Summary

The mechanism and the kinetics of metal-catalyzed radical polymerization were investigated by spectroscopic methods and by PREDICI® simulation. A particular focus was on Cu- and Fe-mediated atom-transfer radical polymerization (ATRP) in aqueous solution of poly(ethylene glycol)ether methacrylate (PEGMA) and on monomer-free model systems.

The propagation kinetics of PEGMA in aqueous solution were determined between 20 and 77 °C via PLP-SEC. The significant dependence of k_p on monomer content is due to the difference in the degree by which internal rotations of the transition state for propagation are hindered.

Chain-length-dependent termination was analyzed in terms of the composite model for PEGMA in aqueous solution via SP-PLP-EPR. The termination rate coefficient for two radicals of chain-length unity, $k_t^{1,1}$, scales with the inverse viscosity of the solution prior to polymerization. The composite-model parameters for the short-chain and long-chain regime, α_s and α_l , respectively, are independent of water content, whereas the crossover chain length, i_c , decreases toward higher dilution.

Cu-mediated ATRP in aqueous solution of the monomer-free model systems and of PEGMA polymerizations with CuBr/2,2'-bipyridine acting as the catalyst and 2-hydroxyethyl 2-bromoisobutyrate (HEMA-Br) as the initiator were studied via online Vis/NIR spectroscopy. In the monomer-free model system, PEGMA was replaced by poly(ethylene glycol) dimethylether (PEO) to mimic an ATRP situation. The SP-PLP-EPR technique was used for the first time to measure an ATRP deactivation rate coefficient, k_{deact} , in aqueous solution. Excess NaBr has been added to the polymerization system to avoid water-assisted dissociation of the Br-Cu species.

The activation-deactivation equilibrium constant, K_{ATRP} , was measured at different water concentrations. In both the model system and the PEGMA polymerization, K_{ATRP} increases by about three orders of magnitude in passing from the bulk monomer toward a water

environment. Since k_{deact} is independent of water content, the change in K_{ATRP} is essential due to the effect of the aqueous environment on the activation rate coefficient, k_{act} .

Kinetic analysis of the model system in conjunction with PREDICI[®] simulation under variation of NaBr concentration shows that NaBr does not affect k_{act} and k_{deact} , and thus has no impact on K_{ATRP} . PREDICI[®] simulation of the ATRP systems however tells that the concentrations of water and NaBr influence dispersity and the degree of chain-end functionality. Addition of at least five equivalents salt with respect to the total catalyst concentration are essential for carrying out successful ATRP experiments in aqueous solution.

Fe-mediated RDRP studies were performed with the bio-inspired protoporphyrin IX containing a ferric ion catalyst with an additional axial bromide ligand, Fe/Br-mesohemin-(MPEG₅₀₀)₂. The catalyst was kindly provided by the Matyjaszewski group.^[1] The Fe-catalyst was studied by combined Mössbauer and online Vis/NIR spectroscopic analysis for the relevant Fe species. The interplay between ATRP and an organometallic reaction (OM), which includes the reaction of propagating radicals with Fe^{II}, may occur depending on the ratio of Fe^{II}/Fe^{III} concentrations.

The SP-PLP-EPR method was also applied to measure k_{deact} for the Fe^{III}/Br-mesohemin-(MPEG₅₀₀)₂ catalyst in aqueous solution. Toward higher water content, k_{deact} increases by about one order of magnitude from 30 to 90 wt% H₂O, which is beneficial for ATRP control in diluted aqueous solution.

The activation–deactivation equilibrium and the addition of radicals to the Fe^{II} catalyst, $k_{\text{add,Fe}}$, were measured for the Fe/Br-mesohemin-(MPEG₅₀₀)₂ complex via UV/Vis spectroscopy in combination with stopped-flow injection. K_{ATRP} was found to be insensitive toward water content in the concentration range between 50 and 70 wt% H₂O, whereas $k_{\text{add,Fe}}$ exhibits an increase by a factor of five. It could be shown that k_{deact} exceeds $k_{\text{add,Fe}}$ by almost one order of magnitude, and that the control operates exclusively by ATRP.

The rate coefficients determined within this thesis allow for the prediction of dispersity, chain-end functionality and conversion vs time profiles for Cu- and Fe-mediated ATRP of PEGMA in bulk and aqueous solutions with the investigated catalysts and with catalysts of similar reactivity.

1

Introduction

Polymeric products continue to replace many conventional materials such as iron, aluminum, glass and wood.^[2] Especially in automotive, aviation and high-tech industries polymeric products are favored because of their low specific weight, high resistance to corrosion and mostly cheaper fabrication and processing.^[2,3] Aside the usage in the heavy industry, polymeric materials are also of growing importance for optical data chips, coatings, and medical applications. The majority of industrially produced polymers, e.g., polyethylene (PE) and polystyrene (PS), are prepared by conventional radical polymerization.

The so-obtained polymers exhibit no chain-end functionality and broad molar-mass distributions, which restricts the possibility to achieve polymeric materials with complex architecture and topology. Such precisely tailored polymers with targeted properties may, however, be synthesized via reversible deactivation radical polymerization (RDRP).^[4–6] Such methods are based on an activation–deactivation equilibrium, in which the growing radical is either in the deactivated “dormant” state or in the active state where chain growth may occur. RDRPs provide access to next-generation specialty polymers, additives and materials. The most known RDRP methods are atom-transfer radical polymerization (ATRP),^[6–10] reversible addition-fragmentation chain-transfer (RAFT) polymerization,^[11–16] nitroxide-

mediated polymerization (NMP),^[17] stable-radical-mediated polymerization (SRMP),^[18] and organometallic radical polymerization (OMRP).^[19]

Several RDRPs are industrially licensed including applications as drug delivery systems, self-healing materials, coatings, adhesives, surfactants, dispersants, lubricants, gels, thermoplastic elastomers, nanocomposites, and electronic materials.^[6,18,20–24] Enormous progress has been achieved in recycling and reducing the amount of metal catalysts, which promotes the industrial interest RDRPs.

The present thesis primarily focuses on the mechanism and kinetics of ATRP in aqueous solution. The ATRP technique has been developed independently by Matyjaszewski^[25] and Sawamoto^[26] in 1995. Mechanistically, ATRP is similar to the transition-metal-catalyzed atom-transfer radical addition (ATRA) or Kharasch-addition.^[27–29] In ATRP, an organic radical is released by halogen transfer from an alkylhalide under the action of transition-metal catalyst. Via reverse transfer of the halogen atom, the radical species is deactivated.

ATRP is a robust and versatile RDRP method, which has been used for polymerization of a wide range of monomers in bulk, in solution and in heterogeneous systems.^[6,30] ATRP in aqueous solution appears to be even more attractive, as water is non-toxic, cheap, and environmentally benign. Moreover, ATRP in aqueous solution should enable faster polymerization rate as compared to organic solvents.^[20,31,32] The enhanced rate is associated with a higher activation–deactivation–equilibrium constant. Catalysts of high activity may be used in combination with special ATRP techniques, such as ARGET, ICAR, or *e*ATRP, which allow for a significant lowering of the metal concentration.^[33–35] The associated low catalyst levels are also desirable because of toxicity concerns and cost reduction.

Cu-mediated ATRP has been extensively studied in organic solvents.^[34–44] A variety of ligands has been used for Cu-mediated ATRP. They allow for the effective tuning of catalytic activity and the application toward a wide range of monomers.^[8,36] Kinetic studies in aqueous solution are however rare and focus on electrochemical investigations or extrapolation of kinetic data measured in organic solvents toward the polarity of water.^[43,45–47] That there are so few kinetic studies in aqueous solution is due to the enhanced complexity of Cu-mediated ATRP induced by side reactions of the catalyst with water

and by the dependence of the propagation rate on the monomer concentration in aqueous solution.

An attractive alternative to the Cu-mediated ATRP is the Fe-mediated ATRP because of the lower toxicity concerns and the broad availability of iron.^[48,49] Only very poor knowledge exists about Fe-mediated ATRP in aqueous solution so far.^[1,50–54] The present thesis aims to providing accurate kinetic data on Fe-based ATRP in aqueous solution, which may allow for evaluation of the potential of this novel type of RDRP.

The reversible deactivation of radicals in Fe-based ATRP is mediated by an Fe^{III} catalyst. The reaction of radicals with Fe^{II} is relevant in Fe-mediated organometallic radical polymerizations (OMRP), but may also contribute to the ATRP scheme.^[5,19,49] Experimental and computational studies into MMA polymerization showed that both ATRP and organometallic reactions may operate simultaneously.^[19,48,55,56] Investigations into α -diimine iron complexes showed that the ligand may affect the dominating polymerization mechanism. With electron-donating groups ATRP is favored, whereas electron-withdrawing groups prefer the reaction via instable organometallic species resulting in β -hydrogen elimination.^[48,57,58] The interplay of ATRP and organometallic reactions of Fe-based catalyst in aqueous solution has not been investigated in literature before.

In the present study, spectroscopic techniques will be used to investigate the mechanism and kinetics of Cu- and Fe-based RDRP. For monomer-free model systems, as well as for actual polymerization systems of slow reaction rate, time-resolved UV/Vis/NIR spectroscopy is used.^[57,59–61] For very fast reactions, UV/Vis spectroscopy is carried out in conjunction with stopped-flow injection. Electron paramagnetic resonance (EPR) spectroscopy has turned out to be a valuable tool for the investigations into the kinetics of radical polymerization by which the type and concentration of radical species may be reliably measured.^[62–65] In conjunction with single-pulse–pulsed laser polymerization (SP–PLP) highly time-resolved EPR spectroscopy has become a powerful technique for kinetic measurements of fast reaction steps such as radical–radical termination or ATRP deactivation.^[62,66,67] For Fe-based RDRP, ⁵⁷Fe Mössbauer spectroscopy is helpful to provide information on spin state and oxidation state and to distinguish between the participating iron species.^[57,58,68] All these techniques will be applied

in the current study toward elucidating detailed ATRP kinetics in aqueous solution.

The kinetic studies will be extended up to high pressure to gain further mechanistic insight. For Fe-mediated ATRPs it has been reported that, depending on the ligand system, the activation–deactivation–equilibrium constant, K_{ATRP} , changes with pressure.^[57,69,70] The reported high pressure data for Cu systems exhibit a significantly enhanced K_{ATRP} upon increasing pressure and thus a higher polymerization rate.^[60,61] This rate acceleration is not accompanied by a higher dispersity of the polymer.^[60,61] The improved livingness of such high pressure ATRPs has been used to synthesize high molar-mass polymethacrylates and polystyrenes.

The present study deals with the in-depth investigation of the mechanism and kinetics of metal-catalyzed RDRPs and focuses on Cu- and Fe-mediated ATRP. Both catalyst systems will be examined in a monomer-free model system as well as during actual polymerizations. The study provides the first kinetic measurements of K_{ATRP} and the deactivation rate coefficient in aqueous solution for Cu- as well as for Fe-mediated ATRP. Wherever possible, the experiments will be accompanied by simulations with the program package PREDICI®.

For the investigation of the ATRP system, the propagation rate coefficient, k_p , and the composite-model parameters for termination of the monomer under investigation are required. Therefore, the propagation kinetics of the water-soluble monomer poly(ethylene glycol) methyl ether methacrylate (PEGMA) will be studied in section 3 in the absence of any metal catalyst. The dependence of k_p on monomer concentration will be determined with pulsed laser polymerization in combination with size-exclusion chromatography (PLP–SEC). The composite-model parameters for termination will be deduced via the SP–PLP–EPR technique.

Section 4 addresses the investigation of Cu-mediated ATRP with the CuBr/2,2′-bipyridine catalyst. The relevant reactions will be examined by FT–Vis/NIR spectroscopy and by SP–PLP–EPR spectroscopy within a wide range of monomer-solvent compositions. To obtain further mechanistic insight into K_{ATRP} via the reaction volumes, the Cu-mediated ATRP is studied up to 2000 bar.

Section 5 deals with mechanistic and kinetic investigations into the

porphyrin-based Fe catalysts recently developed by Simakova et al.^[1] The relevant Fe species will be examined by ^{57}Fe Mössbauer as well as by UV/Vis spectroscopy. In addition, the relevant ATRP parameters, k_{act} , k_{deact} and K_{ATRP} will be determined via SP-PLP-EPR, and UV/Vis spectroscopy in conjunction with stopped-flow injection. The spectroscopic techniques will also be applied to capture the potential interplay of OM reactions and ATRP equilibria.

2

Theoretical Background

2.1 Propagation

The propagation describes the reaction of monomer molecules, M, with a radical, R_n^\bullet , with n -numbers of monomer units resulting in new radical R_{n+1}^\bullet .

The rate of consumption of monomer is described by:

$$-\frac{d[M]}{dt} = k_p \cdot [M] \cdot [R^\bullet] \quad (2.2)$$

2.1.1 Dependence on Monomer concentration

The propagation may be assumed to be a chemical controlled reaction. The absolute value of k_p is determined by the partition functions and the Gibbs energies of the reactants and of the activated

complex. Detailed investigation of the propagation rate coefficient in polar solvents, especially water, revealed a dependency of k_p on the initial monomer concentration.^[71–77]

The increase in k_p might be caused by a higher monomer concentration in the vicinity of the propagating radical, by a lower activation energy in water or by a higher pre-exponential Arrhenius factor.

In case of polymerizations in aqueous solution with good water-soluble monomers, a higher monomer concentration in the vicinity of the radical does not explain the increase in k_p . This assumption requires an enormously large concentration gradient. Especially at highly diluted systems, all monomers would have been located in the direct vicinity of the propagation radical.

A variation of the activation energy of k_p has also been investigated for methacrylic acid (MAA) and acrylic acid (AA).^[72,75,76] It has been found that the activation energy is more or less insensitive to a variation of monomer concentration. However, slight changes of the activation energy cannot be ruled out.

The variation of k_p may be assigned to a change in the pre-exponential factor, which is composed by the partition function per volume for the reactants, \tilde{q}_M and \tilde{q}_R , and for the activated complex, \tilde{q}^\ddagger - the Eyring-Equation:

$$k_p = \kappa \cdot \frac{k_B \cdot T}{h_p} \cdot \frac{\tilde{q}^\ddagger}{\tilde{q}_M \cdot \tilde{q}_R} \cdot \exp\left(-\frac{E_0}{k_B \cdot T}\right) \quad (2.3)$$

where κ is the transmission coefficient, h_p the Planck constant and E_0 the difference of zero-point energies of the reactants of the transition state.

The pre-exponential factor is determined by the geometry of the rotating groups in the reactants and the activated complex as well as the rotational potentials of the relevant internal motions of the activated complex - the propagating center.^[78] Strong interactions of monomer molecules with the activated complex may result in a hindrance of the internal rotational and vibrational motions of the activated complex via intermolecular interactions. The lower internal rotational mobility leads to a reduced pre-exponential factor and thus a lower k_p .

2.1.2 Size-Exclusion Chromatography

Size-exclusion chromatography (SEC) is a technique to separate molecules mainly according to their hydrodynamic volume. In SEC a diluted polymer is passed through a column that contains a porous material. The separation is based on the diffusion of the polymer coils into the different sized pores of the stationary phase. Polymers with a low-molar-mass and small hydrodynamic volume will spend more time in the column than polymers with a high-molar-mass and high hydrodynamic volume as more pores are accessible. After separation, the relative concentration of the chains can be detected by different methods, e.g., absorption of UV-light or refractive index (RI).

The retention times depend on the experimental conditions such as polymer type, column type, flow rate, etc. Since the separation is by size and not by molar mass, the SEC setup has to be calibrated to obtain the molar mass of the polymer under investigation. Calibration standards are only available for a limited number of polymers. Without such standards, the molar-mass distribution can be estimated via a universal calibration.

To use a universal calibration, the SEC setup has to be calibrated with a standard. After calibration, the MMD of the polymer can be calculated via the Kuhn–Mark–Houwink–Sakurada equation, which describes the correlation of the intrinsic viscosity, $[\eta]$, and relative molecular mass, K and a are the Kuhn–Mark–Houwink–Sakurada parameters.

$$[\eta] = K \cdot M_r^a \quad (2.4)$$

Usually the intrinsic viscosity can be described by the following equation as the product of the hydrodynamic volume, V_h , and the molar mass, M .

$$[\eta] = \frac{2.5 \cdot N_A}{V_h \cdot M} \quad (2.5)$$

The combination of the two Equations 2.4 and 2.5, and the

knowledge of the Kuhn–Mark–Houwink–Sakurada parameters for the polymer used for calibration and for the polymer under investigation allow for the desired calculation of molar-mass via equation:

$$\lg M_{r,P} = \frac{1}{1 + a_p} \cdot \lg \frac{K_{St}}{K_p} + \frac{1 + a_{St}}{1 + a_p} \cdot \lg M_{r,St} \quad (2.6)$$

with the subscript P denoting the polymer under investigation and St the polymer used as the calibration standard.

2.1.3 PLP–SEC Technique

The PLP–SEC combines the pulsed-laser-polymerization with the size-exclusion chromatography. The PLP–SEC is the recommended technique by the IUPAC to determine propagation rate coefficients.

In PLP–SEC experiments, a mixture of monomer, photoinitiator and optionally of a solvent is irradiated by a sequence of very short laser pulses at a constant repetition rate, ν_{rep} , and thus at a constant time interval, t_0 . Each laser pulse generates almost instantaneously initiator radicals which start the chain growth by adding to the monomer. Because of the high radical concentration produced by each laser pulse, termination of the growing radicals occurs right after their formation by one of the subsequent laser pulses. In an ideal PLP–SEC experiment, multimodal molar-mass distributions (MMDs) are obtained with individual maxima resulting from the preferential termination of the macroradicals after multiples of t_0 .

Between two laser pulses the polymer grows. The kinetic chain length, L , reached during a growth time, t_0 , is usually best identified with the point of inflection (POI) on the low-molecular-mass side of the PLP-induced Peaks.^[79] For macroradicals which do not experience chain transfer or other side reactions, L is given by the following equation:

$$L = k_p \cdot [M] \cdot t_0 \quad (2.7)$$

The occurrence of additional POI's in the MMD at multiples of L is

an important internal consistency criterion for reliable k_p evaluation.

2.2 Termination

Termination is characterized by the reaction of two radicals. The radicals can react either by combination or disproportionation. The ratio of both termination modes is mainly monomer dependent. Highly substituted and bulky monomers favor the termination via disproportionation. In this case, the two radicals react to an unsaturated and saturated polymer species without change in chain length. In case of less steric monomers the termination occurs via combination of two radicals to one polymer species with the sum of chain length of each radical.

The termination rate is described by the following equation:

$$\frac{dc_R}{dt} = -2 \cdot k_t \cdot c_R^2 \quad (2.8)$$

$$k_t = k_{t,\text{combination}} + k_{t,\text{disproportionation}} \quad (2.9)$$

2.2.1 Chain-length Dependent Termination^[62,80]

During a radical polymerization there are macroradicals with different chain lengths present. The longer the chain length, the higher is the hydrodynamic radius and thus the lower is the diffusion coefficient.

This relationship can be expressed by the Stokes-Einstein equation:

$$D_i = \frac{k_B \cdot T}{6 \cdot \pi \cdot r_i \cdot \eta} \quad (2.10)$$

where D_i is the diffusion coefficient for macromolecular species with a chain length i , k_B is the Boltzmann constant, T the temperature, r_i the hydrodynamic radius for macromolecular species with a chain length i and η is the viscosity of the reaction mixture.

For small macroradicals, the termination rate coefficient for chain-length unity, $k_t^{1,1}$, is supposed to be controlled by center-of-mass diffusion. Thus the associated diffusion rate coefficient k_{diff} may be expressed by the Smoluchowski equation:

$$k_t^{1,1} = k_{\text{diff}} = 4 \cdot \pi \cdot P_{\text{spin}} \cdot N_A \cdot (D_A \cdot D_B) \cdot R_c \quad (2.11)$$

where P_{spin} is the probability of encounter involving a singlet electron pair, N_A the Avogadro constant, D_A and D_B are the diffusion coefficients of species A and B, and R_c is the capture radius of the radicals.

Since the termination of short macroradicals is diffusion controlled, the termination rate coefficient depends on the chain length i and j of the associated radicals and may be described by $k_t^{i,j}$, the power-law exponent α and $k_t^{1,1}$.

$$k_t^{i,j} = \frac{1}{2} \cdot k_t^{1,1} \cdot \left(\frac{1}{i^\alpha} + \frac{1}{j^\alpha} \right) \quad (2.12)$$

In case of laser-induced polymerization all radicals are generated simultaneously and have the same chain length at the same time. Therefore, Equation 2.12 is simplified to following expression:

$$k_t^{i,i} = k_t^{1,1} \cdot (i^{-\alpha}) \quad (2.13)$$

However, this simple equation does not consider that power-law

exponent α change with the chain length. To overcome this problem, Smith *et al.* introduced the following equations for short-chain radicals $i \leq i_c$ and long-chain radicals $i \geq i_c$. i_c is the so-called crossover chain-length at which point the diffusion controlled polymerization transfers to the segmental diffusion controlled polymerization.

$$k_t^{i,i} = k_t^{1,1} \cdot (i^{-\alpha_s}), \quad i \leq i_c \quad (2.14)$$

$$k_t^{i,i} = k_t^{1,1} \cdot (i_c)^{-\alpha_s + \alpha_l} \cdot i^{-\alpha_l}, \quad i \geq i_c \quad (2.15)$$

2.2.2 SP–PLP–EPR technique

The SP–PLP–EPR technique allows for high time-resolved and precise measurement of the radical concentration after single pulse laser initiation. The high time resolution of the EPR is well suited for the measurement of chain-length dependent termination, especially for short-chain radicals.

Because of the fast initiation and simultaneous propagation of the radicals, the length of propagation chains is proportional to the time t after laser pulsing.

$$i = k_p \cdot [M] \cdot t \quad (2.16)$$

The combination of the Equations 2.8, 2.14 and 2.16 and subsequent integration leads to the following expression for the radical concentration for the chain-length dependent termination:

$$\frac{c_R^0}{c_R(t)} - 1 = \frac{2 \cdot k_t^{1,1} \cdot c_R^0 \cdot t_p^\alpha}{1 - \alpha} t^{1-\alpha} \quad (2.17)$$

Where t_p denotes the characteristic time for a propagation step $([M] \cdot k_p)^{-1}$. Via a double logarithmic plot of Equation 2.17, the measured radical concentration results in linear plot with two different slopes. The intersect of the two slopes denotes the crossover chain length i_c . The

slope yields $1-\alpha$ and thus an access to composite-model exponents.

Equation 2.16 does not consider the right chain-length for very short radicals. Therefore, Russel *et al.* proposed a more precise analysis of the chain length:

$$i = k_p \cdot [M] \cdot t + 1 \quad (2.18)$$

Similar to Equation 2.17, the combination of Equation 2.8, 2.14 and 2.16 yields following more precise expression for the determination of the composite-model parameter:

$$\frac{c_R^0}{c_R(t)} - 1 = \frac{2 \cdot k_t^{1,1} \cdot c_R^0 \cdot \left((k_p \cdot [M] \cdot t + 1)^{1-\alpha_s} - 1 \right)}{k_p \cdot [M] \cdot (1 - \alpha_s)}, \quad i \leq i_c \quad (2.19)$$

2.3 Atom Transfer Radical Polymerization

2.3.1 Mechanism of ATRP^[6,20,81]

The kinetics of ATRP is superimposed on a conventional radical polymerization scheme. The ATRP mechanism is shown in Scheme Scheme 2.1. Even though ATRP has been performed with a series of transition metals, the study in hand focusses on Fe- and Cu-mediated ATRP. In metal-catalyzed ATRP, the radical propagation occurs contemporaneously with a reversible deactivation of radicals. The deactivation is mediated by Fe^{III} or Cu^{II} ($\text{Mt}^{z+1}/\text{L}_n\text{-X}$) and the metal is reduced to one oxidation state to Fe^{II} or Cu^{I} (Mt^z/L_n), respectively, with simultaneous formation of an alkyl halide. The activation rate coefficient, k_{act} , describes the rate of formation of the transient radical, R^\bullet , whereas the rate coefficient, k_{deact} , quantifies the rate of formation of the alkyl halide, R-X . The ratio of these two rate coefficients describes the ATRP equilibrium constant, $K_{\text{ATRP}} = k_{\text{act}}/k_{\text{deact}}$.

