pasteur Institute of Iran, Tehran.

8. Scholarships and grants:

Grant for Young Researchers in Exteremophiles 2006 Congress: 450€ (2006, France)

10. Books

2001: Participation in editing of a Biochemistry book for master-science exam under supervision of Mir publication, Iran

11. Conference Presentations

- Poster Presentation

- 1- “Evaluation of Viscosity of Exopolysaccharides Produced by Native Moderately Halophilic Bacteria”, 8th National Congress of Microbiology. (May 23-25, 2006, Esfahan, Iran)
- 2- “Screening and Primary Identification of Native Moderately Halophilic EPS-Producing Bacteria”, 11th International Symposium on Microbial Ecology, August 20-25, 2006, Vienna Austria
- 3- “The effect of Physicochemical Factors on Production of Exopolysaccharide by a Halophilic Bacterium Related to *Vibrio* Genus“, Exteremophiles 2006 Conference, September 17-21 2006, Brest, Brittany, France

4- "Comparing the effect of different classes of CpG-ODN on human neutrophil survival and activation", 14th International Congress of Immunology, August 22-27. 2010. Kobe, Japan.

5- "connecting myelin membrane turnover with autoimmunity", 2nd International SFB TRR 43 Symposium, May 15 – 17, 2014, Berlin/Potsdam, Germany

- Oral presentation

1- "Using Taguchi Method for Optimizing the Production of Exopolysaccharide by a Halophilic Bacterium Related to Vibrio Genus.", 14th National and 2th International Conference of Biology, Tehran, Iran, 29-31 August, 2006.

2- "Role of microglia in myelin turnover". Myelintreffen 24-25. April, 2014 Max Planck Institute for Experimental Medicine, Göttingen, Germany