Scheme 2.1: Mechanism of Fe- or Cu-mediated ATRP; $\text{Mt}^{\text{Z}}/\text{L}_n$ represents the Fe or Cu catalyst in the lower oxidation state and $\text{Mt}^{\text{Z}+1}/\text{L}_n\text{-X}$ the Fe or Cu catalyst in the higher oxidation state with the transferred halide, R-X refers to dormant alkyl halide species, R^\bullet to the propagating radical, M to monomer, k_{t} the termination rate coefficient and k_{p} to the propagation rate coefficient. The activation and deactivation rate coefficients are described by k_{act} and k_{deact} , respectively.

In ATRP as well as in all radical polymerizations, radical–radical termination cannot be avoided. Each termination step yields to the accumulation of the deactivator Fe^{III} - or Cu^{II} -species, the so-called Persistent Radical Effect (PRE). The accumulation of the deactivator species slows down the polymerization rate. Moreover, termination leads also to a lower degree of chain-end functionality.

By properly selecting the reaction conditions, the amount of terminated chains can be lowered, as well as a high degree of control and livingness can be achieved. To match the reaction conditions to the high number of potential ATRP catalyst and initiators, various ATRP procedures have been invented. These procedures can be described by different initiation methods or different methods to reduce or reverse the accumulation of the persistent radical. A few methodologies are explained in the following.

A “normal” ATRP is initiated by the reaction of lower oxidative catalyst, e.g., Fe^{II} or Cu^{I} with an alkyl halide which is usually of chain length unity and a monomeric unit. The structure of the alkyl halide may be close to the structure of the monomer. To ensure an efficient initiation, the formed radicals by the activation step should exhibit the same reactivity as the radicals generated from the growing chain. This method can be used for accessing more complex polymer architectures

such as star polymers by using multifunctional chain initiators. However, this method is mainly suited for non-oxygen sensitive catalysts. Moreover, this technique is not suited for high active catalysts because of the accumulation of persistent radical.

In reverse ATRP (R-ATRP), the alkyl halide and the catalyst in the lower oxidation state are produced in equal amounts in situ via the decomposition of a radical initiator, for example an azo initiator. The initiator decomposition should be fast at the desired polymerization conditions to provide a fast reduction of the higher oxidative catalyst and to enable an immediate initiation of the chain-growth reaction. For fast initiation photoinitiators as well as thermal initiators may be used. This method is favored by the use of the stable oxidation state of the catalyst and is less sensitive to oxygen.

Simultaneous Revers & Normal Initiation (SR&NI) ATRP combines the advantages of normal and R-ATRP. The catalyst is reduced in situ by a thermal initiator. The majority of growing chains is then initiated analogue to the normal ATRP. SR&NI ATRP may be operated with substoichiometric amounts of catalyst to alkyl halide.

In Activators Generated by Electron Transfer (AGET) ATRP, reducing agents are used to generate in situ the catalyst in the lower oxidation state. Because of the usage of a reducing agent, the formation of new growing chains as a byproduct of reduction process with a thermal radical initiator can be ruled out. As in SR&NI ATRP the initiator type and amounts can be selected independently.

The techniques R-ATRP, SR&NI, and AGET ATRP are based on a rapid and single reduction of the catalyst in the higher oxidation state. This rapid reduction may result in a high radical concentration and subsequent radical-radical termination thus leads to the accumulation of the persistent radical and a simultaneous loss of the activator species. The accumulation of the persistent radical results also in a lower radical concentration and thus a slower polymerization rate. A continuous generation of the activator species may be desirable to increase the equilibrium concentration of growing radicals.

In Initiators for Continuous Activator Regeneration (ICAR) ATRP a thermal radical initiator is added to the polymerization solution which decomposes slowly during the polymerization and progressively reduces the catalyst in the higher oxidation state. The ATRP initiation occurs by an alkyl halide. The regenerative concept of the catalyst in the

lower oxidation state allows for a reduction of the used catalyst concentration to a ppm level. However, the slow initiator decomposition results in the formation of a background polymer, which increases the dispersity of the polymer.

In Activators ReGenerated by Electron Transfer (ARGET) ATRP, the thermal radical initiator is replaced by reducing agent that constantly regenerates the lower oxidation state of the catalyst. This method strongly reduces the formation of background polymer.

The newest method is the *e*ATRP in which the reduction of the metal catalyst is realized by an electrochemical potential. This method allows a very precise reduction rate of the catalyst by change the electrical current.

The different initiation methods will be addressed throughout the present work. The normal and reverse ATRP are most suited for kinetic studies because of the absence of background initiation and unknown reduction mechanism during an ARGET ATRP. However, ICAR and ARGET ATRP are very attractive techniques for the polymer synthesis due to the lower catalyst concentration and high livingness. These key features may also important for cost reduction for industrial use.

2.3.2 Kinetics of ATRP

The polymerization rate in ATRP under equilibrium conditions depends on the size of K_{ATRP} as well as on the concentration of the activator catalyst, Mt^Z/L , the deactivator species $\text{Mt}^{Z+1}/\text{L-X}$, and the alkyl halide, R-X , as described in the following equation:

$$R_p = -\frac{d[\text{M}]}{dt} = k_p \cdot [\text{M}] \cdot [\text{R}^*] = k_p \cdot [\text{M}] \cdot K_{\text{ATRP}} \cdot \frac{[\text{Mt}^Z/\text{L}][\text{R-X}]}{[\text{Mt}^{Z+1}/\text{L-X}]} \quad (2.20)$$

Based on Equation 2.20 K_{ATRP} may be determined by measuring the polymerization rate, the concentrations of the associated catalyst, the alkyl halide species and the monomer concentration (for details see chapter 4.2.2).

The degree of polymerization, DP , of the polymer synthesized via ATRP may be calculated by the ratio of consumed monomer, $[M]_0 \cdot conv$, to the initial concentration of the alkyl halide. The number average molar mass of the polymer, M_n , may be estimated by the product of DP and the molar mass of the monomer.

$$DP = \frac{[M]_0 \cdot conv}{[R-X]_0} \quad (2.21)$$

A well-controlled ATRP results in low dispersities, $\bar{D} = M_w/M_n$, and needs sufficient concentration of the ATRP deactivator. The dispersity may be predicted with Equation 2.22. The dispersity decreases with conversion, towards smaller initiator concentration and with decreasing ratio of k_p and k_{deact} .

$$\bar{D} = \frac{M_w}{M_n} = 1 + \frac{1}{DP} + \left(\frac{[R-X]_0 \cdot k_p}{k_{deact} \cdot [Mt^{z+1}/L-X]} \right) \cdot \left(\frac{2}{conv} - 1 \right) \quad (2.22)$$

Besides a narrow molar mass distribution of the polymer, it is also very important to obtain a polymer with a high degree of chain-end functionality (CEF). The chain-end functionality allows for a further ATRP polymerization to achieve more complex polymer architectures. Since, radical–radical termination cannot be avoided in ATRP, the degree of CEF decreases with higher conversion and higher termination rate. The loss of CEF can be described with the following equation where $[T]$ is the concentration of dead chains without a halogen end-group.

$$[T] = 2k_t \cdot [R^\bullet]^2 \cdot t = \frac{2k_t \cdot d\ln(1 - conv)^2}{k_p^2 \cdot dt} \quad (2.23)$$

2.3.3 The Persistent Radical Effect

In ATRPs without a regenerative concept of the catalyst, termination of radicals results in the accumulation of the persistent radical, i.e., the

catalyst in the higher oxidation state capped with a halogen. This accumulation is called the *Persistent Radical Effect* (PRE). To describe the PRE for ATRP and to estimate the activation-deactivation equilibrium constant, Fischer introduced the so-called $F([Y])$ -function (Equation 2.24). In order to remain consistent with previous works, $[I]_0$ represents $[R-X]_0$, $[C]_0$ refers to $[Mt^z/L]$, and $[Y]$ to $[Mt^{z+1}/L-X]$.

$$F([Y]) = \frac{([C]_0)^2}{3([C]_0 - [Y])^3} - \frac{[C]_0}{([C]_0 - [Y])^2} + \frac{1}{([C]_0 - [Y])} \quad (2.24)$$

Equation 2.24 is only valid for equimolar concentration of $[C]_0$ and $[I]_0$, and less reactive catalysts. Therefore, Tang *et al.* introduced a modified $F([Y])$ -function, which also holds for the non-equimolar case and for highly reactive catalyst.

$$F([Y]) = \left(\frac{[I]_0[C]_0}{[C]_0 - [I]_0} \right)^2 \left(\frac{1}{[C]_0^2([I]_0 - [Y])} + \frac{2}{[I]_0[C]_0([C]_0 - [I]_0)} \right. \\ \left. \cdot \ln \left(\frac{[I]_0 - [Y]}{[C]_0 - [Y]} \right) + \frac{1}{[I]_0^2([C]_0 - [Y])} \right) \quad (2.25)$$

$$F([Y]) = 2 \cdot k_t \cdot K_{\text{model}}^2 \cdot t + c' \quad (2.26)$$

The $F([Y])$ -function can only be applied in case of normal, reverse SR&NI or AGET ATRP, in which the activation-deactivation equilibrium can be reached. This equation does not consider the continuous reduction of the persistent radical. Therefore, the $F([Y])$ -function is typically determined from normal ATRP procedures. The time-dependent concentrations of the persistent radical species may be measured via online UV/Vis or Vis/NIR spectroscopy as detailed in chapter 4 and 5.3.

By plotting the $F([Y])$ -function versus time, the equilibrium constant K_{ATRP} can be determined from the slope. The estimation of K_{ATRP} requires the knowledge of termination rate coefficient, k_t . To avoid chain-length dependent variation of k_t , it is favorable to estimate K_{ATRP} via a monomer-free model system.

The termination rate coefficient in a monomer-free model system may be estimated via the assumption that the termination is accessible

by the diffusion controlled limit of the reaction (k_t^D). The detailed derivation of the following equation is described elsewhere. k_t^D may be estimated from reciprocal viscosity of the solution.

$$k_t^D = \frac{R \cdot T}{3 \cdot \eta(T, p)} \quad (2.27)$$

2.4 Experimental Techniques

2.4.1 Fourier-Transform Near-Infrared Spectroscopy

The Fourier-transform near-infrared (FT-NIR) spectroscopy is a powerful technique to determine a near-infrared spectrum of chemical substances. A scanning interferometer splits a beam of light into at least two components and then recombines these with a variable phase difference. The most common interferometer is a continuous-wave Michelson interferometer. After determination of the temporal coherence of the resulting beam, the raw data in the time domain are converted into frequency-domain data by Fourier-transformation.

Like every optical spectroscopy, the signal intensity is directly proportional to the concentration of the investigated substance and can be described by the Lambert–Beer’s law:

$$A(\tilde{\nu}) = \log \frac{I_0}{I} = \varepsilon(\tilde{\nu}) \cdot c \cdot d \quad (2.28)$$

Where $A(\tilde{\nu})$ is the absorbance at a specific wavenumber, ($\tilde{\nu}$). The concentration of the substance is denoted with c , the optical path length is d and the extinction coefficient for a specific wavenumber is $\varepsilon(\tilde{\nu})$.

The linearity of the Lambert–Beer’s law has been checked for all detectors within the spectral range of interest as detailed in refs.^[82]

2.4.2 Mössbauer spectroscopy

Mössbauer spectroscopy is based on the recoilless nuclear resonance absorption of γ -radiation by atomic nuclei bound in a solid phase. The most common form is the Mössbauer absorption spectroscopy, where a solid sample is exposed to a beam of gamma radiation and a detector measures the intensity of the beam after passing through the sample. The gamma-ray source needs to be of the same element as the sample nuclei, e.g. ^{57}Fe . The source for ^{57}Fe γ -radiation consists of ^{57}Co , which decays by electron capture to an excited state of ^{57}Fe , which in turn decays to a ground state emitting a gamma-ray of the appropriate energy. Because of the difference in chemical environments, the nuclear energy levels of the sample are shifted in different ways. These energy shifts result in large changes in absorbance, and the sample is no longer in resonance with the γ -radiation of the source. To bring the two nuclei back into resonance, the energy of the gamma ray is slightly changed by using the Doppler effect.

Shown in Figure 2.1 is an exemplary Mössbauer absorbance spectrum with the characteristic parameters. The isomer shift, $\delta / \text{mm s}^{-1}$, provides direct information on the oxidation state and spin state and may provide information about the ligand sphere of the investigated nuclei. The quadrupole splitting, ΔE_Q , a doublet of the resonance line occurs in case of unsymmetrical charge distribution of d-electrons. The peak area of the Mössbauer spectrum is proportional to the relative concentrations of the associated species in case that the relaxation rates and Lamb Mössbauer factors are identical – which they are in most cases. The line width, Γ , is determined at the half maximum.

Figure 2.1: Mössbauer spectrum of Fe^{III}/Cl-mesohemin-(MPEG₅₀₀)₂ in bulk solution recorded at 13 K. The Mössbauer doublet is characterized by the isomer shift, δ / mm s⁻¹, the quadrupole splitting, ΔE_Q , and the line width, Γ , at half maximum.

2.4.3 EPR spectroscopy

Electron paramagnetic resonance (EPR) spectroscopy is used for studying materials with unpaired electrons. The basic concepts of EPR are similar to those of NMR spectroscopy. Instead of exciting the spins of atomic nuclei, the electron spins are excited.

An EPR spectrum is typically presented as the first derivation of the absorbance spectrum. The hyperfine structure of the resonance lines provides information about the molecular structure. The EPR spectroscopy was applied in combination with single-pulse-pulsed laser polymerization (SP-PLP-EPR). This setup consists of an excimer laser (351 nm), which is placed in front of the EPR spectrometer. The cavity of the EPR spectrometer is equipped with a grid for irradiation with the laser light. A detailed description is found elsewhere.^[62]

2.4.4 Stopped-Flow Injection

Stopped-Flow measurements are used to study the chemical kinetics of fast reactions in solution. A Stopped-Flow setup may be combined with different spectroscopic and scattering of radiation methods, e.g. UV/Vis, NMR, IR, etc. The stopped-flow technique benefits from usage of small reaction volumes, very short mixing period and the kinetic equations for modeling are equivalent to those used in conventional methods.

In stopped-flow injection techniques, the sample solutions are forced from syringes into a mixing chamber. After a very short time of flow – a few ms – the flow is stopped suddenly when the observation cell is filled. The measurement is triggered by an opposing piston that is linked with the observation cell.

3

Kinetics of Poly(ethylene glycol) methyl ether methacrylate

Within the last years monomers with poly(ethylene glycol) (PEG) side chains have gained more and more attention. Depending on the length of the PEG units, these polymers are water soluble and show a tuneable lower critical solution temperature (LCST).^[83–85] PEG-based polymers and co-polymers are used in a wide field of applications such as biocompatible coatings for magnetic resonance tomography contrast agents,^[86] drug delivery systems,^[21,87] surfactants,^[12] co-monomers in emulsion copolymerization^[88] or in the synthesis of bioconjugates.^[89] Polymers with a short PEG side chain are applied as dental soft lining materials^[90] or as polymer gel electrolytes in lithium batteries.^[91]

PEG monomers are also widely used for RDR polymerizations such as RAFT and ATRP.^[1,33,92,93] A key advantage is the good solubility in water. Moreover, these monomers offer a weakly interacting and unreactive side chain which is important for polymerization systems with sensitive control agents. PEG methacrylates also provide a less sophisticated kinetic scheme with no side reactions such as backbiting.

Despite the growing scientific attention and importance of this type of monomers, the knowledge of polymerization kinetics is not adequately developed. Optimization and control of tailored polymers largely benefit from the accurate knowledge of rate coefficients.

In this chapter the rate coefficients for propagation, k_p , and the

chain-length-dependent termination, $k_t^{i,j}$, plus the associated composite-model parameters of poly(ethylene glycol) methyl ether methacrylate (PEGMA) are investigated in aqueous solution via PLP–SEC and SP–PLP–EPR, respectively.

3.1 Propagation rate coefficient by PLP–SEC of Poly(ethylene glycol) methyl ether methacrylate¹

Since the introduction of the PLP–SEC technique, which combines pulse-laser polymerization (PLP) with size-exclusion-chromatography (SEC) by Olaj *et al.*^[94,95], reliable propagation rate coefficients were determined for a large set of monomers. For several monomers in bulk, e.g., styrene,^[96] methacrylate-,^[97–100] and acrylate-type monomers,^[101,102] critically reviewed rate coefficients were reported. During recent years an enormous progress was made in the understanding of polymerization kinetics in aqueous solution by the investigation of acrylic acid,^[74,76,103–105] methacrylic acid^[75,106] and water-soluble amides.^[71,107]

However, for PEG monomers only a few investigations of k_p were reported. These reports are limited to k_p of the monomer poly(ethylene glycol) ethyl ether methacrylate (PEGEEMA) in bulk or ionic liquids.^[108,109]

This subchapter deals with the investigation of k_p via PLP–SEC in aqueous solution for poly(ethylene glycol) methyl ether methacrylate (PEGMA), which is considered with an average M_n of 500 g/mol as one of most frequently used PEG monomers in literature.^[6,21,33,52,85,92,110,111]

3.1.1 Structural analysis of PLP–SEC curves

PLP–SEC experiments to determine k_p were conducted in the concentration range from 5 wt% PEGMA in water up to bulk PEGMA

¹ All PLP–SEC experiments were carried out by Stella Weber during her bachelor thesis.

Figure 3.1: Molar mass distribution (solid lines) and associated first-derivate curves (dotted lines) for poly(PEGMA) samples from PLP experiments on aqueous solutions at 50 wt.% PEGMA, Darocur acting as initiator $c_{\text{ini}} = 5 \cdot 10^{-2} \text{ mol L}^{-1}$, $\nu_{\text{rep}} = 10 \text{ Hz}$, 30 °C (A) and bulk at $c_{\text{ini}} = 5 \cdot 10^{-2} \text{ mol L}^{-1}$, $\nu_{\text{rep}} = 15 \text{ Hz}$, 77 °C (B).

polymerization at temperatures from 22 to 77 °C. To match the PLP consistency criteria for reliable PLP–SEC experiments, initiator concentration and laser pulse repetition rate were varied. The number of applied laser pulses has been selected such as to keep monomer conversion below 10 % in order to keep monomer concentration almost constant and, on the other side, provide a sufficient amount of polymer for SEC analysis.

Shown in Figure 3.1 are typical MMD curves (solid lines) and associated first-derivate curves (dotted lines) obtained for poly(PEGMA) samples in aqueous solution and bulk PLP experiments at different reaction conditions. Depicted in Figure 3.1A is a PLP structure which is

typical for experiments carried out between 22 and 40 °C in bulk and aqueous solution, and is close to the low-termination-rate-limit (LTRL).^[112] Above 40 °C, the PLP structure changes to the one presented in Figure 3.1B which corresponds to the intermediate-termination case.^[112] In both cases the resulting first-derivative curves show several pronounced maxima, whose positions correspond to the inflection points (POI) of the MMD.

The high-molar-mass material between 10^6 and 10^7 g · mol⁻¹ without PLP structure results from continuous polymerization during and after the PLP experiment. However, the determination of k_p is not affected by this high-molar-mass material as k_p has been deduced according to Equation 2.7 from POIs at significantly lower molar masses.

A selection of arithmetic mean k_p values (complete Table see Appendix Table A2 to Table A5) deduced from the position of the POIs is listed in Table 3.1 together with all relevant experimental conditions, which are initiator concentration, c_{ini} , laser repetition rate, ν_{rep} , and monomer concentration in wt% and mol · L⁻¹. The ratio of the molecular masses at the first and second POI plus the ratio of the second and third POIs, M_1/M_2 and M_2/M_3 , respectively, is added to proof consistency and reproducibility of the measurement.

The occurrence of at least two POIs, with a multiple molecular mass of the first POI, is an important consistency criterion for reliable k_p determination via PLP–SEC.^[94,95] As can be seen from Table 3.1, the ratio of M_1/M_2 lies always above the expected value of 0.5 whereas the ratio of M_2/M_3 fulfills the expectations of 0.66. This behavior may be explained by the PLP structure. For the PLP structure close to the LTRL case, the molar mass of the first POI is estimated to be too high due to broadening and overlapping of each single signal in the MMD.^[79,113] In case of intermediate termination, the overlapping and broadening effects have only a minor influence on the POIs because of a better signal separation.^[113] The higher deviation at 10 and 5 wt% PEGMA may be caused by a low S/N ratio and monomer conversion up to 15 %.

Despite the inaccuracy of the first POI, the PLP structures provide up to six POIs. This high number of POIs allows for a particularly precise determination of k_p . Shown in Figure 3.2 are the experimental k_p values reduced by the arithmetic mean k_p values plotted against the i -th inflection point from which k_p has been calculated. The k_p values

Table 3.1: Selection of measured k_p data in dependence on ν_{rep} , initiator and monomer concentrations at 22 °C. M_1/M_2 and M_2/M_3 represents the ratio of molecular weight at particular POIs (see Table A2 to Table A5 for complete table). The k_p values are the arithmetic mean values of the second and higher POIs.

CPEGMA	CPEGMA	CInitiator	ν_{rep}	M_1/M_2	M_2/M_3	k_p

Figure 3.2: Normalized k_p values determined from the i^{th} POI, i , of various PEGMA-H₂O-compositions (PEGMA : H₂O) at 22 °C. a.-c.: $c_{\text{ini}} = 2 \cdot 10^{-2}$ mol L⁻¹, $\nu_{\text{rep}} = 20$ Hz. d.-e.: $c_{\text{ini}} = 2 \cdot 10^{-2}$ mol L⁻¹, $\nu_{\text{rep}} = 15$ Hz. f.: $c_{\text{ini}} = 2 \cdot 10^{-2}$ mol L⁻¹, $\nu_{\text{rep}} = 10$ Hz. The solid represent the arithmetic mean value of k_p from the second and higher POIs.

obtained from the first POI is always 10 to 20 % above the k_p values derived from the higher POIs. The deduced k_p values from the second and higher POIs are relatively constant and yield precise k_p values with a uncertainty of 5 %.

A further inaccuracy of k_p has been reported for high ν_{rep} . With higher ν_{rep} , k_p increases because of the change in PLP structure toward the LTRL case and thus stronger overlap. To check for a dependency on ν_{rep} , the laser pulse repetition rate has been varied between 1 and 70 Hz. As seen in Table 3.1 and Figure A3, k_p increases with ν_{rep} higher than 20 Hz. This behavior is in agreement with findings by Beuermann,^[79] and can be explained by the change of the PLP structure toward the LTRL.

The determined k_p values have also been checked for independency of the initiator concentration to prove the consistency criterion, which is fulfilled in the investigated concentration range between $5 \cdot 10^{-1}$ and $5 \cdot 10^{-2} \text{ mol} \cdot \text{L}^{-1}$ (Figure A4).

Because of the above-described effects, arithmetic mean k_p -values have been determined from the second and higher inflection points with low ν_{rep} between 5 and 15 Hz, and initiator concentrations between $2 \cdot 10^{-2}$ and $5 \cdot 10^{-2} \text{ mol} \cdot \text{L}^{-1}$.

3.1.2 Temperature and concentration dependence of k_p

As is known from other water-soluble monomers such as acrylic acid (AA)^[104], methacrylic acid (MAA)^[114], prop-2-enamides^[71], *N*-vinyl pyrrolidone^[73] and *N*-vinyl formamide^[107], the solvent water has an significant influence on the propagation rate coefficient, k_p , the Arrhenius parameter A_0 , the pre-exponential factor, and a weaker effect on E_A , the activation energy. These studies showed that k_p and A_0 increase toward lower monomer concentration.

To quantify the influence of the water concentration and the temperature on PEGMA polymerization, the k_p data were determined ranging from PEGMA bulk toward 90 wt% H₂O at 22, 30, 40, 60 and 80 °C. The water dependency will also be correlated to the structural aspects of PEGMA.

The first part of this subchapter deals with the estimate of A_0 and E_A for PEGMA in bulk. A_0 and E_A are obtained via the Arrhenius-relationship of k_p . The absolute k_p values and their dependency on water content will be discussed in the second part of this section.

The Arrhenius plots for different monomer concentrations are shown in Figure 3.3. Although these Arrhenius plots in Figure 3.3 show some scattering and indicate that the activation energy is slightly higher at lower temperatures, the k_p data have been fitted with a single straight line for each solvent composition. All data points exhibit a linear dependency and may therefore be represented by linear fits. The following discussion focuses on the Arrhenius parameter for bulk PEGMA, which is represented by the black line.

For PEGMA in bulk an E_A of 22 kJ mol^{-1} has been estimated. This value is in a good agreement with other methacrylate type monomers, e.g., methyl methacrylate (MMA), butyl methacrylate (BMA) and dodecyl methacrylate (DMA), and indicates a certain family behavior.^[97,100]

Depicted in Table 3.2 are E_A , A_0 and k_p values at 25°C for different water-soluble methacrylic monomers, such as MAA, 2-hydroxyethyl methacrylate (HEMA) and PEGEMA. Except for MAA, each monomer exhibits an E_A in the range of 22 kJ mol^{-1} in bulk which agrees with the obtained value for PEGMA. The slightly higher $E_A = 24 \text{ kJ mol}^{-1}$ for PEGEMA may be caused by the structural difference through an additional CH_2 -group at the end as well as the shorter poly(ethylene glycol) ether group.

The small E_A value of MAA, 16 kJ mol^{-1} , demonstrates that MAA does not behave like a typical methacrylate. The difference with MAA may be explained by a special behavior of the carboxylic end group which affects the reaction barrier of the propagation process by hydrogen-bonded interactions.^[72,114] All other examples of water-soluble monomers have an ester functionality which may interact only to a weaker extent with the radical functionality of the propagating radical.

The fact that the monomer interacts with the radical functionality may also influence the vibrational and rotational motion in the transition state for propagation. For this reason it seems worthwhile to compare the second Arrhenius parameter, A_0 , which is linked to the mobility of the radical, for PEGMA with the other monomers in Table 3.2.

Figure 3.3: Variation of k_p for PEGMA with temperature and three different monomer mass fractions in aqueous solution. The straight lines represent an Arrhenius fit.

The A_0 values in Table 3.2 are varying by one order of magnitude from $A_0 = 0.4 \cdot 10^6 \text{ L mol}^{-1} \text{ s}^{-1}$ for MAA to $A_0 = 8.9 \cdot 10^6 \text{ L mol}^{-1} \text{ s}^{-1}$ for HEMA. A_0 for PEGMA lies in the middle of these values at $3.5 \cdot 10^6 \text{ L mol}^{-1} \text{ s}^{-1}$ which is not surprising, as MAA and HEMA are monomers with special properties.

The very small A_0 for MAA might be explained by the carboxylic acid group of MAA. The carboxylic acid group is known to strongly interact with other MAA molecules, as is shown by the spectroscopic detection of cyclic MAA dimers.^[115] For this reason, it is expected that MAA in bulk exhibits a high barrier for internal rotational motion of the transition state and thus A_0 is strongly reduced.^[75]

On the contrary, HEMA is a carboxylate ester with a hydroxyethyl group. The ester group and the short side chain may weakly interact

Table 3.2: Activation energies, Arrhenius pre-exponential factors and k_p -values at 25 °C for different methacrylic monomers in bulk.

	E_A / kJ mol ⁻¹	A_0 / (10 ⁶ L mol ⁻¹ s ⁻¹)	k_p / L mol ⁻¹ s ⁻¹
Methacrylic acid ^[75,106]	16	0.4	600
2-Hydroxyethyl methacrylate ^[99]	22	8.9	1200
PEGEEMA ^[109]	24	9.3	489
PEGMA	22	3.5	500

with the propagation center of HEMA. The weak interaction yields a higher internal rotational freedom, which is reflected by a high $A_0 = 8.9 \cdot 10^6$ L mol⁻¹ s⁻¹.

Besides the almost identical poly(ethylene glycol) side chain, PEGMA and PEEGEMA are distinguished by a shorter poly(ethylene glycol) side chain for PEGEEMA. Because of the shorter side chain, it is expected that the rotational mobility of the radical functionality is increased, and thus results in a higher A_0 . It should be noted that E_A and A_0 are correlated with each other and a higher estimated E_A for PEGEEMA may yield accordingly a higher A_0 .

Since the vibrational and rotational motions of the transition state are linked to A_0 , it seems necessary to check the impact of the water concentration on the activation energy, E_A , and the pre-exponential Arrhenius factor, A_0 . Shown in Figure 3.3 are the Arrhenius plots for bulk, 30 and 50 wt% PEGMA water mixtures. The fits of bulk and 30 wt% PEGMA feature a similar slope, whereas the linear increase of 50 wt% PEGMA is lower. The activation energy for bulk, 50 wt% and 30 wt% PEGMA has been determined to be 22 kJ mol⁻¹, 19 kJ mol⁻¹, 23 kJ mol⁻¹, respectively (see also Table 3.3). As shown in Figure 3.3, k_p increases additionally with the water content.

To check the quality of the Arrhenius plots, 95% joint confidence intervals (JCI) were estimated for the measured concentration range. Depicted in Figure 3.4 are JCIs corresponding to the Arrhenius plots in

Figure 3.4: 95 % joint confidence region for the Arrhenius parameters of k_p for PEGMA for various monomer mass fractions in aqueous solution. The symbols (X) indicate the best estimates of Arrhenius activation energy and pre-exponential factor.

Figure 3.3. These JCIs were obtained by a nonlinear least-squares fit assuming a constant error of k_p as suggested by van Herk.^[116] The JCIs are not overlapping, however regarding the experimental uncertainty of $\Delta E_A = \pm 2 \text{ kJ mol}^{-1}$ it may be justified to assume that the activation energy is independent of monomer concentration, and $E_A = 21 \text{ kJ mol}^{-1}$. This behavior has also been observed for MAA, various acrylamides and AA at high monomer concentrations, those activation energies are also independent of monomer concentration.^[71,104,114]

E_A being independent of the water concentration indicates that H_2O has no effect on the reaction barrier of the propagating radicals of PEGMA and thus the increase in k_p is not induced by lowering the reaction barrier. Considering the absence of hydrogen-bonded interactions of PEGMA with itself and with the aqueous environment it

could be expected that water has no effect on the reaction barrier. For MAA it has been reported that hydrogen-bonded interactions with water molecules appear to have an almost identical effect on the reaction barrier as MAA molecules.^[114]

Since an increase in k_p may not be induced by a change of E_A , another fact that needs to be discussed is the impact of water content on A_0 . Shown in Figure 3.5 are the estimated A_0 values for bulk, 50 and 30 wt% under the assumption that E_A is constant at 21 kJ mol⁻¹. From bulk to 50 and 30 wt% PEGMA/H₂O A_0 increases in a linear fashion by a factor 4 from 3.5 to 9.3 and 14.4 · 10⁶ L mol⁻¹ s⁻¹, respectively.

Listed in Table 3.3 are the estimated A_0 and associated k_p values at 25 °C for bulk, 50 and 30 wt% PEGMA in water. Although an increase in A_0 with the water concentration is associated with an increased k_p , the k_p values exhibit an increase only by a factor of 3 instead of a factor 4 as it was found for A_0 . However, this increase is still consistent with the previously discussed theory of a better rotational motion and thus a higher k_p .

The same behavior has been observed for MAA in water. In contrast to PEGMA, A_0 for MAA exhibits a stronger increase, by one order of magnitude, from bulk $A_0 = 4.0 \cdot 10^5$ L mol⁻¹ s⁻¹ toward $A_0 = 3.64 \cdot 10^6$ L mol⁻¹ s⁻¹ at 5 wt% MAA.^[75,114] It should be noted that due to the high molar mass of PEGMA the concentration of 30 wt% PEGMA correspond to 0.57 mol · L⁻¹, whereas 5 wt% MAA in water compares to 0.59 mol · L⁻¹ which is almost the same molar monomer concentration.

Shown in Figure 3.6 is a semi-logarithmic plot for the A_0 -values of PEGMA and MAA versus monomer concentration at 20 °C. A_0 was calculated from the k_p values extracted from Figure 3.7 below with the approximation of E_A being independent of monomer concentration. The A_0 values for PEGMA are by one order of magnitude above the ones for MAA bulk. At infinite dilution, the difference is reduced to a factor of 4.

A_0 for PEGMA increases in a linear fashion from bulk toward highly diluted aqueous solutions. On the contrary, the water dependence of A_0 for MAA may follow an exponential course. Between 50 wt% and bulk MAA the increase in A_0 is almost identical to the one for PEGMA. At higher water concentration above 50 wt% the increase in A_0 for MAA is more pronounced.

Figure 3.5: Variation of A_0 for PEGMA with the water content. The A_0 are obtained from the Arrhenius plot of Figure 3.3 under the assumption that E_A is constant at 21 kJ mol^{-1} . The straight lines represent the best fit (the results are replicated in Table 3.3).

Table 3.3: Arrhenius parameter and k_p for PEGMA at 25°C for various PEGMA/ H_2O mixtures.

wt% PEGMA	100	50	30
$E_A / \text{kJ mol}^{-1}$	21 ± 2	21 ± 2	21 ± 2
$A_0 / (10^6 \text{ L mol}^{-1} \text{s}^{-1})$	$2.1 \leq 3.5 \leq 8.0$	$5.9 \leq 9.3 \leq 10.7$	$6.2 \leq 14.4 \leq 23.0$
$k_p(25^\circ\text{C}) / \text{L mol}^{-1} \text{s}^{-1}$	500	1400	1700

The stronger water dependency of A_0 for MAA might be explained by the carboxylic moiety which allows for stronger intermolecular interactions through hydrogen bonds and dipole-dipole interactions.

Figure 3.6: Variation of A_0 with monomer concentration in aqueous solution for MAA and PEGMA at 20 °C. A constant E_A for MAA and PEGMA were used with 16 kJ mol⁻¹ for MAA and 21 kJ mol⁻¹ for PEGMA.

For bulk polymerization, the interactions of MAA may be stronger with the propagating center. This leads to a more pronounced retardation of k_p . Upon replacing MAA by H₂O molecules in the direct vicinity of the propagating center at high dilution, the interaction of water molecules weakens the influence of MAA molecules on the propagating center and result in a better internal rotational freedom of the radical functionality.^[106]

PEGMA, on the contrary, bears a very weak proton acceptor side chain with weak dipole-dipole interactions. This leads to a small hindrance of the internal rotational mobility. The fluidizing effect of water is less pronounced for monomers with a high mobility even in bulk.

As described above, A_0 increases with the water content and that E_A is independent of the H₂O concentration. The next part focusses on the water dependency of k_p in correlation with the obtained Arrhenius parameters.

The k_p values in bulk of various water-soluble methacrylates show a

correlation between A_0 and k_p . The k_p values for different water-soluble methacrylates such as MAA, HEMA and PEGEEMA in bulk at 25 °C are listed in Table 3.2. The structure of PEGEEMA and PEGMA is almost identical, therefore the k_p values are very similar with 490 L mol⁻¹ s⁻¹ for PEGEEMA and 500 L mol⁻¹ s⁻¹ for PEGMA.^[109]

For HEMA, a much higher k_p value of 1200 L mol⁻¹ s⁻¹ was obtained than for PEGMA.^[99] The relatively high k_p in bulk may be explained by the short alcoholic side chain, which provides a small dipole-dipole moment and thus a weak hindrance to internal rotational mobility. This is also reflected in the high A_0 value.

Although MAA exhibits the smallest A_0 from the listed monomers the k_p value is slightly higher than for PEGMA due to the lower activation energy.

After discussing the differences of k_p in bulk, the change of k_p with monomer concentration is of interest, since the evolution of k_p with monomer concentration varies with the type of monomer.^[71,76,114] The comparison focus on MAA and PEGMA. The already investigated water-soluble amides are not considered here because they represent a completely different monomer family.

From the right column of Table 3.1 the following conclusion can be drawn: k_p is strongly decreasing from highly diluted solutions of PEGMA, $k_p = 3200$ L mol⁻¹ s⁻¹, toward bulk polymerization, $k_p = 500$ L mol⁻¹ s⁻¹. Shown in Figure 3.7 is the variation of k_p over the entire concentration range for PEGMA and MAA in aqueous solution at 20 °C.

The data for PEGMA plotted in Figure 3.7 were fitted with the following expression:

$$k_p / (\text{L mol}^{-1} \text{s}^{-1}) = 5643 - 1086 \cdot \ln(c_{\text{PEGMA}} / (\text{wt}\%) + 5.989) \quad (3.1)$$

As seen in Figure 3.7, k_p increases toward lower monomer concentration. The propagation rate coefficient of PEGMA increases by a factor of 7 from bulk, $k_p = 500$ L mol⁻¹ s⁻¹, toward infinite dilution, $k_p \approx 3700$ L mol⁻¹ s⁻¹. For methacrylic acid (MAA) a stronger increase by a factor 13 of k_p has been observed from bulk, $k_p = 600$ L mol⁻¹ s⁻¹, toward

Figure 3.7: Variation of k_p with monomer concentration for polymerizations of PEGMA in water with different initiator concentration at 22°C.

infinite dilution, $k_p \approx 7500 \text{ L mol}^{-1} \text{s}^{-1}$. This increase in k_p becomes more pronounced in highly diluted solutions of PEGMA and MAA. PEGMA shows an almost linear increase in k_p from bulk toward 30wt% PEGMA, whereas MAA shows a very weak increase in k_p above 60 wt%. For higher dilutions, the increase in k_p is more pronounced for both monomers. The increase in k_p for MAA is however significantly stronger than for PEGMA. The stronger water influence at higher dilution is consistent with the findings for A_0 , shown in Figure 3.6. Through the connection of A_0 and k_p , the strong increase in k_p may be explained by the higher internal rotational freedom of the transition state for propagation.

The influence of the ethylene glycol side chain of PEGMA may explain the difference between the absolute values of k_p at infinite dilution with $k_p = 3700 \text{ L mol}^{-1} \text{s}^{-1}$ for PEGMA compared to $k_p \approx 7500 \text{ L mol}^{-1} \text{s}^{-1}$ for MAA. The tenfold higher A_0 value in combination with a smaller k_p for PEGMA suggests that the internal rotational freedom of the transition state for propagating radical is less hindered and that the

fluidizing effect of water is less pronounced for monomers with high A_0 values in bulk.

3.1.3 Dependence of k_p on NaBr concentration

Figure 3.8: Variation of k_p with sodium bromide and laser repetition rate at 50 wt% PEGMA and 22 °C.

In later chapters the mechanism, equilibrium constant, deactivation rate coefficient of ATRP will be investigated under polymerization conditions. As described in chapter 4, ATRP in water requires a high excess of sodium bromide (NaBr) to the solution to prevent halide dissociation. Therefore it seems necessary to check for potential variations of k_p with sodium bromide concentration.

Depicted in Figure 3.8 is the variation of k_p for 50 wt% PEGMA in H_2O with and without NaBr (0.5 mol L^{-1}) at 22 °C. Within the calculations of k_p with NaBr the change of density and viscosity due to the addition of NaBr has been ignored.

The k_p values exhibit a small variation with laser repetition rate. As described in chapter 3.1.1, a lower k_t may shift the PLP structure to the LTRL, which yields a slightly higher k_p .

At $\nu_{\text{rep}} = 10$ Hz and 0.5 mol L^{-1} NaBr k_p is $1435 \text{ L mol}^{-1} \text{ s}^{-1}$ and thus agrees within experimental error with $k_p = 1400 \text{ L mol}^{-1} \text{ s}^{-1}$ measured without added NaBr. Consequently, k_p appears to be independent of NaBr concentration. This behavior is in agreement with the assumption that PEGMA has no ionized form which may interact with bromide or sodium ions. The same behavior has already been observed for non-ionized MAA and AA in aqueous solution.^[72,76]

3.2 Termination rate coefficient by SP–PLP–EPR of Poly(ethylene glycol) methyl ether methacrylate

Information about the termination kinetics is important for conventional radical polymerization and for predictions of these polymerizations. In contrast, RDRP reactions experience only small or even insignificant termination in the equilibrium state. However, for determination of individual reaction rate coefficients of RDRP, e.g., the rate of deactivation, k_{deact} , in ATRP, the knowledge of the termination rate, especially of chain-length-dependent termination rate coefficients, $k_t^{i,j}$, is crucial.

For the direct measurement of the radical concentration, the combination of single-pulse (SP) pulsed laser polymerization (PLP) with electron paramagnetic resonance (EPR) spectroscopy has evolved as a reliable tool for the determination of chain-length-dependent termination rate coefficients.

In this section, the termination rate coefficient and the composite-model parameters were determined for 30, 50 and 70 wt% PEGMA in aqueous solution at 20 °C via SP–PLP–EPR.

3.2.1 EPR spectrum of PEGMA

The EPR spectrum of methacrylates may be distinguished by a characteristic splitting pattern which mainly results from interactions of the unpaired electron with hydrogen atoms and the presence of different conformers in solution. Depicted in Figure 3.9 is the EPR spectrum measured during a polymerization of PEGMA in 50 wt% water. The spectrum was recorded with a 3 G modulation amplitude in conjunction with a modulation frequency of 100 kHz, a receiver gain of 84 and an attenuation of 13 dB under continuous laser irradiation at 20 Hz and 20 °C. A typical methacrylate spectrum consists of 13 lines, 5 more intense lines at a distance of ca. 20–25 G and 8 inner lines.^[117–120] The intensity of the 8 inner lines is strongly temperature dependent and decreases toward lower temperature.^[120] Because of the hindrance of the rotation around the C_α – C_β backbone axis, two conformers with different

coupling constants of methylene hydrogen atoms coexist and contribute to the overall EPR spectrum. This effect has also been observed for monomers with a sterically demanding side group like *tert*-butyl methacrylate and generally at high monomer conversions.^[117,120,121] Figure 3.9 shows a spectrum with 5 intense lines, in which the 8 inner lines cannot be distinguished anymore due to the steric demands of the poly(ethylene glycol) side chain.

Figure 3.9: EPR spectrum of PEGMA 50 wt% in aqueous solution at 20 °C with a 3 G modulation amplitude, a modulation frequency of 100 kHz, a receiver gain of 84 and an attenuation of 13 dB under laser irradiation at 20 Hz. The red arrow indicates the field position for the measurement of concentration vs time profiles.

3.2.2 Composite-model parameters

Single laser pulse experiments for the determination of the composite-model parameter $k_t^{1,1}$, α_s , α_l and i_c were carried out at a constant field of 3332 G (indicated by the arrow in Figure 3.9) for various PEGMA-water mixtures at 20 °C.

Darocur has been chosen as the photoinitiator due to its good solubility and the good initiation behavior for methacrylates.^[122] The concentration was set to 0.02 mol · L⁻¹, which yields an initial radical concentration, c_r^0 , of around 1 · 10⁻⁵ mol · L⁻¹ per laser pulse. A monomer conversion up to 15 % may be reached, which was substantiated by FT-NIR spectroscopy. Because of the fast initiation and the fast first propagation step, no interference of the signals derived from initiator on propagating radicals were observed. The monomer concentration has been kept low and was determined from the arithmetic mean of the conversion measured before and after laser pulsing.

Shown in Figure 3.10 are the normalized time-resolved EPR spectra for 30, 50 and 70 wt% PEGMA that have been recorded at the signal maximum of 3332 G and 20 °C. For a better signal-to-noise ratio at least 20 individual concentration vs time traces were co-added. After laser irradiation at $t = 0$, the radical concentration increases instantaneously by initiator decomposition plus the subsequent addition to the monomer and decreases by radical-radical termination. Because of enhanced termination at lower PEGMA and higher H₂O content, the radical decay becomes faster from 70 to 30 wt% PEGMA. From the SP-PLP-EPR spectra, the composite-model parameters were deduced by a two-step procedure.

In the first evaluation step, the composite-model parameters i_c and α_l were determined by plotting $\log(c_r^0/c_r - 1)$ vs $\log(t)$ according to Equation 2.17. Depicted in Figure 3.11 is an example of the corresponding plot for 70 wt% PEGMA in water at 20 °C. Two straight lines may be fitted to the double-log plots, one for short-chain radicals at $t \leq i_c$ and the other for long-chain radicals $t \geq i_c$. The slope of each fit corresponds to $1 - \alpha$. The intersection of the straight lines indicates the crossover time t_c , which yields the crossover chain length i_c by multiplying with k_p and monomer concentration. The data of k_p required for the composite-model parameter were previously determined in chapter 3.1.

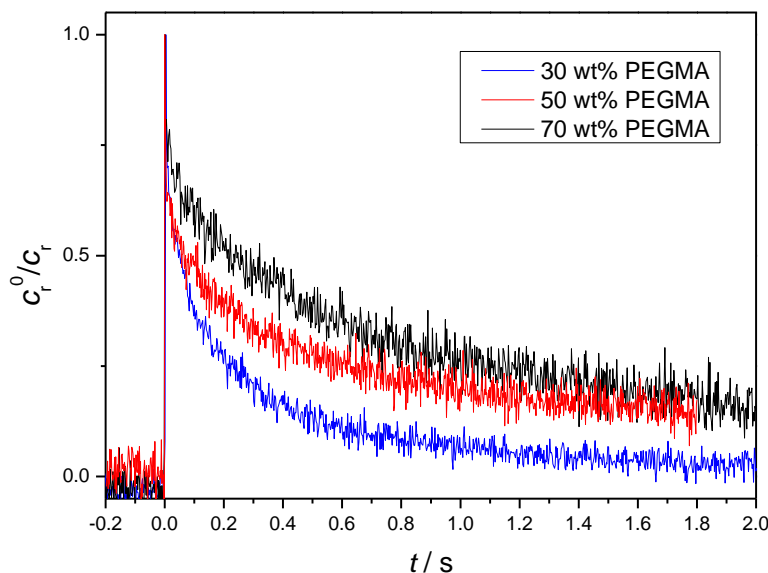

Figure 3.10: Normalized radical concentration vs time profiles for PEGMA in aqueous solution with 30, 50 and 70 wt% PEGMA at a constant magnetic field of 3332 G and 20 °C.

In Table 3.4 the composite-model parameters are listed, as determined by the double-log plot for 30, 50 and 70 wt% PEGMA in aqueous solution at 20 °C. For the long-chain radicals at 30, 50 and 70 wt% PEGMA, α_l has been determined to be 0.28, 0.30 and 0.25, respectively. For 30 and 50 wt% PEGMA, the uncertainty is higher as for 70 wt% and lies around $\Delta\alpha_l = 0.10$. The α_l values for all concentrations are in agreement with theoretical α_l values around 0.10 to 0.25 for the long-chain radicals.^[123–125] Moreover, various methacrylates provide an α_l value around 0.20. No dependence on the size and structure of the side chain has been found for the methacrylates.^[63,117,118]

The α_s values deduced from the short-chain region are similar for all PEGMA mixtures: $\alpha_s \approx 0.65$. The double-log procedure, however, does not adequately represent termination kinetics at very short chain lengths. Consequently, $k_t^{1,1}$ and α_s values were determined according to Equation 2.19.

Figure 3.11: Double-log plot of the SP-PLP-EPR data for PEGMA/H₂O in 70 wt% PEGMA at 20 °C. Analysis of the long-chain regime yields α_l ; the crossover chain length i_c is obtained by the intersection of the two straight lines. An accurate number for α_s is obtained by the procedure illustrated in Figure 3.12.

Table 3.4: Composite-model parameters α_s , α_l and crossover chain length i_c for various PEGMA compositions in aq. solution estimated by the double-log procedure.

system at 20 °C	α_s	α_l	i_c
70 wt% PEGMA	0.63 ± 0.05	0.25 ± 0.09	200 ± 80
50 wt% PEGMA	0.63 ± 0.04	0.30 ± 0.11	150 ± 70
30 wt% PEGMA	0.69 ± 0.07	0.25 ± 0.09	70 ± 20
DMA bulk ^[126]	0.65 ± 0.08	0.17 ± 0.04	150

In this second evaluation step, the measured EPR data for $i \leq i_c$ are plotted as $c_r^0/c_r - 1$ vs. time. They were fitted by a least-squares procedure, as illustrated in Figure 3.12. i_c is again obtained by the intersection of the straight lines from the double-log plot (Figure 3.11) and will be discussed in detail later. The fit in Figure 3.12 yields α_s as a single composite-model parameter and $k_t^{1,1} \cdot c_r^0$ as a combined value. From calibration with TEMPOL, as described in chapter 7.4.3, the initial radical concentration c_r^0 is available and thus are $k_t^{1,1}$ values.

The obtained α_s and $k_t^{1,1}$ values are listed in Table 3.5 together with the measured viscosity (η) of the mixture prior to polymerization and the product of $k_t^{1,1} \cdot \eta$. As mentioned above, the α_s values are little higher than the ones obtained by the procedure shown in Figure 3.11 due to the correct consideration of short chains. The α_s values vary around 0.69 with no obvious concentration dependence. The values fit also very well to results obtained with various other methacrylates, whose α_s were determined to be around 0.65.^[117,118,127] In contrast, for acrylates α_s values of 0.80 have been found.^[63,128]

The deduced $k_t^{1,1}$ values are summarized in Table 3.5. For PEGMA in water, $k_t^{1,1}$ increase from $k_t^{1,1} = 4.3 \cdot 10^6 \text{ L mol}^{-1} \text{ s}^{-1}$ at 70 wt% PEGMA to $k_t^{1,1} = 27.4 \cdot 10^6 \text{ L mol}^{-1} \text{ s}^{-1}$ at 30 wt% PEGMA. Since the termination kinetics of radicals with hypothetical chain length unity is strongly diffusion controlled, $k_t^{1,1}$ should be proportional to solution fluidity, i.e. the inverse viscosity η^{-1} . As a consequence, $k_t^{1,1}$ is described by the two Equations 2.10 and 2.11. An upper limit for $k_t^{1,1}$ may be expressed by $k_t^{\max} = 1RT/3\eta$, which is the so-called diffusion limit. The values for the diffusion limit lie above the measured data due to the neglect of a shielding of the radical site in Equation 2.11.

Illustrated in Figure 3.13 are experimental $k_t^{1,1}$ data and the calculated k_t^{\max} values. Both coefficients show a similar slope with increasing water content and thus $k_t^{1,1}$ behaves as expected. In the same context the product of $k_t^{1,1} \cdot \eta$ should yield a constant value for each solvent mixture. This is indeed the case as the values in Table 3.5 are all close to $1.3 \cdot 10^8 \text{ L mol}^{-1} \text{ mPa}$. The product $k_t^{1,1} \cdot \eta$ relates to the

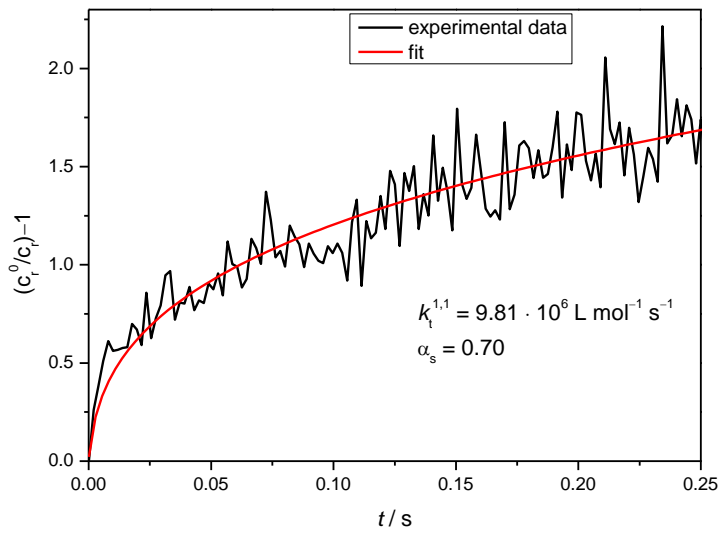

Figure 3.12: Least-squares fit for the determination of α_s and $k_t^{1,1}$ for 50 wt% PEGMA/H₂O at 20 °C. The solid line corresponds to the best fit.

Table 3.5: Termination rate coefficient $k_t^{1,1}$ and α_s for various PEGMA/H₂O mixtures at 20 °C estimated by a least-square fit. Additional values for $k_t^{1,1} \cdot \eta$ and viscosity are given for the particular system.

system at 20 °C	α_s	$k_t^{1,1} /$ ($10^6 \text{ L mol}^{-1} \text{ s}^{-1}$)	$\eta /$ (mPa · s)	$k_t^{1,1} \cdot \eta /$ ($10^8 \text{ L mol}^{-1} \text{ mPa}$)
70 wt% PEGMA	0.67	4.3 ± 1.2	29.4	1.3
50 wt% PEGMA	0.70	9.8 ± 1.2	12.3	1.2
30 wt% PEGMA	0.69	27.4 ± 3.5	4.68	1.3
DMA bulk ^[126]	0.65	28.5 ± 1.5	4.63	1.3

Figure 3.13: Solvent dependence of $k_t^{1,1}$ and diffusion limit for various PEGMA/H₂O compositions at 20 °C.

hydrodynamic radius, r_h , and shielding of the radical site.^[129]

PEGMA as a sterically demanding monomer is structurally similar to DMA. Both monomers possess a long side chain and an α -methyl group. They exhibit a similar viscosity at 20 °C. In Table 3.5 are listed the $k_t^{1,1}$, α_s , η and $k_t^{1,1} \cdot \eta$ values for DMA in bulk at 20 °C. For 30 wt% PEGMA in H₂O $k_t^{1,1}$ is $27.4 \cdot 10^6 \text{ L mol}^{-1} \text{ s}^{-1}$ and DMA bulk $k_t^{1,1}$ is $28.5 \cdot 10^6 \text{ L mol}^{-1} \text{ s}^{-1}$. Both values of $k_t^{1,1}$ lie in the same range and are in good agreement with theoretical expectations due to similar viscosities of 30 wt% PEGMA and DMA bulk being 4.68 and 4.63 mPa · s, respectively. Yet, it should be considered that the knowledge of the viscosity does not provide $k_t^{1,1}$, as R_c and the hydrodynamic radius may vary with the type of monomer. As PEGMA and DMA are structurally similar, it seems reasonable to assume that both monomers provide a similar R_c/r_h .

Since $k_t^{1,1}$ is closely connected to viscosity, it seems plausible to extrapolate $k_t^{1,1}$ values at given temperatures via the viscosity of the actual mixture. It has also been shown that $k_t^{1,1}$ has a more or less comparable temperature dependence as the inverse

viscosity.^[62,122,128,130,131] Therefore it is not necessary to measure $k_t^{1,1}$ values for every temperature. In favorable cases, only a single $k_t^{1,1}$ value in combination with viscosity measurements may allow to estimate $k_t^{1,1}$ values.^[126,130,131] The same appears to be true for α_s being independent of temperature and solvent mixture composition.^[62,122,128]

However, the characteristic composite-model parameter i_c is not necessarily independent of temperature and solvent composition. i_c is estimated by the intersection of the straight lines in Figure 3.11, which were used to determine the power-law exponents in Figure 3.11 and Figure 3.14.

As seen in Figure 3.11 and Figure 3.14, the i_c values exhibit a solvent dependency and i_c is decreasing from 200 toward 70 for 70 and 30 wt% PEGMA in aqueous solution. In Table 3.4 are listed the i_c values for various PEGMA/H₂O mixtures at 20 °C. Similar high i_c values between 200 and 100 were also found for sterically demanding monomers such as DMA, *tert*-butylmethacrylate, EHMA and dodecylacrylate (DA).^[126,128]

The difference in i_c might be caused by chain-length-dependent propagation, which would result in a lower α_s value. This theory can be discarded in this case as α_s is independent of water concentration. This is in agreement with other observations for α_s being independent of temperature and solvent type.^[62,128]

The influence on i_c of a too high k_p can be excluded. To achieve a constant i_c , k_p would have to be by a factor 2 lower to 900 L mol⁻¹ s⁻¹ for the experiments with higher water content. Such low k_p value would not be consistent with the findings in chapter 3.1.

A final explanation for a changing i_c with the solvent environment and monomer cannot be given at this point. An increasing i_c with longer side chain has been reported for vinyl acetate and vinyl pivalate as well as for acrylates.^[128,131] This effect is explained by the assumption that i_c is related to chain flexibility and that chains with more spherical pendant groups exhibit a higher i_c due to higher stiffness.^[117] For acrylates it has been found that i_c decreases from bulk to solutions in toluene.^[128]

For DMA and EHMA it has been observed that i_c is temperature dependent which has been assigned to a better chain flexibility at elevated temperatures.^[126] This observation suggests enhanced segmental mobility at higher temperature which allows for easier entanglement of macroradicals already at smaller size of the growing radicals. This explanation is corroborated by the assumption that the

Figure 3.14: Double-log plot of the SP-PLP-EPR data for PEGMA/H₂O in 30 wt% PEGMA at 20 °C. Analysis of the long-chain regime yields α_l , the crossover chain length i_c is obtained by the intersection of the two straight lines.

crossover-chain length is associated with a transition from translational diffusion control to segmental diffusion control toward larger i . According to this argument, the lowering of i_c toward higher water content indicates increasing mobility. This interpretation is consistent with the observed enhancement of PEGMA k_p upon passing to higher water content.

Apart from the correlation of i_c with chain flexibility within a monomer family, i_c should be considered as an empirical parameter, which describes the transition from translational diffusion control of short-chain radicals toward the segmental diffusion control of long-chain radicals.

4

Cu-mediated ATRP in aqueous solution

This chapter deals with the measurement of ATRP-relevant rate coefficients and equilibrium constants for the CuBr/2,2'-bipyridine catalyst in aqueous solution. The ATRP parameters will be investigated for the monomer-free model system and an actual polymerization with PEGMA via both online FT-Vis/NIR spectroscopy and the highly time-resolved SP-PLP-EPR technique. The deactivation rate coefficient, k_{deact} , is directly measured in aqueous solution for the first time. The precise knowledge of ATRP rate coefficients allows for the prediction of polymerization rate, monomer conversion vs time, dispersity and chain-end functionality. Therefore, the measurements are accompanied with PREDICI[®] simulations to provide further guidance for suitable reaction conditions.

With the exception of electro-chemical studies by the Matyjaszewski group,^[43,47] in which ATRP equilibrium constants and rate coefficients have been measured via cyclovoltametry in aqueous solution, such ATRP data have so far been only obtained either by extrapolation via linear solvation energy correlations, by analysis in terms of Kamlet-Taft parameters or by scaling against solvent polarity and dielectric constant of the organic solvents.^[46] Extrapolation of K_{ATRP} values measured in organic solvents on a polarity scale suggests that K_{ATRP} in an aqueous environment should be by one to four orders of magnitude above K_{ATRP} in typical organic solvents.^[42] This enhancement of K_{ATRP} may probably

be due to an increase of k_{act} because of the higher charge of Cu^{II} and because of Cu^{I} complexes potentially occurring as non-charged species.^[132] The preference for $[\text{Cu}^{\text{II}}\text{L}_n\text{X}]^+[\text{X}]^-$ over $[\text{Cu}^{\text{I}}\text{L}_n]^+[\text{X}]^-$ in highly polar solvents has also been predicted by quantum-chemical calculations.^[41] The direct measurement of k_{act} , k_{deact} and K_{ATRP} in aqueous solution in the present study aims at understanding the increase in K_{ATRP} .

However, the kinetics of ATRP in aqueous solution are complicated due to potential halide dissociation of the penta-coordinated $[\text{Cu}^{\text{II}}\text{L}_n\text{X}]^+[\text{X}]^-$ complex and formation of a hydrated halide ion, which as shown in the lower part of Scheme 4.1 below.^[38] Polar solvent molecules, such as H_2O , also occupy coordination sites and substitute the halide ligand to the inactive $[\text{Cu}^{\text{II}}\text{L}_n(\text{H}_2\text{O})]^{2+}$ deactivator complex due to the absence of halide.

Matyjaszewski *et al.* showed that the unfavorable transformation to the hydrated species occurs up to 92 % for $[\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}]^+[\text{Br}]^-$ in pure water.^[38] The associated reduction in deactivator concentration results in poor control of the ATRP. By adding halide ions, e.g., sodium salts or organic halide salts, the dissociation equilibrium may be shifted to the side of the active ATRP species $\text{Cu}^{\text{II}}\text{L}_n\text{X}$.^[38]

4.1 Monomer-Free Model System²

Due to the absence of monomer, the reaction scheme for the monomer-free ATRP model system consists of three reaction steps: ATRP activation, ATRP deactivation and termination of two small radicals. This simplified model system is perfectly suited for the direct investigation of the effect of water on the activation–deactivation equilibrium without the interference PEGMA propagation kinetics which depends on water concentration.

The measurements of the equilibrium constants for a monomer-free model system, K_{model} , and of the activation rate coefficients, k_{act} , were

² Reproduced with permission from Smolne, S.; Buback M. *Macromolecular Chemistry and Physics* **2015**, 216, 894-902, Copyright 2015 John Wiley and Sons.

carried out in a solvent mixture of H₂O and poly(ethylene glycol)dimethyl ether (PEO). PEO has been selected as co-solvent to mimic the polymerization of poly(ethylene glycol) methyl ether methacrylate (PEGMA). Solvent compositions between 20 and 80 wt% H₂O were chosen. A large body of ATRPs with PEGMA in the presence of 50 to 70 wt% water have already been reported.^[33,108,133]

To estimate K_{model} and k_{act} , online FT-Vis/NIR spectroscopy has been applied for the quantitative analysis of the persistent radical concentration, $[\text{Cu}^{\text{II}}(2,2'\text{-bipyridine})_2\text{Br}]^+[\text{Br}]^-$. To gain further mechanistic insights, K_{model} has been measured at pressures up to 2000 bar for deducing reaction volumes, ΔV_{R} . Via PREDICI[®] modeling it was checked, whether the obtained rate coefficients may be used for estimates of $[\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}]^+[\text{Br}]^-$ concentration at widely varying contents of the sodium salt, e.g., of NaBr.

4.1.1 Determination of K_{model}

As shown in the upper part of Scheme 4.1, the copper-mediated ATRP mechanism consists of reversible oxidation of a tetra-coordinated copper(I)-ligand complex, $[\text{Cu}^{\text{I}}\text{L}_n]^+[\text{X}]^-$, with an alkyl halide, R-X, to produce a penta-coordinated $[\text{Cu}^{\text{II}}\text{L}_n\text{X}]^+[\text{X}]^-$ species and an alkyl radical, R[•].^[6,39] The activation rate coefficient is denoted by k_{act} , whereas the back reaction occurs with the deactivation rate coefficient, k_{deact} . The radical produced by the activation step may add to a monomer molecule, M, with the propagation rate coefficient k_{p} and may terminate with another radical, with the rate coefficient k_{t} . Both k_{p} and k_{t} should be identical to the associated rate coefficients of conventional radical polymerization of M. The ratio k_{act} to k_{deact} represents the ATRP equilibrium constant, $K_{\text{ATRP}} = k_{\text{act}}/k_{\text{deact}}$. Higher K_{ATRP} is associated with faster ATRP.

The measurement of K_{model} in aqueous solution is especially challenging because of various side reactions. The most important side reaction is the potential dissociation of the penta-coordinated $[\text{Cu}^{\text{II}}\text{L}_n\text{X}]^+[\text{X}]^-$ complex and formation of a hydrated halide ion, as shown in the lower part of Scheme 4.1.^[38] The equilibrium constant for the halide dissociation is denoted by K_{X} , which provides a measure for the strength of the halide complex. H₂O molecules may occupy coordination

Scheme 4.1: Suggested mechanism of Cu-mediated ATRP in aqueous solution; L_n ligand with n complexing sites, R-X initiator, M monomer, R^\bullet propagating radical, k_p propagation rate coefficient, k_t termination rate coefficient, K_x halide dissociation equilibrium constant, $K_{\text{aq}}(\text{Mt})$ equilibrium constant of water complexation, $K_{\text{aq}}(\text{X})$ equilibrium constant for hydration of the halide ion.

sites and substitute the halide ligand. This dissociation side reaction may lead to hydration of both the $[\text{Cu}^{\text{II}}\text{L}_n]^{2+}$ and $[\text{X}]^-$ species. These processes are quantified by the equilibrium constants $K_{\text{aq}}(\text{Mt})$ and $K_{\text{aq}}(\text{X})$, respectively. Due to the absence of halide the produced $[\text{Cu}^{\text{II}}\text{L}_n(\text{H}_2\text{O})]^{2+}$ is unable to deactivate radicals. The equilibria represented by $K_{\text{aq}}(\text{X})$ and $K_{\text{aq}}(\text{Mt})$ are established almost immediately. It appears justified to include these side equilibria into a single equilibrium constant, K_x .

To measure K_{model} and in order to avoid hydration and dissociation of the Cu^{II} -complex, up to 1000 equivalents NaBr relative to copper concentration have been added to the solution. Previous studies indicated that such high quantities of NaBr are required for shifting the equilibrium more or less quantitatively towards the ATRP-active halide complex.^[38]

K_{model} was determined from the $[\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}]^+[\text{Br}]^-$ complex concentration vs time traces for the monomer-free model system in water-PEO solutions. The $[\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}]^+[\text{Br}]^-$ concentration was measured via the Vis/NIR absorption of the copper d-d-transition.

Figure 4.1 shows a so-obtained spectral series for $7 \text{ mmol} \cdot \text{L}^{-1}$ $[\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}]^+[\text{Br}]^-$, 500 equivalents of NaBr and $91 \text{ mmol} \cdot \text{L}^{-1}$ HEMA-Br in a 50 wt.% water-PEO mixture at 22°C . The increase of $[\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}]^+[\text{Br}]^-$ concentration with time, indicated by the direction of the arrow in Figure 4.1, was quantitatively monitored via the absorbance between 13300 and 11400 cm^{-1} . The absorbance between 15500 and 8500 cm^{-1} is assigned to the $[\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}]^+[\text{Br}]^-$ -species. The absorption between 10500 and 9500 cm^{-1} at $t = 0$ may not be assigned to the d-d absorption of the $[\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}]^+[\text{Br}]^-$ complex, therefore the integration is limited to 11400 cm^{-1} . The increase in Cu^{II} -concentration results from termination of radicals according to Scheme 4.1.

It has been reported that some Cu^{I} /ligand systems may disproportionate in aqueous solution.^[134] This is obviously not the case with the Cu^{I} -complex under investigation, at least not on the time scale of the experiments. Measurements over several hours, in the absence of the initiator R-X, showed no Cu^{II} evolution and no Cu^0 was produced, which would indicate Cu^{I} species undergoing disproportion. There is also no indication of Cu^{II} comproportionation, which would require trace amounts of Cu^0 . In contrast to the stable Cu/bpy system the Cu/Me₆TREN complex disproportionates in a few minutes.^[135] The reason for the difference is not yet clear. Perhaps the conjugated π -system of bpy contributes to stabilization against disproportionation.

The equilibrium constant for the model system, K_{model} , was estimated from the Fischer-Fukuda-equation modified by Matyjaszewski *et al.* for systems with large equilibrium constants and non-equimolar initial concentrations, i.e., via the so-called F[Y]-function,^[45]:

$$F([Y]) = \left(\frac{[I]_0[C]_0}{[C]_0 - [I]_0} \right)^2 \left(\frac{1}{[C]_0^2([I]_0 - [Y])} + \frac{2}{[I]_0[C]_0([C]_0 - [I]_0)} \right. \\ \left. \cdot \ln \left(\frac{[I]_0 - [Y]}{[C]_0 - [Y]} \right) + \frac{1}{[I]_0^2([C]_0 - [Y])} \right) \quad (4.1)$$

$$F([Y]) = 2 \cdot k_t \cdot K_{\text{model}}^2 \cdot t + c' \quad (4.2)$$

Figure 4.1: FT-Vis/NIR spectral series recorded during the reaction of $7 \text{ mmol} \cdot \text{L}^{-1}$ $\text{Cu}^{\text{I}}(\text{Bpy})_2\text{Br}$, $91 \text{ mmol} \cdot \text{L}^{-1}$ HEMA-Br and 500 equivalents of NaBr in a 50 wt.% water-PEO mixture at 22°C and ambient pressure. The absorbance of the Cu^{II} complex increases with time t . The dashed lines denote the upper and lower limiting wavenumbers for integration. Integrated absorbance due to the Cu^{II} complex was determined from the absorbance difference to the spectrum recorded at $t = 0$.

The initial concentrations of initiator and of the Cu^{I} -complex are represented by $[\text{I}]_0$ and $[\text{C}]_0$, respectively. The time-dependent concentration of the Cu^{II} complex is denoted by $[\text{Y}]$. Equation 4.1 holds for situations where only a single Cu^{II} -complex is present, i.e., without taking the dissociation of the $[\text{Cu}^{\text{II}}\text{L}_n\text{X}]^+[\text{Br}]^-$ complex and subsequent halide hydration into account. Analysis of K_{model} via Equation 4.2 should however be valid at large excess concentration of NaBr.

Figure 4.2: Plot of the normalized $F[Y]$ -function vs. time for a reacting system containing 70 wt% water, $7 \text{ mmol} \cdot \text{L}^{-1} \text{ Cu}^{\text{I}}(\text{Bpy})_2\text{Br}$, as well as 5, 50, and 1000 equivalents of NaBr at 22°C with HEMA-Br acting as the initiator.

Shown in Figure 4.2 are three normalized $F[Y]$ -functions plotted vs. time t , measured with 5, 50 and 1000 equivalents of NaBr being added to a reacting mixture composed of 70 wt% water in PEO with $7 \text{ mmol} \cdot \text{L}^{-1} [\text{Cu}^{\text{I}}(\text{bpy})_2]^+[\text{Br}]^-$ and with HEMA-Br acting as the initiator. Straight-line behavior, as predicted by Equation 4.2, is only seen for the data measured upon the addition of 1000 equivalents of NaBr. The strong curvature of the $F[Y]$ -function for 5 equivalents of NaBr and the weak curvature for 50 equivalents of NaBr indicate the presence of additional copper species at these lower NaBr levels. Straight-line behavior probably occurs from 300 to 500 equivalents NaBr on. Thus the analyses for K_{model} have been carried out with NaBr being present in large excess.

With the termination rate coefficient, k_t , being known, the slope of the linear $F[Y]$ -plot yields the ATRP equilibrium constant K_{model} . For the low-molar-mass model system, k_t may be identified with $k_t^{1,1}$, the rate coefficient for termination of two radicals of chain length unity, which is

accessible from literature in conjunction with viscosity being measured for the particular solvent system.^[69] The viscosity of the solution depends on the water-PEO ratio as well as on the concentration of NaBr and has been measured by means of a falling ball viscometer for the pure solvents and for three solvent mixtures with and without excess NaBr. Alternatively, $k_t^{1,1}$ may be determined via pulsed-laser experiments in conjunction with highly time-resolved EPR spectroscopy.^[62] The two approaches result in $k_t^{1,1}$ values which differ by a factor of 4. As k_t exhibits a square-root dependence, the associated uncertainty of the K_{model} reduces to a factor of 2.^[69]

K_{model} has been determined for a wide range of PEO-H₂O compositions. Due to the insolubility of the copper complex in H₂O, K_{model} for pure water has been deduced by linear extrapolation of the K_{model} data in Figure 4.3 for the model system CuBr(2,2'-bipyridine)/HEMA-Br obtained in solvent mixtures of different PEO-water content at 22 °C. The solvent compositions include situations which mimic polymerization conditions. Most of the reported ATRPs with PEGMA were obtained at about 70 wt% water.^[33,108,133]

Figure 4.3 shows the steep increase of K_{model} towards higher water content. At 22 °C, K_{model} increases by about a factor of 100, from $4.7 \cdot 10^{-8}$ to $4.6 \cdot 10^{-6}$, in passing from 20 to 80 wt% H₂O. Linear extrapolation on the semi-log scale, $\ln K_{\text{model}}$ vs wt% H₂O toward pure water yields $K_{\text{model}} = 2.5 \cdot 10^{-5}$ and $K_{\text{model}} = 1.5 \cdot 10^{-8}$ results for pure PEO. Thus K_{model} varies within the entire H₂O-PEO range by a factor 1500. A change of this size is also predicted by the correlation via the Kamlet-Taft relationship for the difference between K_{model} for H₂O and polar solvents such as dimethyl formamide.^[42]

On the basis of linear solvation energy correlations and of electrochemical measurements, the Kamlet-Taft parameters predict K_{model} in a water environment to be by a factor of 10^3 to 10^4 above K_{model} in a purely organic environment,^[42] which is in agreement with the data in Figure 4.3. It was also reported that K_{model} of the CuBr/Me₆TREN system increases by a factor of 100 from an organic solvent toward pure water.^[47] Matyjaszewski *et al.* predicted K_{model} for CuBr/HMTETA in aqueous solution to be $5.9 \cdot 10^{-5}$, which is close to our estimated value for the bipyridine system to be $2.5 \cdot 10^{-5}$. Such difference in K_{ATRP} has also been observed for K_{model} with HMTETA and bipyridine in acetonitrile solution. For the initiator methyl 2-bromo-*iso*-butyrate

Figure 4.3: Plot of $\ln K_{\text{model}}$ vs. the weight fraction of water in H₂O-PEO mixtures for the monomer-free model system CuBr/ 2,2'-bipyridine at 22 °C. The open squares are measured data to which the straight line has been fitted.

(MBriB), the resulting value for CuBr/HMTETA/MBriB is $K_{\text{model}} = 2.8 \cdot 10^{-8}$ which is about four times above the value for CuBr/Bpy/MBriB, $K_{\text{model}} = 7.3 \cdot 10^{-9}$.^[59,60]

K_{model} has additionally been measured as a function of pressure. The experiments were carried out from 500 to 2000 bar for $5 \text{ mmol} \cdot \text{L}^{-1}$ $\text{Cu}^{\text{I}}(\text{bpy})_2\text{Br}$, at HEMA-Br concentrations between 40 and 70 $\text{mmol} \cdot \text{L}^{-1}$, and in H₂O-PEO mixtures containing 30, 50 or 70 wt.% water at 22 °C. Plotted in Figure 4.4 are the obtained K_{model} data. Absolute K_{model} increases with water concentration as shown for ambient pressure in Figure 4.3. The data in Figure 4.4 demonstrates that the relative increase in K_{model} with pressure is not affected by the water content. The slope to the straight lines in Figure 4.4 yields the reaction volume, ΔV_{R} , according to the relation:^[59]

$$\left[\frac{\delta \ln(K_{\text{model}})}{\delta p} \right] = - \frac{\Delta V_{\text{R}}}{R \cdot T} \quad (4.3)$$

ΔV_{R} is close to $-14 \text{ cm}^3 \text{ mol}^{-1}$ irrespective of the concentration of water contained in the H_2O -PEO mixture. The negative ΔV_{R} value indicates that the pressure effect results from the stronger contraction of the ligand sphere with the Cu^{II} -complex being a stronger Lewis acid than the Cu^{I} species, as has been suggested for polar organic solvents.^[59] That ΔV_{R} does not significantly vary with solvent environment indicates that the pressure dependence reflects an intrinsic effect of the copper–ligand system under investigation. Toward higher pressure, the penta-coordinated Cu^{II} -complex is favored over the tetra-coordinated Cu^{I} -complex because of reduced molar volume resulting from the higher oxidation state and the higher coordination.

Figure 4.4. Plot of $\ln K_{\text{ATRP}}$ vs. pressure at 22 °C for the monomer–free model system with $7 \text{ mmol} \cdot \text{L}^{-1}$ $\text{Cu}(\text{bpy})_2\text{Br}$ in acetonitrile as well as in different H_2O -PEO solvent mixtures. The slope of the straight lines yields the reaction volume, ΔV_{R} , for each mixture.

4.1.2 Determination of k_{act}

In order to elucidate, to which extent the observed changes in $K_{\text{model}} = k_{\text{act}}/k_{\text{deact}}$ are due to effects on the activation rate coefficient, k_{act} , the deactivation rate coefficient, k_{deact} , or on both coefficients, trapping experiments with TEMPOL have been performed. The strategy is the same as described by Fischer *et al.* using TEMPO.^[136] To allow for first-order kinetics, both TEMPOL and the Cu^I-complex were used in a ten-fold to twenty-fold excess relative to initiator concentration, [R-X].

$$-\frac{d[\text{RX}]}{dt} = k_{\text{act}} \cdot [\text{RX}] \cdot [\text{Cu}^{\text{I}}\text{L}] \quad (4.4)$$

$$\rightarrow -\frac{d\ln([\text{RX}])}{dt} \approx k_{\text{act}} \cdot [\text{Cu}^{\text{I}}\text{L}]_0 \quad (4.5)$$

Illustrated in Figure 4.5A is the pseudo-first-order plot according to Equation 4.5 for the system $[\text{Cu}^{\text{I}}(\text{bpy})_2]^+[\text{Br}]^-$ with HEMA-Br as the initiator reacting at 22 °C in a water-PEO mixture containing 50 wt% H₂O. The Cu^I-complex concentration was obtained from the difference between the selected initial Cu^I concentration and the measured Cu^{II}-complex concentration. The slope of the straight line fit yields $k_{\text{act}} = 2.3 \cdot \text{L mol}^{-1} \cdot \text{s}^{-1}$.

Figure 4.5B illustrates the dependence of k_{act} and k_{deact} on water content for the system $\text{Cu}^{\text{I}}(\text{bpy})_2\text{Br}/\text{HEMA-Br}$ in H₂O-PEO mixtures at 22 °C. The activation rate coefficient increases with the water content of the solvent mixture as does K_{model} , which is evidenced from $k_{\text{deact}} = K_{\text{model}}/k_{\text{act}}$ being insensitive towards water content (Figure 5B). The extrapolated limiting value of k_{act} is enhanced by a factor of 1500 in passing from a PEO to a hypothetical pure water environment, i.e., from $4.8 \cdot 10^{-2} \text{ L mol}^{-1} \cdot \text{s}^{-1}$ to $66 \text{ L mol}^{-1} \cdot \text{s}^{-1}$, respectively. Matyjaszewski *et al.* already demonstrated that the better stabilization of the Cu^{II}-complex in more polar organic solvents enhances k_{act} .^[41] As a highly polar solvent, water follows this trend. For 22 °C, k_{act} in acetonitrile was found to be $4 \cdot 10^{-2} \text{ L mol}^{-1} \cdot \text{s}^{-1}$ which is close to the associated value for PEO.^[36]

It should be mentioned that k_{act} strongly increases toward higher

Figure 4.5: (A) Determination of k_{act} by a pseudo-first-order plot for the reaction of $1.5 \cdot 10^{-2} \text{ mol} \cdot \text{L}^{-1}$ $\text{Cu}^{\text{I}}(\text{bpy})_2\text{Br}$, $8 \cdot 10^{-4} \text{ mol} \cdot \text{L}^{-1}$ HEMA-Br, and $3.0 \cdot 10^{-2} \text{ mol} \cdot \text{L}^{-1}$ TEMPOL at 22 °C in a water-PEO mixture containing 50 wt.% H_2O . (B) Dependence of k_{act} and k_{deact} on H_2O content for the reaction of $\text{Cu}^{\text{I}}\text{bpy}_2\text{Br}$ with HEMA-Br in water-PEO solutions at 22 °C.

water concentration, from 70 wt% water to pure water by about one order of magnitude. Matyjaszewski *et al.* reported that k_{act} of the more active system Cu/Me₆TREN increases by a factor of ten from a water (82 wt%) mixture with oligo(ethylene oxide) monomethyl ether acrylate (OEOA) to pure water with 2-hydroxyethyl α -bromoisobutyrate (HEBiB) being the initiator.^[47]

The deactivation rate coefficient, k_{deact} , which is obtained from k_{act} and K_{model} to be $2.5 \cdot 10^6 \text{ L mol}^{-1} \cdot \text{s}^{-1}$ at 22 °C and ambient pressure is by no more than a factor of three below the number reported for solution in acetonitrile: $k_{\text{deact}} = 8.5 \cdot 10^6 \text{ L mol}^{-1} \cdot \text{s}^{-1}$.^[36] It has been suggested that k_{deact} decreases towards more polar solvents.^[41] Thus k_{deact} in aqueous solution should be lower than in acetonitrile. Figure 4.5B reveals no such trend. Within experimental accuracy, k_{deact} is insensitive towards water content. The observed high k_{deact} in an aqueous environment explains, why narrow molar mass distributions are obtained in aqueous-solution ATRPs irrespective of water content.^[33,108,137]

The results in Figure 4.5B demonstrate that the strong variations of K_{model} are essentially due to changes of k_{act} . The poor sensitivity of k_{deact} suggests that small amounts of NaBr are sufficient to guarantee good control during ATRP even at low Cu^{II} deactivator levels.

4.1.3 Modeling

The rate coefficients k_{act} and k_{deact} have been deduced from experiments carried out under high loads of NaBr. As it is desirable to run ATRP experiments at significantly smaller amounts of added salt, it appears interesting to find out, whether the K_{model} and k_{act} values from studies at high NaBr content are also valid at far lower NaBr concentration and thus may be used to identify optimum ATRP conditions at reduced levels of added NaBr.

Plotted in Figure 4.6 is a spectral series measured for 3 mM $[\text{Cu}^{\text{II}}(\text{bpy})_2]^{2+}(\text{TfO})^{-2}$ dissolved in an H_2O -PEO mixture initially containing 70 wt% water to which NaBr has been successively added. The spectrum with lowest absorbance in the 13000 cm^{-1} region refers to a solution without added NaBr. Because of the weak bonding between copper and the triflate moiety, $[\text{Cu}^{\text{II}}(\text{bpy})_2(\text{H}_2\text{O})]^{2+}$ should be the dominant species when NaBr is absent. Upon the addition of NaBr, the spectrum first changes strongly, but finally added NaBr results in no further absorbance increase. At these higher NaBr contents, the equilibrium seems to be almost completely shifted to the side of $[\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}]^+[\text{Br}]^-$. Under the assumption of $[\text{Cu}^{\text{II}}(\text{bpy})_2]^{2+}(\text{TfO})^{-2}$ not being present and of $[\text{Cu}^{\text{II}}(\text{bpy})_2(\text{H}_2\text{O})]^{2+}$ concentration being given by the difference between the measured $[\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}]^+[\text{Br}]^-$ concentration and the initial $[\text{Cu}^{\text{II}}(\text{bpy})_2]^{2+}(\text{TfO})^{-2}$ concentration, the equilibrium constant K_x may be calculated from Equation 4.6.

$$K_x = \frac{[\text{Cu}^{\text{II}}\text{bpy}_2\text{Br}_2][\text{H}_2\text{O}]}{([\text{Cu}]_{\text{tot}} - [\text{Cu}^{\text{II}}\text{bpy}_2\text{Br}_2])[\text{Br}^-]} \quad (4.6)$$

For 70 wt% water K_x is determined to $4.3 \cdot 10^3$ and the Matyjaszewski group estimated K_x for $\text{Cu}^{\text{II}}\text{Br}/\text{Me}_6\text{TREN}$ in 82 wt% water to be $6.2 \cdot 10^2$. Due to the different definitions of K_x the latter value has been multiplied by the water concentration for better comparison.

The K_x values differ by a factor of seven. Taking into account that the K_x value of the present study would decrease by the addition water, the difference is not large. It should be noted that K_x exhibits a strong dependence on solvent-composition. Perhaps the ligand may also affect K_x .

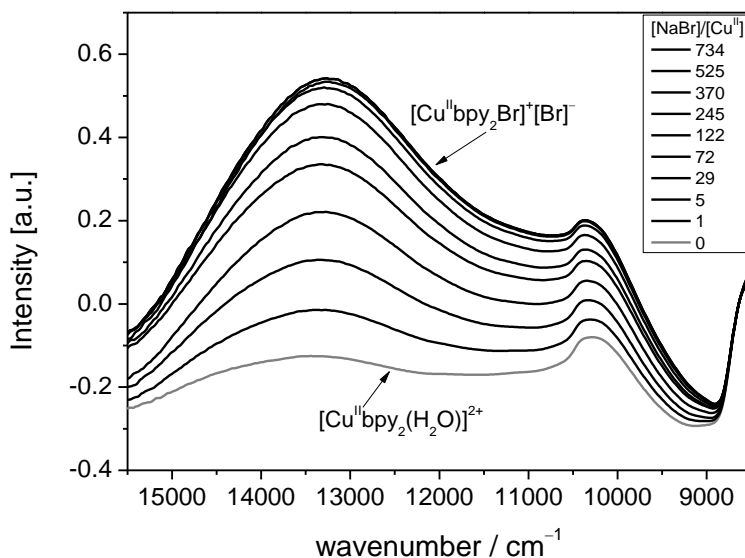

Figure 4.6. Spectral series measured on $3 \text{ mmol} \cdot \text{L}^{-1}$ $[\text{Cu}^{\text{II}}\text{bpy}_2]^{2+}(\text{TfO})_2$ dissolved in a solution of 70 wt.% water and 30 wt.% PEO at 22°C upon successive addition of NaBr. The spectrum with lowest absorbance refers to the solution without added NaBr.

The data in Figure 4.6 demonstrate that relatively small amounts of NaBr are capable of stabilizing a considerable fraction of $[\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}]^+[\text{Br}]^-$ species. Thus ATRP in aqueous solution should be feasible at modest amounts of added NaBr.^[33]

A PREDICI[®] model was developed which takes the independently measured rate coefficients k_t and k_{act} as well as the equilibrium constants K_{model} and K_x into account. Shown in Table 4.1 are the reaction steps implemented into the PREDICI[®] simulation of the monomer-free model system CuBr, 2,2'-bipyridine and HEMA-Br in PEO-H₂O solution. The rate coefficients k_{act} , k_{deact} and k_t have been introduced as a function of PEO-H₂O mixture composition and of measured viscosity. The dissociation and association of bromide is described by the rate coefficients k_{diss} and k_{ass} , respectively. k_{diss} has been adopted to be $1 \cdot 10^4 \text{ mol} \cdot \text{L}^{-1} \cdot \text{s}^{-1}$ which value ensures immediate equilibration of the dissociation and association processes. k_{ass} is estimated from the product

Table 4.1. Reaction scheme for PREDICI® modeling of the monomer-free model system CuBr, 2,2'-bipyridine, and HEMA-Br in PEO-H₂O solution.

Figure 4.7. $[\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}]^+[\text{Br}]^-$ concentration of the monomer-free model system plotted vs. time for the reaction of CuBr, 2,2'-bipyridine, and HEMA-Br in PEO-H₂O solutions containing different amounts of NaBr. The dashed lines represent the associated PREDICI® simulations.

of k_{diss} and K_x .

Plotted in Figure 4.7 are the measured Cu^{II} data (symbols) together with the associated PREDICI[®]-modelled curves (dashed lines). The open symbols refer to $[\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}]^+[\text{Br}]^-$ measured for an H_2O -PEO mixture with 70 wt.% water initially containing $7 \text{ mmol} \cdot \text{L}^{-1}$ $[\text{Cu}^{\text{I}}(\text{bpy})_2]^+[\text{Br}]^-$, different amounts of initiator and of NaBr at 22°C ; \bullet : $90 \text{ mmol} \cdot \text{L}^{-1}$ HEMA-Br, $350 \text{ mmol} \cdot \text{L}^{-1}$ NaBr; \square : $53 \text{ mmol} \cdot \text{L}^{-1}$ HEMA-Br, $35 \text{ mmol} \cdot \text{L}^{-1}$ NaBr; Δ : $7 \text{ mmol} \cdot \text{L}^{-1}$ HEMA-Br, $0 \text{ mmol} \cdot \text{L}^{-1}$ NaBr. Toward lower NaBr content, the $[\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}]^+[\text{Br}]^-$ absorbance is low and is overlapped by the one of the $[\text{Cu}^{\text{II}}(\text{bpy})_2(\text{H}_2\text{O})]^{2+}$ complex. The individual concentrations of $[\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}]^+[\text{Br}]^-$ (and of $[\text{Cu}^{\text{II}}(\text{bpy})_2(\text{H}_2\text{O})]^{2+}$) have been deduced from the overlapping absorbance bands by means of the known molar extinction coefficients, ε , of the $[\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}]^+[\text{Br}]^-$ and $[\text{Cu}^{\text{II}}(\text{bpy})_2(\text{H}_2\text{O})]^{2+}$ complexes and the measured equilibrium constant, K_x , for these two species according to Equation 4.7, in which l denotes the optical path length.

$$\begin{aligned} \text{Cu}_{\text{absorbance}} = & c([\text{Cu}^{\text{II}}\text{bpy}_2(\text{H}_2\text{O})]^{2+}) \cdot \varepsilon_{[\text{Cu}^{\text{II}}\text{bpy}_2(\text{H}_2\text{O})]^{2+}} \cdot l \\ & + c([\text{Cu}^{\text{II}}\text{bpy}_2\text{Br}]^+[\text{Br}]^-) \cdot \varepsilon_{[\text{Cu}^{\text{II}}\text{bpy}_2\text{Br}]^+[\text{Br}]^-} \cdot l \end{aligned} \quad (4.7)$$

Figure 4.7 illustrates the close agreement of measured and PREDICI[®]-modelled data at widely differing NaBr concentrations. Listed in Table 4.2 are the values used for PREDICI[®] modeling. The initial initiator concentration, $[\text{I}]_0$, and the NaBr concentration listed in Table 4.2 are the ones selected for the experiments. The termination rate coefficient, k_t , has been modified according to the viscosity change which accompanies the addition of NaBr. The only one quantity which was adjusted, however only within the limits of experimental accuracy of ± 30 per cent, was k_{act} . The close agreement of simulated and measured $[\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}]^+[\text{Br}]^-$ vs. t traces achieved by the minor adjustment of k_{act} (see Table 4.2) is strongly indicative of the measured equilibrium constant and rate coefficients being independent of NaBr concentration.

Table 4.2: Rate coefficients and equilibrium constants used for modeling the measured $[\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}]^+[\text{Br}]^-$ vs. t traces for $7 \text{ mmol} \cdot \text{L}^{-1}$ $[\text{Cu}^{\text{I}}(\text{bpy})_2]^+[\text{Br}]^-$ and HEMABr reacting in an H_2O -PEO solution containing 70 wt.% water. The termination rate coefficient, k_t , has been corrected for the measured viscosity change upon the addition of NaBr.

4.2 Kinetics of Cu-mediated ATRP in aqueous solution

A deeper understanding of the impact of a water environment on ATRP has been achieved by studying Cu-mediated ATRP model systems. It has been shown that the strong increase of the activation–deactivation equilibrium is mainly due to the enhancement of the activation step, whereas the deactivation is not significantly dependent on water concentration.

Because of the difficulties associated with the fast deactivation step, k_{deact} in the monomer-free model systems was only indirectly determined via the equilibrium constant and k_{act} . To measure k_{deact} during Cu-mediated ATRP, the SP–PLP–EPR technique has been applied.^[66] Such direct measurement should also be carried out, as the activation–deactivation equilibrium constant for the actual polymerization may differ from the one obtained for the model system. Moreover, the data for the model system consider only radicals of chain length unity and may not fully reflect by the polymerizing system.^[60,126] Furthermore, during actual ATRP the solvent is initially a mixture of solvent and monomer, which gradually changes due to the replacement of monomer by polymer. For this reason, it seems mandatory to investigate the influence of the solvent/monomer/polymer mixture on K_{ATRP} .

The online spectroscopic measurement of the PEGMA concentration in combination with the accumulation of Cu^{II} allows for the direct measurement of K_{ATRP} during polymerization.^[60,138] The challenges of the procedure are due to the copper catalyst possibly undergoing several side reactions in aqueous solution and to the conversion-dependence of propagation kinetics in aqueous solution. The direct measurement of the activation–deactivation equilibrium constant during a polymerization will help to better understand ATRP and may allow for PREDICI® simulations of monomer conversion vs time traces, of dispersity and of chain-end functionality in actual ATRPs.

4.2.1 Determination of k_{deact}

This section deals with the SP–PLP–EPR measurement of the ATRP deactivation rate coefficient, k_{deact} , for the $[\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}]^+[\text{Br}]^-$ complex within a wide range of PEGMA–H₂O mixtures. The k_{deact} values are estimated via PREDICI[®] modeling.^[66] Because of the excess of halide salts used in these polymerizations, the notation of $[\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}]^+[\text{Br}]^-$ and $[\text{Cu}^{\text{I}}\text{L}_n]^+[\text{Br}]^-$ are simplified to $\text{Cu}^{\text{II}}/\text{L-Br}$ and $\text{Cu}^{\text{I}}/\text{L}$ within what follows.

Illustrated in Scheme 4.2 is the scenario for the measurement of the ATRP deactivation rate coefficient, k_{deact} . The experiment is started in a reversed fashion with the catalyst in the higher oxidation state, e.g., $\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}$. The starting reagents are marked red. Darocur 1173 (Darocur) acts as the photoinitiator to produce primary radicals, which add to monomer molecules, M. The propagating radical, R^\bullet , reacts with the $\text{Cu}^{\text{II}}/\text{L-Br}$ deactivator complex to generate the alkyl halide, R-Br , and the $\text{Cu}^{\text{I}}/\text{L}$ complex. In addition to ATRP deactivation, the radicals may also undergo conventional radical–radical termination.

In Cu-mediated ATRP, at least two types of paramagnetic species are present: the $\text{Cu}^{\text{II}}/\text{L-Br}$ species and the propagation radical. The EPR spectra for quantification of the $\text{Cu}^{\text{II}}/\text{L-Br}$ species have been measured before and after SP application. The SP–PLP–EPR technique has been used to measure the PEGMA radical concentration vs time traces.

Shown in Figure 4.8 are the EPR spectra of the two paramagnetic species. Figure 4.8A shows the pseudo-stationary EPR spectrum of PEGMA radicals recorded in the presence of Cu^{II} . The spectrum was recorded between 3285 and 3385 G with a pulse repetition rate of 20 Hz at 20 °C to identify the appropriate field position for time-resolved detection of PEGMA radical at a constant magnetic field, which is indicated by the arrow in Figure 4.8A. The EPR spectrum of PEGMA radicals is identical to the one in solvent mixtures without Cu (cf. Figure 3.9, p. 46).

Scheme 4.2: SP-PLP-EPR measurement of k_{deact} . The starting components, i.e., the photoinitiator Darocur 1173, the monomer M, and the $\text{Cu}^{\text{II}}/\text{L-Br}$ complex are marked red. The primary radicals are generated by a laser pulse which produces primary propagation radicals R_1^\bullet which grow to propagating radicals, R_n^\bullet , of chain length n . $\text{Cu}^{\text{I}}/\text{L}$ and $R_n\text{-Br}$ are produced by the deactivation step.

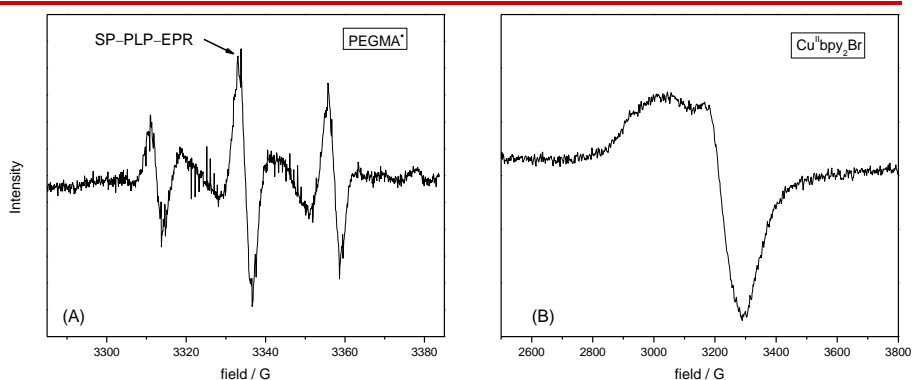

Figure 4.8: (A) Pseudo-stationary spectrum of PEGMA radicals recorded in 50 wt% H_2O with a laser repetition rate of 20 Hz at 20 °C. The arrow indicates the magnetic field position for the SP-PLP-EPR experiment. (B) EPR spectrum of $\text{Cu}^{\text{II}}\text{bpy}_2\text{Br}$ for a stationary ATRP in 50 wt% H_2O at 20 °C.

Illustrated in Figure 4.8B is the EPR spectrum of a 3 mM solution of the $\text{Cu}^{\text{II}}/\text{L-Br}$ species recorded between 2500 and 3800 G. The broad unsymmetrical singlet spectrum is characteristic of Cu^{II} -complexes.^[39,66] The Cu^{II} spectrum is used to monitor the conversion of the $\text{Cu}^{\text{II}}/\text{L-Br}$ catalyst during SP–PLP–EPR experiment.

For the time-resolved SP–PLP–EPR experiments, the system under investigation contains 1 mM of $\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}$ and 20 mM of Darocur in different solution mixtures of PEGMA, containing between 30 and 70 wt% H_2O . Darocur was chosen as the photoinitiator because of the good solubility in water and the strong absorption at the laser wavelength of 351 nm. An excess of 500 equivalents of NaBr with respect to $\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}$ has been added to the solution in order to prevent halide dissociation.

Shown in Figure 4.9A are the $[\text{PEGMA}^\bullet]$ vs time traces recorded at 20 °C in solution of 50 wt% H_2O . The black line refers to the concentration vs time trace without $\text{Cu}^{\text{II}}/\text{L-Br}$ being present. The blue concentration vs time profile shows the experimental SP–PLP–EPR data for 1 mM $\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}$ in solution of 50 wt% H_2O . The red line represents the associated PREDICI® modeling. An intense burst of PEGMA^\bullet is produced at $t = 0$, when the laser pulse is applied to the sample. The decay in $[\text{PEGMA}^\bullet]$ is significantly accelerated by $\text{Cu}^{\text{II}}/\text{L-Br}$ due to the ATRP deactivation. In the absence of $\text{Cu}^{\text{II}}/\text{L-Br}$ the decay in radical concentration occurs entirely by conventional radical–radical termination. Shown in Figure 4.9B are the corresponding spectra of $\text{Cu}^{\text{II}}/\text{L-Br}$ prior to the experiment and after application of 10 laser pulses. The conversion of $\text{Cu}^{\text{II}}/\text{L-Br}$ is well below 10% as deduced from the associated double integrals of the $\text{Cu}^{\text{II}}/\text{L-Br}$ EPR spectra. Thus, only minor amounts of $\text{Cu}^{\text{I}}/\text{L}$ are formed, which ensures that the activation reaction does not occur to any significant amount and may be neglected.

Therefore the reaction is adequately represented by the three reaction steps listed in Table 4.3: propagation (4.8), ATRP deactivation (4.9) and conventional radical–radical termination (4.10). These reaction steps are implemented into the PREDICI® model along with the propagation rate coefficient as well as the composite-model parameters for chain-length-dependent termination as detailed in chapter 3. The knowledge of these parameters in combination with the

Figure 4.9: (A) PEGMA radical concentration vs time recorded via the time-resolved SP-PLP-EPR spectroscopy. The black line represents the SP-PLP-EPR experiment without $\text{Cu}^{\text{II}}\text{bpy}_2\text{Br}$ being present. The blue line refers to the experiment with 1 mM $\text{Cu}^{\text{II}}\text{bpy}_2\text{Br}$. Both concentration vs time profiles were measured in solution of 50 wt% H_2O at 20 °C and at a constant magnetic field position of 3332 G. (B) EPR spectra of $\text{Cu}^{\text{II}}/\text{L-Br}$ for before (black line) and after laser pulse application (red line).

Table 4.3: Reaction scheme used for PREDICI® modeling of the PEGMA radical concentration vs time traces.

$\text{R}^\bullet + \text{M} \xrightarrow{k_p} \text{R}^\bullet_{n+1}$	(4.8)
$\text{Cu}^{\text{II}}\text{bpy}_2\text{Br} + \text{R}^\bullet \xrightarrow{k_{\text{deact}}} \text{Cu}^{\text{I}}\text{bpy}_2 + \text{R-Br}$	(4.9)
$\text{R}^\bullet + \text{R}^\bullet \xrightarrow{k_t} \text{R-R}$	(4.10)

measured $\text{Cu}^{\text{II}}/\text{L-Br}$ concentration and the absolute radical concentration allows for estimating k_{deact} via PREDICI® modeling.

The radical concentration vs time trace in Figure 4.9A was modeled via PREDICI®, which results in a close agreement with the experimental

data, as seen in Figure 4.9A. The k_{deact} value was estimated from the fit to be $k_{\text{deact}} = 6.3 \cdot 10^5 \text{ L mol}^{-1} \text{ s}^{-1}$. The absolute k_{deact} value thus is of the same order of magnitude as found for other Cu-mediated ATRP systems in organic solvents. For DMA with CuBr/HMTETA, $k_{\text{deact}} = 8 \cdot 10^5 \text{ L mol}^{-1} \text{ s}^{-1}$ has been reported.^[66] For PMDETA being the ligand, k_{deact} amounts to $2 \cdot 10^6 \text{ L mol}^{-1} \text{ s}^{-1}$.^[66]

Analogous to the k_{deact} measurement in solution with 50 wt% H₂O, further experiments with 30 and 70 wt% H₂O were conducted to check for a potential water dependency of k_{deact} . The resulting k_{deact} values in 30, 50 and 70 wt% H₂O at 20 °C are listed in Table 4.4. The k_{deact} values exhibit a slight decrease, by a factor of 1.5, in passing from 30 to 70 wt% H₂O. In view of the experimental accuracy, it may be concluded that k_{deact} is independent of water concentration, which is consistent with what has been found for the model system in chapter 4.1.

The k_{deact} values estimated via SP-PLP-EPR are by a factor of 4 below the ones obtained for the monomer-free model system, where k_{deact} is $2.6 \cdot 10^6 \text{ L mol}^{-1} \text{ s}^{-1}$. The lower k_{deact} values for the polymerization system are a consequence of the back-strain effect for methacrylate type monomers.^[139] As a consequence of the α -methyl group of the penultimate methacrylate unit in the polymeric chain, a steric strain is induced that hinders the addition of the bromide to the radical, and thus reduces k_{deact} . In the model system, the methacrylate ATRP initiator has no penultimate unit to induce such a steric strain. A difference of this magnitude between model system and polymerization system is known from Cu-mediated ATRP.^[126]

Even if k_{deact} for the polymerization system is smaller than for the model system, the polymerization is expected to be well controlled. Such high k_{deact} values in the order of magnitude between $5 \cdot 10^5$ and 10^6 are associated with fast deactivation providing efficient control over a polymerization. This is especially true, if additional Cu^{II}/L-Br is added to the solution to ensure the presence of a sufficient amount of the deactivator complex from the beginning of the polymerization.

Table 4.4: k_{deact} values for Cu-mediated ATRP with CuBr/bpy deduced via SP-PLP-EPR at 20 °C.

wt% H ₂ O	$k_{\text{deact}} / 10^5 \text{ L mol}^{-1} \text{ s}^{-1}$
30	7.8 ± 1.5
50	6.3 ± 1.7
70	5.5 ± 2.0

4.2.2 Determination of K_{ATRP}

The increase of K_{model} with increasing water content (see chapter 4.1.1) should also be studied for K_{ATRP} of actual ATRP, in particular to check for the effect of changes in solvent composition due to monomer-to-polymer conversion.

This section deals with the measurement of K_{ATRP} for the ATRP of PEGMA in aqueous solution using Cu^IBr/bpy₂ as the catalyst and HEMA-Br as the initiator. K_{ATRP} is estimated via the simultaneous measurement of monomer conversion and of Cu^{II}/L-Br concentration by online time resolved FT-Vis/NIR spectroscopy.

According to Equation 4.11 the overall polymerization rate, R_p , is proportional to the equilibrium constant, K_{ATRP} , and the ratio of the Cu^I/L and Cu^{II}/L-Br concentration:^[140]

$$R_p = k_p \cdot [R] \cdot [M] = k_p \cdot K_{\text{ATRP}} \cdot \frac{[\text{Cu}^{\text{I}}] \cdot [\text{RX}]}{[\text{Cu}^{\text{II}}]} \cdot [M] \quad (4.11)$$

$$K_{\text{ATRP}} = - \frac{[\text{Cu}^{\text{II}}]}{k_p \cdot [\text{Cu}^{\text{I}}] \cdot [\text{RX}]} \frac{d \ln[M]}{dt} \quad (4.12)$$

where k_p is the propagation rate coefficient, and $[\text{RX}]$ and $[M]$ represent

the concentration of the ATRP initiator and of the monomer, respectively. The Cu^{I} concentration was deduced from the difference of the initial Cu^{I} concentration and the measured time-dependent Cu^{II} concentration, $[\text{Cu}^{\text{I}}] = [\text{Cu}^{\text{I}}]_0 + ([\text{Cu}^{\text{II}}] - [\text{Cu}^{\text{II}}]_0)$. Similarly, the RX concentration was estimated via the difference of the initial RX concentration and the measured Cu^{II} concentration.

Shown in Figure 4.10 is a series of Vis/NIR absorbance spectra measured during an ATRP of PEGMA in 50 wt% H_2O starting with 8 mM $\text{Cu}^{\text{I}}/\text{L}$, 1.8 mM $\text{Cu}^{\text{II}}/\text{L-Br}$ and 5 mM HEMA-Br at 20 °C. Additional $\text{Cu}^{\text{II}}/\text{L-Br}$ was added to obtain better control to reduce polymerization rate, thus making concentration measurements easier. Figure 4.10A shows the evolution of $\text{Cu}^{\text{II}}/\text{L-Br}$ concentration with time. To deduce $\text{Cu}^{\text{II}}/\text{L-Br}$ concentration, the absorbance band was integrated between 13 500 and 11 000 cm^{-1} , as is indicated by the dashed lines, and calibrated against three known concentrations of $\text{Cu}^{\text{II}}/\text{L-Br}$. Monomer conversion was measured via the first overtone of the unsaturated C–H stretching vibration of PEGMA as shown in Figure 4.10B. The absorbance band was integrated between 6212 and 6120 cm^{-1} as indicated by the dashed lines. The arrows in Figure 4.10 indicate the direction of change with time t .

Illustrated in Figure 4.11A are the associated $\ln([\text{M}]_0/[\text{M}])$ (black curve) and monomer conversion (blue curve) vs time traces for the measurements shown in Figure 4.10. The associated $\text{Cu}^{\text{II}}/\text{L-Br}$ concentration vs time plot of Figure 4.10 is shown in Figure 4.11B. The concentration vs time traces yield a lower polymerization rate below 200 seconds, as will be discussed below.

After 300 seconds, the slope of the $\ln([\text{M}]_0/[\text{M}])$ vs time plot is almost constant and a monomer conversion close to 90 % is reached. Referring to Equation 4.12, it is interesting to note that the slope of $\ln([\text{M}]_0/[\text{M}])$ vs time is constant over a wide range although the $\text{Cu}^{\text{II}}/\text{L-Br}$ concentration (see Figure 4.11B) increases significantly. This behavior may be assigned to the increase in k_p toward lower monomer concentration, which compensates the accumulation of $\text{Cu}^{\text{II}}/\text{L-Br}$. In contrast to ATRPs in organic solvents, k_p of ATRPs in aqueous solution exhibits a strong dependency on water content, which has to be taken into account in the determination of K_{ATRP} . To estimate K_{ATRP} , the k_p values (see chapter 3.1) have to be selected according to the actual monomer concentration.

Figure 4.10: Vis-NIR spectral series recorded during ATRP of PEGMA with starting concentrations of 8 mM $\text{Cu}^{\text{I}}/\text{L}$, 1.8 mM $\text{Cu}^{\text{II}}/\text{L-Br}$ and 5 mM HEMA-Br in solution of 50 wt% H_2O at 20 °C. The dashed lines denote the upper and lower limiting wavenumbers for integration. (A) The absorbance of the $\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}$ complex increases with time t . The absolute $\text{Cu}^{\text{II}}/\text{L-Br}$ concentration was estimated via a calibration with $\text{Cu}^{\text{II}}/\text{L-Br}$ (1, 3 and 7 mM) without R-X being present. (B) Spectral series of PEGMA with time. The arrow indicates the direction for the absorbance change with time.

With the monomer concentration vs time traces, the k_p values and the $\text{Cu}^{\text{II}}/\text{L-Br}$ concentration are known, the K_{ATRP} values were estimated from the first derivative of the $\ln([M]_0/[M])$ vs time plots.

Depicted in Figure 4.12 are K_{ATRP} data obtained during the course of the ATRP described above. The data is from the analysis of the measured conversion vs time behavior. Within the first 200 seconds, a strong increase in K_{ATRP} by almost two orders of magnitude, from $3 \cdot 10^{-7}$ to $4 \cdot 10^{-5}$, is observed. The low K_{ATRP} value in the initial period may be caused by the lower ATRP equilibrium of HEMA-Br which acts as the initiator. Since HEMA-Br was also used as R-X species for the monomer-free model system, this pre-equilibrium should be similar to the activation-deactivation equilibrium for the monomer-free model system: $K_{\text{model}} = 7 \cdot 10^{-7}$. The subsequent increase up to 300 seconds is associated with the transition from the pre-equilibrium to the actual

Figure 4.11: (A) $\ln([M]_0/[M])$ (black) and conversion (blue) vs time curves for ATRP of PEGMA with initial concentrations of 8 mm Cu^I/L , 1.8 mm $\text{Cu}^{II}/\text{L-Br}$ and 5 mm HEMA-Br in 50 wt% H_2O at 20 °C. (B) The $\text{Cu}^{II}/\text{L-Br}$ concentration versus time curve for the same experiment as in (A).

polymerization equilibrium of PEGMA-Br. After the initiator equilibrium period, K_{ATRP} increases slightly by a factor of about 2 toward high conversion. It may be assumed that K_{ATRP} for the ATRP equilibrium is constant at a value of $8 \cdot 10^{-5}$. As indicated in Figure 4.12, K_{ATRP} is almost independent of the monomer conversion and thus of polymer content.

To check for a potential dependency on water content as it was found for K_{model} , K_{ATRP} was measured for different water concentrations between 30 and 80 wt% H_2O . The analysis of K_{ATRP} was performed analogous to the procedure described above. Depicted in Figure 4.13 are the estimated average values of K_{ATRP} (black squares) from at least two independent K_{ATRP} measurements for various water concentrations and Cu concentrations. K_{ATRP} increases by more than order of magnitude, from $1 \cdot 10^{-5}$ at 30 wt% H_2O toward $4 \cdot 10^{-4}$ at 80 wt% H_2O . This finding also indicates that the increase in K_{ATRP} is primarily influenced by the absolute water content.

Similarly high K_{ATRP} values as the one at 80 wt% H_2O have been reported for the very active $\text{CuBr}/\text{Me}_6\text{TREN}$ and CuBr/TPMA catalysts systems in MMA in bulk ATRPs where K_{ATRP} amounts to $7.8 \cdot 10^{-4}$ and

Figure 4.12: K_{ATRP} values estimated via 4.12 versus time and monomer conversion for ATRP of PEGMA with starting concentrations of 8 mm $\text{Cu}^{\text{I}}/\text{L}$, 1.8 mm $\text{Cu}^{\text{II}}/\text{L-Br}$ and 5 mm HEMA-Br in 50 wt% H_2O at 20 °C. K_{ATRP} is initially lower due to the lower equilibrium constant associated with the initiator fragments (grey box), but reaches a constant value of $8 \cdot 10^{-5}$.

$9.4 \cdot 10^{-5}$, respectively.^[60] The strong increase of K_{ATRP} with the water content is a key feature of ATRP in aqueous solution. The increase of K_{ATRP} by an aqueous environment may allow for a fast ATRP rate which is otherwise, in organic solvents, only achieved by using very active catalysts such as Me_6TREN and TPMA. Moreover, such high K_{ATRP} values are suitable for ATRP techniques according to the regenerative concept for the Cu^{II} -catalyst thereby reducing the Cu concentration to a ppm level.

Included in Figure 4.13 are the K_{model} values from chapter 4.1.1. Interestingly the K_{ATRP} values exceed K_{model} by almost two orders of magnitude. This finding is consistent with measurements of MMA in organic solvents using PMDETA and HMTETA as the ligands to Cu.^[60]

Figure 4.13: K_{ATRP} (black squares) and K_{model} (red circles) versus the water concentration in wt% at 20 °C.

For the Cu/HMTETA complexes, K_{ATRP} is by a factor 120 above K_{model} . For Cu/PMDETA the difference is even slightly higher with the factor being 160. The difference in K_{ATRP} and K_{model} is most likely caused by the back-strain effect.^[60,126] In case of low K_{model} values, the ATRP rate may be controlled by the bond dissociation energy of R-X. In this case, the back-strain effect contributes to the dissociation of R-X and results in a high K_{ATRP} .

Despite the difference in absolute values, the results of this work demonstrate that the increase of K_{ATRP} with the water content is almost identical to the one for K_{model} . The difference between K_{model} and K_{ATRP} reduces from a factor of 100 at 30 wt% H₂O towards a factor of 60 at 80 wt% H₂O. Via $K_{\text{ATRP}} = k_{\text{act}}/k_{\text{deact}}$, k_{act} may be calculated from the K_{ATRP} values of this chapter and the k_{deact} values deduced from the SP-PLP-EPR experiment. As the k_{deact} values are more or less independent of water content, k_{act} is essentially responsible for the increase in K_{ATRP} . The k_{act} values are almost 20 times higher than in the model system. Such high k_{act} in combination with constant k_{deact} suggest that polymerization

rate may be tunable by the water content without compromising the ATRP control. This effect will be addressed in more detail in the next section.

4.2.3 Impact on polymerization

The purpose of measuring the activation–deactivation equilibrium for a monomer-free model system and polymerization system with monomer is the perspective to predict polymer relevant properties such as dispersity, molecular mass and chain-end functionality. Additionally, the kinetic data allow for the prediction of conversion vs time profiles. Moreover, modeling a polymerization may also provide guidance how much halide salts may be necessary to achieve an efficient control over the polymerization.

To predict the dispersity, conversion and the influence on halide salts, a PREDICI[®] model has been used for a PEGMA ATRP in water with HEMA-Br acting as an initiator. The reaction scheme for the PREDICI[®] model is shown in Table 4.5 and is divided in four different parts: the conventional kinetics without Cu, the ATRP pre-equilibrium of HEMA-Br, the ATRP equilibrium for PEGMA and the halide dissociation equilibrium.

The water dependency of k_p (chapter 3.1) is included to the model as well as the chain-length dependency of $k_t^{i,i}$ (chapter 3.2) and the dependence of $k_t^{i,i}$ with fluidity. The activation and deactivation rate coefficients are based on the values for the monomer-free model ATRP with HEMA-Br (cf. chapter 4.1). The k_{act} and k_{deact} values for the PEGMA ATRP are known from chapter 4.2. The equilibrium for the halide dissociation should be equal to the one discussed for the model system in chapter 4.1.3.

For ATRP in aqueous solution it is particular interesting to check for the effects of variation of halide salt concentration. Shown in Figure 4.14 are the simulated dispersities (black curve) and the chain-end functionality (blue curve) of a PEGMA polymerization versus the NaBr equivalents with respect to the total Cu concentration, $[Cu]_{tot}$. The PREDICI[®] simulations were performed with a constant initial

composition of 50 wt% PEGMA, 3 mM $\text{Cu}^{\text{I}}(\text{bpy})_2$, 1 mM $\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}$ and 3 mM HEMA-Br up to a monomer conversion of 75 %.

The data in Figure 4.14 show that the addition of up to 5 equivalents of NaBr relative to the total copper concentration results in a significant reduction of dispersity for the produced polymer. Upon further addition of NaBr only minor improvements of dispersity are achieved.

As seen in Figure 4.14, additional 5 to 50 equivalents of NaBr further improve the chain-end functionality drastically from 30 % to almost 90 %. Furthermore, the reaction time is influenced by NaBr concentration (not shown in Figure 4.14). In the case of no NaBr addition, the simulation yields a reaction time of ca. 40 minutes for

Figure 4.14: PREDICI® simulations for a PEGMA polymerization and the influence of the NaBr concentration on the dispersity (black curve) and chain-end functionality (blue curve). The NaBr concentration is given in equivalents in respect with the total Cu concentration, $[Cu]_{tot}$. The PREDICI® model consists of the reactions in Table 4.5 and was simulated with 3 mM $Cu^{II}bpy_2$, 1 mM $Cu^{II}bpy_2Br$ and 3 mM HEMA-Br in 50 wt% H_2O . The grey box shows the sodium bromide concentration range for a well-controlled polymerization.

reaching a monomer conversion of 75 %. The reaction time for 75 % conversion reduces to 33 minutes upon the addition of 50 equivalents NaBr. The added NaBr stabilizes the $Cu^{II}/L-Br$ complex, which reduces radical termination and enhances the polymerization rate.

Although the dispersity is around 1.20 with 15 equivalents and may not significantly further lowered with higher NaBr content, even lower dispersities would be desirable for a better control over the polymerization. The dispersity may be further reduced by the selection of an initiator with higher pre-equilibrium constant and thus larger k_{act} . The k_{act} for the alkyl initiator, HEMA-Br, which was used for the simulations in Figure 4.14, is about 20 times below the one for PEGMA. Simulations with an identical k_{act} for the pre-equilibrium and

equilibrium in combination with 50 equivalents of NaBr at otherwise identical ATRP parameters as applied in Figure 4.14, showed that the dispersity is reduced to 1.10. This improvement in dispersity is achieved by a shorter initiation phase and thus a concerted start of the chain-growth.

However, a 10 times higher activation rate coefficient for the pre-equilibrium than for the polymerization equilibrium would result in an enormously high radical concentration and thus in high amounts of termination of initiator-derived radicals would occur. Because of the high termination rate of initiator radicals, the chain-end functionality would be strongly reduced below 60 %.

These findings are especially important for polymerizations with methacrylates, since K_{ATRP} is by almost two orders of magnitude above the associated K_{model} and the corresponding initiation pre-equilibrium. As a consequence, the used ATRP initiator should be almost as active as the polymeric R-X species for polymerizations with methacrylates. HEMA-Br may not be perfectly suited, but has been used because of the very good solubility in solutions containing high fractions of water. Moreover, dispersities as low as 1.20 may be considered as an indication of well-controlled polymerization.

In addition to the impact of NaBr on the control over polymerization, the influence of water concentration on dispersity and polymerization rate is of particular interest. The PREDICI® model was used to simulate reaction time and dispersity for different water concentrations. The concentrations used for the PREDICI® simulations were identical to the ones presented before, with 3 mM $\text{Cu}^{\text{I}}(\text{bpy})_2$, 1 mM $\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}$ and 3 mM HEMA-Br. The sodium bromide concentration was kept constant at 50 equivalents of total copper content.

Shown in Figure 4.15 are the results of the PREDICI® simulations for the effect of water on dispersity and reaction time. The dispersity of the polymerization vs the water concentration is depicted in black, whereas the reaction time up to 75 % monomer conversion vs water concentration is depicted in blue. Toward higher water content, the dispersity increases from 1.05 to 1.40 at 80 wt% H_2O . This increase in dispersity is induced by the high K_{ATRP} at high water content. For such high K_{ATRP} 's normal ATRP is not effective any more. This unfavorable effect may be counterbalanced by using of a higher initial NaBr addition, a higher initial $\text{Cu}^{\text{II}}/\text{L-Br}$ concentration or by the introduction

Figure 4.15: PREDICI® simulations for the variation of dispersity (black triangles) and reaction time (blue squares) with water concentration. The PREDICI® simulations for a PEGMA polymerization were calculated for 3 mM $\text{Cu}^{\text{I}}(\text{bpy})_2$, 1 mM $\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}$ and 3 mM HEMA-Br.

of an ARGET or ICAR ATRP protocol.

Even though higher water contents may result in a loss of control, the reaction is highly accelerated by water and the time to reach 75 % conversion reduces from 330 minutes at 30 wt% water to 15 minutes at 80 wt% H_2O . This acceleration toward higher water content is the most important feature of Cu-mediated ATRP in aqueous phase. This effect allows for a reduction of the Cu concentration without compromising reaction time. Moreover, such highly active catalysts systems are favorable for ATRPs in which regenerative concepts such as ICAR or ARGET ATRP are used.

To check the accuracy of the PREDICI® simulations, a set of PEGMA polymerization with various Cu catalyst concentrations and different amounts of water were carried out. The resulting polymer was analyzed by SEC with dimethylacetamide (DMAc) as the eluent, because of a

better solubility of the high conversion polymer. However, the molecular mass of the polymer could not be determined, due to the missing Kuhn–Mark–Houwink–Sakurada coefficients for this eluent.

Nevertheless, the measured dispersity of the polymer was compared to calculated dispersity of the PREDICI® simulations. In Table 4.6 are listed the measured dispersities for various PEGMA ATRPs with the associated initial $\text{Cu}^{\text{I}}/\text{L}$ and $\text{Cu}^{\text{II}}/\text{L-Br}$ concentrations, the monomer conversion, and the measured and simulated dispersity of the polymer. The HEMA-Br initiator concentration is equal to the $\text{Cu}^{\text{I}}/\text{L}$ concentration for each experiment and all polymerizations were carried out with an excess of NaBr.

As seen in Table 4.6, the experimental dispersity is in close agreement with the theoretical predictions. The slight deviation is caused by the experimental uncertainty and the disregard of SEC broadening during the simulation. The dispersity for all experiments is between 1.15 and 1.30. The small dispersities of around 1.2 even at high diluted solutions were realized by adding more $\text{Cu}^{\text{II}}/\text{L-Br}$ to the solution. These findings show that the PREDICI® simulations allow for a precise prediction of the dispersity for each polymerization.

The simulations in the present section were focused on the impact of NaBr content and water content on dispersity, chain-end functionality and reaction time. The simulations were carried out for a normal ATRP, however, the kinetic data may also be used for reverse, SR&NI or ICAR ATRP by implementing the literature known decomposition rates of various thermal initiators. It may further be possible to simulate an ARGET and AGET ATRP once the kinetics and mechanism of the reduction process is known.

The kinetic data were exclusively determined for Cu-mediated ATRP of PEGMA with $\text{CuBr}/2,2'$ -bipyridine. It may however possible to use the data to predict quantitatively the impact on dispersity, chain-end functionality for similar reactive ATRP catalyst, e.g., HMTETA or 4,4'-Di(5-nonyl)-2,2'-bipyridine (dNbpy).

Table 4.6: Comparison of experimental measured dispersity and simulated dispersity for different polymerization conditions with HEMA-Br acting as the initiator. All experiments were carried out in an excess of 50 equivalents NaBr. The measured SEC-spectra are depicted in Figure A5.

Iron-mediated ATRP in aqueous phase

Fe-mediated ATRP is an attractive alternative to the extensively used Cu-mediated ATRP due to low toxicity, good biocompatibility and good accessibility of iron.^[141] Fe-based ATRP in organic solvents has mostly been applied to ATRP of styrene^[55,142,143] and methacrylates,^[144–148] but also to nitriles^[49,149] and, with some complications, also to acrylates.^[55,57,150,151]

The iron catalysts reported to date are mostly based on halides, phosphines, amines, and imines as ligands for the formation of iron complexes.^[5,8,10,49,152] In contrast to Cu-catalysis, iron-halide-mediated ATRP may also be performed in polar solvents without additional specific ligands.^[146] However, Fe-ATRP with these types of ligands is limited to the above-mentioned types of monomers. Even though NMP may be used as a solvent for Fe-based ATRP, attempts in this work to polymerize the structurally similar N-vinylpyrrolidone (NVP) were unsuccessful, most likely due to dimerization of NVP as reported for xanthate-mediated polymerization.^[153] It has been suggested that alkyl halides with some metal complexes may also catalyze NVP dimerization.^[153]

To achieve Fe-based ATRP in aqueous solution, stable and well-defined Fe-ligand systems are required, similar to Cu-mediated ATRP. The highly active Fe-complexes such as $[\text{Fe}^{\text{III}}\text{Br}_3(\text{Solv})]^-$ are not stable in water. Stable amine ligands, that have been used in Cu-mediated ATRP,

often showed unsatisfying activity, low polymerization rates and a lack of control.^[5] A few reports suggest that the amine tris(3,6-dioxahexyl)amine (TDA) may be used in an AGET ATRP.^[52,154] However, experiments with Fe and TDA in this work evidenced a limited solubility and stability of the catalyst in aqueous solution.

Recently, a growing interest in the development of water-soluble porphyrin based ligands has emerged. These bio-inspired Fe-ATRP ligands promise polymerization under bio-relevant conditions, i.e., at low temperature and high water content. Protein-based ATRP ligands with iron-heme centers, such as horseradish peroxidase (HRP),^[155] catalase^[54] and hemoglobin (Hb)^[53] act as ATRP catalysts and may be used to produce high-molecular-mass polymers with narrow MMD.^[5,49]

Matyjaszewski *et al.* reported a modified water-soluble protoporphyrin IX containing a ferric ion with an additional axial bromide ligand (see Figure 5.1), without however performing kinetic studies.^[1] The protoporphyrin-type catalysts has been used within the present study and were kindly provided by the Matyjaszewski group. These complexes have a poly(ethylene glycol) (MPEG) side arm for better solubility. The vinyl moieties from the initial protoporphyrin IX have been removed to prevent polymerization of the ligand itself. Further modifications of the catalyst, which have been tested in this work, involve the replacement of one MPEG side arm with an imidazole or thioether end group to potentially improve the protection against coordinating monomers and solvents. The recently developed mesohemin-(MPEG₅₀₀)₂ catalyst provides a good polymerization control and relatively fast polymerization even at low temperatures in aqueous solution.^[1]

The reversible deactivation of radicals in Fe-based ATRP is mediated by an Fe^{III} catalyst. The reaction of Fe^{II} with radicals is also relevant in Fe-mediated organometallic radical polymerization (OMRP) (see Scheme 5.1 below). Experimental and computational analysis suggest that ATRP as well as organometallic reactions may operate simultaneously.^[5,152] Iron porphyrin complexes are also known to form stable organometallic species in organic solvents by the reaction of alkyl radicals with Fe^{II} or by various other reactions.^[156–160] Thereby, organometallic reactions may not be limited to organic solvents. Organometallic reactions and Fe-mediated ATRP in aqueous solution have not yet been investigated. The relative importance of either

Figure 5.1: Structural formulae for the iron-porphyrin-catalysts investigated in this chapter. The mesohemin-(MPEG₅₀₀)₂ was available as the bromide and chloride derivative. The catalysts were kindly provided by A. Simakova from the Matyjaszewski group.^[1]

pathway has also not been discussed for Fe-porphyrin mediated reactions in aqueous solution.

To gain a better understanding of Fe-mediated RDRP in aqueous solution this chapter deals with the spectroscopic analysis via UV/Vis and Moessbauer spectroscopy of the Fe species occurring during polymerization. Besides the ATRP-relevant Fe^{II}/L and Fe^{III}/L-Br species, it will be checked for organometallic species, Fe^{III}/L-R. Moreover, highly time-resolved EPR, and UV/Vis spectroscopy in combination with Stopped-Flow injection will be used to measure ATRP- and OMRP-relevant parameters, i.e., k_{deact} , K_{ATRP} and $k_{\text{add,Fe}}$, the addition of radicals to Fe^{II}, in various monomer–water mixtures and in monomer-free model systems. Additionally, the experiments are accompanied by size-exclusion chromatography to provide guidance for a suitable selection

of reaction conditions for polymerization.

5.1 Speciation Analysis

This subchapter deals with a detailed investigation into the involved species via online monitoring of the mesohemin-(MPEG₅₀₀)₂ catalyst concentration (Figure 5.1) in PEGMA/H₂O mixtures and in monomer-free model systems via UV/Vis spectroscopy combined with Moessbauer spectroscopy.

Illustrated in Scheme 5.1 are the equilibria involved in Fe-mediated RDRP. The blue box represents the ATRP mechanism without the water-induced halide dissociation as described in chapter 4. To prevent halide dissociation in aqueous solution, the reactions were performed in the presence of an excess of the corresponding sodium halides. According to the ATRP equilibrium, activation of an alkyl halide initiator, R-Br, by Fe^{II}/L generates radicals, R•, and the deactivator complex Fe^{III}/L-Br.

The OMRP equilibrium depicted in the red box describes the reaction of Fe^{II}/L with R• to the organometallic species, Fe^{III}/L-R. This organometallic species may react in different subsequent reactions, the most important ones are the reverse reaction to Fe^{II}/L, i.e., the reversible termination (RT), and the catalytic radical termination (CRT) of two radicals via the Fe^{III}/L-R intermediate species.^[56,58,152] Scheme 5.1 shows that the Fe^{II}/L species participates in both reaction pathways and may be crucial for the selection of the pathway for the subsequent reaction. The focus of the spectroscopic studies centers around the question whether ATRP and OMRP equilibria are both operating with the Fe catalyst under investigation.

To distinguish between the iron species occurring during a polymerization and in a model system, UV/Vis spectroscopy has been applied. Iron porphyrin complexes exhibits a characteristic strong Soret-absorption band at around 400 nm and usually up to four additional, but less intense Q bands between 400 and 800 nm.^[159,161] The intense Soret bands are strongly overlapping which poses problems for

Scheme 5.1: Iron-mediated radical polymerization with a simultaneous ATRP and OMRP equilibrium. Both reaction pathways involve the Fe^{II}-hemin activator complex and growing radicals, R[•]. The potential subsequent reaction of the catalytic radical termination (CRT) is also included.

distinguishing the iron species. However, the iron species provide distinctly different Q band absorption spectra. Shown in Figure 5.2 are the UV/Vis spectra between 400 and 700 nm for Fe/L species in 50wt% H₂O/PEGMA at 22 °C. The black line represents the initial Fe^{III}/L-Br species, which exhibits a characteristic absorption centered around 577 nm. Upon the addition of HEMA-Br which acts as an ATRP initiator, no change of the absorption spectrum is observed. As the original spectrum was retained after addition of HEMA-Br, the Fe^{III} state of the metal was confirmed.

Reported polymerizations of mesohemin-(MPEG₅₀₀)₂ were carried out in a reverse fashion, starting with Fe^{III}/L-Br and ascorbic acid as a reducing agent (AGET ATRP, activators generated by electron transfer, see chapter 2.3).^[1] The recorded Fe/L spectrum in the presence of a tenfold excess of ascorbic acid is almost identical to the initial Fe^{III}/L-Br species (black line) indicating that ascorbic acid provides only an inefficient reduction power. The very slow decay in absorption band suggests that less than one percent of the Fe^{III}/L-Br is reduced to Fe^{II}/L. This finding is important to understand the reported AGET polymerization. The fact that the polymerization rate with this catalyst species was very high, despite the slow reduction rate with ascorbic acid, indicates a high catalytic activity even at ppm levels of Fe^{II}/L. Moreover, the finding suggests that the type of ATRP may be better

Figure 5.2: UV/Vis spectra of the participating mesohemin-(MPEG₅₀₀)₂ species in PEGMA/H₂O mixtures with 50 wt% water at 22 °C. The black line indicates the initial Fe^{III}-Br/L species which was reduced with Na₂S₂O₄ to yield the Fe^{II}/L spectrum (red line). The reaction of Fe^{II}/L and the thermal initiator VA-44 at 65 °C lead to the Fe^{III}/L-R species (brown line). The green line spectrum results from the reversible reaction with HEMA-Br and may be associated with the almost pure Fe^{III}/L-Br. The small variation may be due to traces of Fe^{III}/L-R.

described by an ARGET ATRP, in which the Fe^{II}/L complex is slowly and constantly regenerated.

To obtain an Fe^{II} spectrum, the stronger water soluble reducing agent sodium dithionite (Na₂S₂O₄) was chosen. The reaction with Na₂S₂O₄ yields a different absorption spectrum (red line), which is assigned to the formation of the anticipated Fe^{II}/L complex. The absorption band at 577 nm, associated with the Fe^{III}/L-Br complex, completely disappears and the characteristic double band for Fe^{II} porphyrin complexes at around 466 and 500 nm shows up.^[162,163] The solution with the produced Fe^{II}/L complex was used to check whether and to which extent Fe^{II}/L undergoes either of the two reaction pathways proposed in Scheme 5.1 Fe^{II}/L may react via two pathways:

one option is the reaction with an alkyl halide the other one is the reaction with a radical. The reaction with HEMA-Br yields the green line spectrum which is close to the spectrum of $\text{Fe}^{\text{III}}/\text{L-Br}$. The small difference between the black and green spectra at ca. 540 nm in the absorption may be due to the potential reaction pathway of the $\text{Fe}^{\text{III}}/\text{L-R}$ species. The reaction with HEMA-Br is also reversible, since the formed $\text{Fe}^{\text{III}}/\text{L-Br}$ can again be reduced with $\text{Na}_2\text{S}_2\text{O}_4$ to $\text{Fe}^{\text{II}}/\text{L}$ (not shown).

The second option is the formation of $\text{Fe}^{\text{III}}/\text{L-R}$ species. The absorption due to the $\text{Fe}^{\text{III}}/\text{L-R}$ species is shown in Figure 5.2 as the third iron species (brown line). This species is obtained by the reaction of $\text{Fe}^{\text{II}}/\text{L}$ with the thermal initiator VA-44 at 65 °C, where initiation decomposition is fast, yielding a high radical concentration of PEGMA radicals that may react via the OMRP pathway to the stable $\text{Fe}^{\text{III}}/\text{L-R}$ species. The formation of the $\text{Fe}^{\text{III}}/\text{L-R}$ signal can be monitored via the decrease of the absorption at around 500 nm on a timescale of 10 min (see Figure A6A). Further experiments indicate that the $\text{Fe}^{\text{III}}/\text{L-R}$ species is stable for at least 15 min at 65 °C and, of course significantly longer at 20 °C (see Figure A6B). Stable OM species were also reported for Fe^{II} porphyrins reacting with alkyl radicals.^[156,157,159,160,164]

To obtain further mechanistic insights, UV/Vis measurements were carried out with monomer-free model systems using PEO as solvent, which may be regarded as the saturated analogue of PEGMA. In addition to the strong solvatochromic shift by 70 nm to higher wavelengths, the changes in the UV/Vis absorbance are otherwise identical to the ones observed with the polymeric system (see Figure A7).

Solutions as subjected to UV/Vis spectroscopy were also investigated via ^{57}Fe zero-field Moessbauer spectroscopy to provide direct information on the oxidation and spin states of the Fe species. This information is also used to confirm the assignment from UV/Vis spectroscopy. The experimental procedures to yield the polymer samples subjected to Moessbauer analysis were similar to the ones used for preparing the samples for UV/Vis spectroscopy, except that higher concentrations of each component were used to achieve a sufficiently good signal-to-noise ratio. All Moessbauer spectra were recorded at 80 K and were flash-frozen in liquid nitrogen, and should represent the Fe/L composition at ambient temperature.

Due to the unfavorably large γ -capture cross-section of bromide, the

chloride derivative of the complex was used for the measurements. Previous investigations suggest that the chloride catalyst behaves as does the bromide species. The characteristic absorption of $\text{Fe}^{\text{III}}/\text{L-Br}$ at 577 nm shows a small blue shift of ca. 15 nm due to the stronger Fe-Cl bond with an otherwise almost identical absorption spectrum.

Because of the non-optimum γ -capture cross-section of chloride, all experiments were carried out with no more than 50 eq. of NaCl with respect to the Fe complex in a 50 wt% $\text{H}_2\text{O}/\text{PEGMA}$ mixture. Illustrated in Figure 5.3 are the recorded Moessbauer spectra of $\text{Fe}^{\text{II}}/\text{L}$ obtained by the reaction with 0.5 equivalents of $\text{Na}_2\text{S}_2\text{O}_4$ (A), the $\text{Fe}^{\text{II}}/\text{L}$ reduced by an excess of $\text{Na}_2\text{S}_2\text{O}_4$ (B) and the $\text{Fe}^{\text{III}}/\text{L-R}$ species through the reaction of $\text{Fe}^{\text{II}}/\text{L}$ with VA-44 (C). The associated Moessbauer parameters of the isomeric shift, δ , quadrupole splitting, ΔE_{Q} , line width, Γ , and relative intensity are listed in Table 5.1.

The spectrum of $\text{Fe}^{\text{III}}\text{-Cl/L}$ in solution was also recorded as a reference. The porphyrin-complex in solution is Moessbauer-silent, which is assigned to intermediate spin relaxation.^[165,166] The Moessbauer spectrum of the $\text{Fe}^{\text{III}}/\text{L-Cl}$ complex in bulk, however, shows asymmetric broadened lines (see Figure A8). The situation improves by lowering the temperature for the Moessbauer measurements. The onset of broadening occurs in a temperature range which is characteristic for Fe^{III} porphyrins and can only occur for iron species with an odd number of spin state.^[165,166]

Shown in Figure 5.3A is the Moessbauer spectrum obtained by the reaction of $\text{Fe}^{\text{III}}/\text{L-Cl}$ with 0.5 equivalents of $\text{Na}_2\text{S}_2\text{O}_4$, since $\text{Na}_2\text{S}_2\text{O}_4$ decomposes into two anionic $[\text{SO}_2]^-$ radicals. The spectrum has been fitted with two subfunctions to fit the overall spectrum. The red spectrum was fitted with typical Fe^{II} low spin parameter of $\delta = 0.46 \text{ mm s}^{-1}$ and $\Delta E_{\text{Q}} = 0.29 \text{ mm s}^{-1}$ (see Table 5.1). The blue spectrum was fitted with the parameter $\delta = 0.01 \text{ mm s}^{-1}$ and $\Delta E_{\text{Q}} = 0.10 \text{ mm s}^{-1}$. The broad signal with no quadrupole splitting indicates an Fe^{III} species. It appears reasonable to assume that the absorption can be assigned to $\text{Fe}^{\text{III}}/\text{L-Cl}$ and occurs as a consequence of incomplete reduction. The incomplete reduction may be due to the unstable nature of the formed $[\text{SO}_2]^-$ anionic radicals from $\text{Na}_2\text{S}_2\text{O}_4$ in water. $\text{Na}_2\text{S}_2\text{O}_4$ was dissolved in water prior to adding it to the solution. Under these circumstances a significant amount of $[\text{SO}_2]^-$ may have decomposed before the addition

Figure 5.3: ^{57}Fe Mössbauer spectra recorded at 80 K on a flash-frozen solution of PEGMA/50wt% H_2O . (A) Spectrum of the $\text{Fe}^{\text{II}}/\text{L}$ low spin species (red) after the reaction of $\text{Fe}^{\text{III}}/\text{L}-\text{Cl}$ (blue) with 0.5 eq. $\text{Na}_2\text{S}_2\text{O}_4$. (B) Spectrum of the $\text{Fe}^{\text{II}}/\text{L}$ low spin species (red) and the $\text{Fe}^{\text{II}}/\text{L}$ high spin species (green) after the reaction of $\text{Fe}^{\text{III}}/\text{L}-\text{Cl}$ with 2 eq. $\text{Na}_2\text{S}_2\text{O}_4$. (C) Spectrum of the $\text{Fe}^{\text{III}}/\text{L}-\text{R}$ recorded after the reaction of $\text{Fe}^{\text{II}}/\text{L}$ with VA-44 for 20 min at 65 °C. The associated Mössbauer parameters are listed in Table 5.1.

Table 5.1: Mössbauer parameters from Figure 5.3; δ , ΔE_Q and Γ refer to isomeric shift, quadrupole splitting, and line width, respectively. The spectra were measured at 80 K.

	Iron species	δ / mm s ⁻¹	ΔE_Q / mm s ⁻¹	Γ / mm s ⁻¹	rel. conc. / %
(A)	Fe ^{II} /L $S = 1/2$	0.46	0.29	0.29	35
(A)	Fe ^{III} /L-Br	0.01	0.10	1.64	65
(B)	Fe ^{II} /L $S = 1/2$	0.46	0.27	0.35	66
(B)	Fe ^{II} /L $S = 2$	0.99	2.5	0.37	34
(C)	Fe ^{III} /L-R	0.36	0.53	0.69	100

to the catalyst.

It is interesting to note that the Fe^{III}/L-Cl species is observed in the presence of Fe^{II}, even though the same species is Moessbauer-silent in the absence of other Fe species (see Figure A9A). This situation may be due the interaction with Fe^{II} that induces a change of the spin relaxation times.

To achieve a complete reduction, a second experiment with a twofold excess of Na₂S₂O₄ with respect to Fe^{III}/L-Cl was carried out. Moreover, Na₂S₂O₄ was added to the solution without prior solvation in water. The resulting Moessbauer spectrum is shown in Figure 5.3B. The overall spectrum has again been fitted with two subfunctions, which are assigned to one Fe^{II}/L species with different spin state, high spin and low spin. The red fit has the identical Moessbauer parameters as the one in Figure 5.3A that indicates being the same Fe^{II}/L low spin species. The second subfunction has been fitted with characteristic parameters for a Fe^{II} high spin species with a strong isomeric shift of $\delta = 0.99$ mm s⁻¹ and a high quadrupole splitting of $\Delta E_Q = 2.50$ mm s⁻¹. It cannot be ruled out

that the second Fe^{II}/L high spin species is also present in the mixture associated with Figure 5.3A, but it is not seen due to the low signal-to-noise ratio and being a minor species.

In contrast to the Moessbauer spectrum, the UV/Vis spectra showed no indications of a different spin state of the Fe^{II}/L species. The Fe^{II}/L high spin species may either be a result of the coordination of some dithionite or since some iron porphyrins are known to exhibit a spin cross-over in the investigated temperature range at 80 K, the Moessbauer spectrum of two species may be caused by spin-crossover phenomena.^[167,168] As high spin complexes are favored at elevated temperature, it can be assumed that the Fe^{II}/L high spin species is the dominant species during UV/Vis experiments at 20 °C.

Shown in Figure 5.3C is the Moessbauer spectrum of Fe^{III}/L-R which is obtained by the reaction of Fe^{II}/L with VA-44, and thus PEGMA radicals (R[•]), at 65 °C for 20 min. The overall spectrum has been fitted by a single Fe species. The fitted parameters of $\delta = 0.36 \text{ mm s}^{-1}$ and $\Delta E_Q = 0.53 \text{ mm s}^{-1}$, and the asymmetric peak shape may be assigned to the spectrum of a Fe^{III} species, which differs from the Moessbauer-silent Fe^{III}/L-Cl species. It is reasonable to assume that the spectrum belongs to a Fe^{III} low spin species, since Fe^{III}/L-R species are known to be mostly stable as low spin complexes.^[164] Moreover, the Moessbauer spectrum shows no evidence that the two above described Fe^{II}/L species react in two different pathways. This underlines the assumption above that only Fe^{II}/L high spin species are present during the reaction with R[•] at ambient temperature. The Fe^{II}/L low spin complex may result from the freezing process.

For comparison with the UV/Vis analysis, two more Moessbauer spectra were recorded. One with a typical setting of the polymerization experiment described by Simakova *et. al.* containing Fe^{III}/L-Cl and ascorbic acid and the other one with Fe^{III}/L-Cl and an excess of ascorbic acid to check for a potential reduction.^[1] The obtained Moessbauer spectra showed no absorption (Figure A9B and C). Since Fe^{III}/L-Cl is the only Moessbauer-silent species, this finding indicates that ascorbic acid provides a very low reducing potential during a polymerization and only traces of Fe^{III}-Br/L are reduced to Fe^{II}/L. This result is in agreement with the UV/Vis spectra, which show no change in the absorption spectrum upon adding ascorbic acid.

According to Scheme 5.1, small Fe^{II}/L concentrations are to be

preferred for the ATRP pathway. Very small $\text{Fe}^{\text{II}}/\text{L}$ concentrations in combination with a controlled radical polymerization assume that the rate of the ATRP is faster than the rate for organometallic reactions. Moreover, the polymerization starting with $\text{Fe}^{\text{II}}/\text{L}$ and a thermal radical initiator would provide no control over the polymerization. Although both reaction pathways, ATRP and OM, may occur, in principle, it is most likely that the reaction is dominated by the ATRP pathway. Therefore, it seems reasonable to assume that the mesohemin-(MPEG₅₀₀)₂ catalyst provides control via ATRP.

5.2 Rate coefficients from SP–PLP–EPR analysis

Because of the mechanistic and kinetic complexity induced by the occurrence of simultaneous ATRP and OMRP with iron-mediated RDRP, the precise knowledge of the mechanism of the individual rate coefficients is necessary to gain an adequate understanding and to improve Fe-based RDRP systems. Since the ATRP reaction pathway for the $\text{Fe}^{\text{III}}\text{-Br/L}$ species is favored in the Fe-porphyrin-based RDRP, although the formation of organometallic $\text{Fe}^{\text{III}}\text{-R/L}$ species is possible, the investigation of ATRP-related rate coefficients is more important. Especially the deactivation rate coefficient, k_{deact} , plays a significant role for the control of the polymerization. Moreover, it is interesting to know the extent by which the water concentration may influence ATRP control.

The SP–PLP–EPR technique has been become a versatile tool to determine rate coefficients of radical polymerization.^[62,169] This technique offers the advantage of the direct highly time-resolved measurement of propagating radical concentration after instantaneous pulsed-laser-induced radical initiation.^[62,170] EPR may also allow the measurement of some metal compounds with unpaired electrons such as Cu^{II} or with restrictions high-spin Fe^{III} .^[66,126,170,171]

The SP–PLP–EPR technique in aqueous solution has been applied for the first time in Fe-mediated ATRP.

5.2.1 Measurement of k_{deact} via SP–PLP–EPR

This chapter deals with the measurement of the ATRP deactivation rate coefficient, k_{deact} , within a wide range of PEGMA/H₂O mixtures with the above-described Fe^{III} porphyrin complexes (Figure 5.1) via SP–PLP–EPR. The SP–PLP–EPR experiments may be carried out such that ATRP deactivation kinetics is recorded without the interference by organometallic reactions, as will be shown below.

SP–PLP–EPR studies into k_{deact} are easier to be performed in the case that deactivation rate is much faster than termination. As shown in chapter 3.2, the termination rate of PEGMA is relatively slow compared to radicals with a shorter side chain, e.g., of methyl methacrylate.

It is also advantageous that the sensitivity of EPR towards the detection of methacrylate-type radicals is better than, e.g., of styryl radicals. Moreover, methacrylate-type radicals provide less complicated kinetics due to the absence of backbiting and thus of midchain-radical formation.^[118,119]

Illustrated in Scheme 5.2 is the procedure for measuring k_{deact} . As with the Cu-mediated ATRP studies described in chapter 4.2.1, the experiment is started in the reverse ATRP fashion in which the catalyst is employed in the higher oxidation state, Fe^{III}/L-Br. The starting materials are marked red. Darocur 1173 (Darocur) acts as a water-soluble photoinitiator for producing primary radicals which rapidly react with monomer molecules, M. The propagating radicals, R_n•, react with Fe^{III}-Br/L to generate deactivated alkyl halide, R_n-Br, and Fe^{II}/L.

The system under investigation contains 1.0 mM of the Fe^{III} porphyrin bromide complex, Fe^{III}/L-Br (for the structure see Figure 5.1), and 20 mM Darocur for PEGMA/H₂O mixtures ranging from 30 to 90 wt% H₂O. The initial Fe^{III}/L-Br concentration of 1 mM was chosen to achieve a clear EPR spectrum with a measureable deactivation effect. Higher Fe^{III}/L-Br concentration would lead to faster deactivation, which may cause difficulties at the given time resolution of the EPR setup. Moreover, in order to avoid the reaction of R• with Fe^{II}/L and thus the formation of organometallic species, the laser pulse intensity and the Fe^{III}/L-Br concentration were carefully selected to generate only small amounts of Fe^{II}/L.

Scheme 5.2: SP-PLP-EPR measurement of k_{deact} . The starting components, i.e., the photoinitiator Darocur 1173, monomer M, and the $\text{Fe}^{\text{III}}/\text{L-Br}$ complex are marked red. The primary radicals are generated by a laser pulse which produces propagating radicals, R_n^\bullet , with a chain length n . $\text{Fe}^{\text{II}}/\text{L}$ and $\text{R}_n\text{-Br}$ are produced by deactivation.

As expected, the EPR spectrum of PEGMA radicals in the presence of $\text{Fe}^{\text{III}}/\text{L-Br}$ is identical to the one without any metal in the system (cf. Figure 3.9). The $\text{Fe}^{\text{III}}/\text{L-Br}$ concentration cannot be detected via EPR due to a strong zero field splitting at the given temperatures. The $\text{Fe}^{\text{III}}/\text{L-Br}$ concentration may be detectable at very low temperatures below 20 K, but due to the expansion of water in the EPR flat cell, the temperature cannot be below 273 K. Thus, the catalyst concentration has been measured via UV/Vis spectroscopy. After applying 15 laser pulses, less than 10% of the $\text{Fe}^{\text{III}}/\text{L-Br}$ was converted. Consequently only minor amounts of $\text{Fe}^{\text{II}}/\text{L}$ are produced and the reverse reaction should not occur to a significant extent.

Shown in Figure 5.4 are the $[\text{PEGMA}^\bullet]$ versus time traces recorded at 20 °C for 30, 50, 70 wt% $\text{H}_2\text{O}/\text{PEGMA}$ with 1 mM of $\text{Fe}^{\text{III}}/\text{L-Br}$ and without $\text{Fe}^{\text{III}}/\text{L-Br}$ in 50 wt% $\text{H}_2\text{O}/\text{PEGMA}$. In each case, an intense increase of PEGMA radicals occurs at $t = 0$, when a single laser pulse is applied to the sample. The black line represents the radical decay in the absence of Fe, where only radical-radical termination occurs. The colored lines represent the experiments with $\text{Fe}^{\text{III}}/\text{L-Br}$. The decrease of $[\text{PEGMA}^\bullet]$ via the conventional termination occurs on an at least tenfold longer timescale than the deactivation in experiments with $\text{Fe}^{\text{III}}/\text{L-Br}$.

Figure 5.4: Normalized PEGMA• concentration vs time profiles at 20 °C measured by SP-PLP-EPR with a single laser pulse being applied at $t = 0$. The black line represents the radical decay by conventional radical-radical termination. The colored lines represent the radical decay via ATRP deactivation with 1 mM mesohemin-(MPEG₅₀₀)₂ in mixtures with 30, 50 and 70 wt% H₂O/PEGMA, respectively.

Interestingly, the decrease in PEGMA• concentration in the presence of Fe is faster at higher water contents, although the Fe^{III}/L-Br concentration is identical (1 mM). This observation indicates that ATRP deactivation by Fe^{III}-Br/L becomes faster toward higher water content.

Within successive experiments the radical decay becomes slower, due to Fe^{III}/L-Br conversion to Fe^{II}/L and thus due to a lower catalyst concentration (see Figure A10). The slower decrease of radical concentration suggests that the trapping reaction of R• by Fe^{II}/L may also be slower than the ATRP deactivation. As seen in Scheme 5.1, organometallic reactions may become significant at higher degrees of Fe^{III}/L-Br conversion and thus higher Fe^{II}/L concentration. The precise control of Fe^{III}/L-Br conversion by the number of applied laser pulses contributes a particular advantage of the SP-PLP-EPR technique for measuring ATRP deactivation.

The analysis of k_{deact} is possible by two approaches. The first approach involves computational modeling via the program package PREDICI[®] for fitting the experimental [PEGMA•] vs time profiles. This approach requires an averaged Fe^{III}/L-Br concentration and a calibration of EPR intensity with respect to absolute [PEGMA•]. The calibration of EPR intensity is performed via TEMPOL, as described in chapter 7.4.3. The modeling procedure further requires the precise knowledge of $k_t^{1,1}$ and of the associated composite-model parameters as well as of k_p , such that k_{deact} remains the only unknown parameter to be determined via the fitting of experimental radical concentration vs time data.

The second approach of the analysis of k_{deact} benefits from the high ratio of deactivation over termination rate with the system under investigation. This approach is based on a pseudo first-order reaction of [PEGMA•] in the deactivation process after (5.1).^[67] Since deactivation is a first-order reaction with respect to [R•], whereas radical-radical termination is second order with respect to [R•], termination plays a significant role only right after applying the laser pulse, when the radical concentration is high. At later times, the decay in radical concentration is dominated by deactivation. The radical concentration may be then fitted to a straight line: $\ln([R•]_0/[R•])$ vs time (Eq. (5.1)). This method is particular useful for reactions with a low termination rate and high deactivation rate because no calibration for absolute radical concentration and no literature values for $k_t^{1,1}$ and k_p are required.

$$\frac{d([R•]_0/[R•])}{dt} = k_{\text{deact}} \cdot [\text{Fe}^{\text{III}}\text{Br/L}] \quad (5.1)$$

Shown in Figure 5.5 are results for the two approaches. The plot on the left-hand side represents the PREDICI[®] procedure and the plot on the right-hand side shows the pseudo-first-order plot of $\ln([R•]_0/[R•])$ vs time. The PREDICI[®] modeling in Figure 5.5A yields $k_{\text{deact}} = 1.2 \cdot 10^5 \text{ L mol}^{-1} \text{ s}^{-1}$ in 50 wt% H₂O/PEGMA at 20 °C.

Shown in Figure 5.5B is the plotted pseudo-first-order-approach of $\ln([R•]_0/[R•])$ vs time. The curvature in the early time regime of Figure 5.5B indicates a significant contribution from radical-radical termination and has not been considered in the fitting process. The straight-line fit holds for later time regime when ATRP

Figure 5.5: (A) Absolute PEGMA• concentration vs time profile for mesohemin-(MPEG₅₀₀)₂ in 50 wt% H₂O/PEGMA at 20 °C. The determination of k_{deact} was achieved via PREDICI® modeling. (B) $\ln([R^\bullet]_0/[R^\bullet])$ vs time trace for mesohemin-(MPEG₅₀₀)₂ in 50 wt% H₂O/PEGMA at 20 °C. The curvature in the early time regime indicates the significant contribution of radical-radical termination. A straight line has been fitted to the later time regime when ATRP deactivation controls the decay in radical concentration.

deactivation is the dominant pathway. The slope to the straight line provides the product $k_{\text{deact}} \cdot [\text{Fe}^{\text{III}}/\text{L-Br}]$. The $\text{Fe}^{\text{III}}/\text{L-Br}$ concentration has been measured via UV/Vis spectroscopy before and after applying the laser pulses. The $\text{Fe}^{\text{III}}/\text{L-Br}$ conversion was below 10% and the arithmetic mean value has been calculated from the measured concentrations. Combination of the so-obtained data yields $k_{\text{deact}} = 1.3 \cdot 10^5 \text{ L mol}^{-1} \text{ s}^{-1}$ in 50 wt% H₂O/PEGMA at 20 °C. It is gratifying to note the k_{deact} values from two approaches are in close agreement. The pseudo-first-order plot has been used as the preferred evaluation method in what follows.

Depicted in Figure 5.6 are the k_{deact} values for mesohemin-(MPEG₅₀₀)₂-mediated deactivation for 30, 50, 70, 80 and 90 wt% H₂O/PEGMA at 20 °C obtained via the $\ln([R^\bullet]_0/[R^\bullet])$ vs time approach. The plot shows a strong increase in k_{deact} between 50 and 90 wt% H₂O from $1.5 \cdot 10^4 \text{ L mol}^{-1} \text{ s}^{-1}$ to $3.2 \cdot 10^5 \text{ L mol}^{-1} \text{ s}^{-1}$. The smallest value for $k_{\text{deact}} = 0.95 \cdot 10^4 \text{ L mol}^{-1} \text{ s}^{-1}$ was determined with 30 wt% H₂O, which is by about two orders of magnitude below k_{deact} for a series of Cu-

mediated systems.^[36,66,126]

In contrast, k_{deact} for 90 wt% H₂O was estimated to be $3.2 \cdot 10^5 \text{ L mol}^{-1} \text{ s}^{-1}$ which is more than one order of magnitude above the value for 30 wt% H₂O and is close to the reported value for the Cu-mediated ATRP of DMA with the ligand system 1,1,4,7,10,10-hexamethyltriethylenetetramine (HMTETA): $k_{\text{deact}} = 8 \cdot 10^5 \text{ L mol}^{-1} \text{ s}^{-1}$.^[126] The estimated k_{deact} values in 90 wt% H₂O are also close to the reported values for the highly active tetrabutylammonium [Fe^{III}Br₄] catalyst with MMA in organic phase: being $k_{\text{deact}} = 5.0 \cdot 10^5 \text{ L mol}^{-1} \text{ s}^{-1}$ at 60 °C.^[68] On the other hand, the k_{deact} value in 90 wt% H₂O lies one order of magnitude above the value reported for amine-*bis*(phenolates)iron-mediated deactivation of $k_{\text{deact}} = 2.7 \cdot 10^4 \text{ L mol}^{-1} \text{ s}^{-1}$ at 60 °C.^[67]

As can be seen in Figure 5.6, the strongest increase of k_{deact} occurs between 50 and 90 wt% H₂O in which range PEGMA polymerizations are mostly carried out.^[1,33,52,110] Since an efficient ATRP catalyst is associated with a fast deactivation and thus a high k_{deact} , a higher water content is to be preferred for achieving higher ATRP control. It also can be stated that a certain amounts of water may be necessary for a successfully controlled polymerization. In Figure 5.6, the range of water concentrations in which ATRP of the system under investigation may be effectively controlled is marked by the black box.

In the iron-mediated RDRPs reported so far, e.g., with amine-*bis*(phenolates), elevated temperatures are required to reach a favorable high deactivation rate.^[67,143] The smaller k_{deact} values of these systems are compensated by a high $E_A(k_{\text{deact}})$ of about 35 kJ mol⁻¹ which yields a sufficiently high deactivation rate and thus control at higher temperatures.^[55,58,68,146] In contrast to FeBr₃ and to the amine-*bis*(phenolates)iron systems, mesohemin-(MPEG₅₀₀)₂ benefits from the high k_{deact} at higher water content even at 20 °C.

To discuss the increase in k_{deact} and to make a prediction about k_{deact} at water contents above 90 wt%, it appears useful to compare the deactivation process with the termination of two radicals. Although the deactivation step is a chemical controlled process due to the halide transfer from the catalyst to the radical, the radical as well as the catalyst need to diffuse to each other. Because of the long-chain-PEGMA radical and the bulky catalyst, the diffusion behavior may be similar to the behavior of two long-chain radicals. During the

Figure 5.6: Variation of k_{deact} with water content with PEGMA in mesohemin-(MPEG₅₀₀)₂ mediated ATRP at 20 °C.

SP-PLP-EPR experiment, an average number of 200 monomer units are added to the radical functionality before deactivation by the Fe^{III}/L-Br catalyst occurs. Therefore, it seems reasonable to compare k_{deact} with the $k_t^{200,200}$, which may be calculated according to Equation 2.15 via the data presented in chapter 3.2.

Depicted in Figure 5.7 is the variation of the $k_t^{200,200}$ and of the measured k_{deact} values as a function of water content. The $k_t^{200,200}$ values are by one order of magnitude above the k_{deact} values. Moreover, the $k_t^{200,200}$ values exhibit a linear increase in the concentration range 30 to 70 wt% H₂O, whereas the increase in k_{deact} is best described with an S-shaped function. The dissimilarity of the variation of $k_t^{200,200}$ and k_{deact} on water content demonstrates that k_{deact} refers to no diffusion-controlled process.

It is unlikely that the increase in k_{deact} continues in a pronounced fashion above 90 wt% H₂O, as k_{deact} would approach $k_t^{200,200}$. The deactivation is a chemical controlled process, it may

Figure 5.7: The variation on k_{deact} and $k_t^{200,200}$ with the water content. The $k_t^{200,200}$ values are calculated via Equation 2.15 and the required parameter are used from Table 3.4 and Table 3.5.

be expected that k_{deact} lies always below the diffusion controlled termination reaction of two large radicals. This assumption is also supported by the smaller increase in k_{deact} between 80 and 90 wt% H_2O .

Nevertheless, an increase of k_{deact} with water content has not been reported so far, neither for Cu-based ATRP, nor for Fe-based ATRP. For Cu-mediated systems, measurements and computational calculations indicate that k_{deact} is almost independent of the H_2O content and a minor decrease of k_{deact} has been observed in more polar solvents.^[41]

In order to understand the variation of k_{deact} with water content, the mechanism underlying the deactivation reaction needs to be considered. Even though deactivation is a concerted reaction step consisting of the transfer of bromide from the iron center to the alkyl radical and of a simultaneous reduction from Fe^{III} to Fe^{II} , three factors have to be taken into account: the halide-iron bond strength, the redox potential of the $\text{Fe}^{\text{III}}/\text{Fe}^{\text{II}}$ couple in water and the structural change of the complex. Among these factors, the halide-iron bond strength seems to be the most important one.

It is known from Cu-mediated ATRP that a stronger metal-halogen bond, e.g., in $\text{Cu}^{\text{II}}\text{-Cl}$, results in a k_{deact} which is by about one order of magnitude below the value of the associated Br species.^[36] Moreover, the Cu^{II} complex is more stabilized in polar solvents.^[41,42] To explain the increase in k_{deact} in case of the iron porphyrin system, ligand exchange reactions and Fe-Br bond stability may offer an explanation.

Reported studies into the redox potential in different polar organic solvents showed that the reduction becomes easier in solvents with a high dielectric constant and that a weak coordinating axial ligand such as bromide also facilitates the reduction such as in the case of ATRP.^[172–175] These studies also suggest that the axial ligand exchange is enhanced in more polar and coordinating solvents.^[172,176,177] Water provides both effects in having a high dielectric constant and in coordinating to the catalyst in a labile fashion to form a six-coordinated complex, thus weakening the metal-halide bond. The polyethylene glycol sidechain of PEGMA and of the porphyrin ligand may also coordinate axially in competition to water molecules. Polyethylene glycol exhibits a smaller dielectric constant corresponding to a weaker coordinating ability. This indicates that increasing the water content may favor water coordination, which results in lowering the metal-halide bond strength and thus increases k_{deact} .

The geometry of the complex as the third aspect may have a smaller influence on k_{deact} . Porphyrin structures are pre-organized ligands with a rigid planar structure. Only a minor change in the geometry during the transformation of Fe^{III} to Fe^{II} can be expected. The geometric change is restricted to the exchange of the axial ligand from a five-coordinated Fe^{III} to a four-coordinate Fe^{II} . Potential solvent coordination would increase the coordination number. The planar porphyrin ligand structure will most likely be insensitive toward the reduction from Fe^{III} to Fe^{II} .

To investigate the structural effect on k_{deact} , two further derivatives of the complex were measured with 70 wt% H_2O analogous to the procedure of the mesohemin-(MPEG₅₀₀)₂ catalyst. Shown in Figure 5.8A is the measured time resolved SP-PLP-EPR spectrum of PEGMA radicals with 1 mM Fe^{III} -mesohemin-(MPEG₅₀₀)-imidazole catalyst in 50 wt% H_2O at 20 °C. Depicted in Figure 5.8B is the associated pseudo-first-order plot of $\ln([\text{R}^\bullet]_0/[\text{R}^\bullet])$ vs time.

Figure 5.8: (A) EPR intensity vs time profile for mesohemin-(MPEG₅₀₀)-imidazole in 50 wt% H₂O/PEGMA at 20 °C. (B) $\ln([R^\bullet]_0/[R^\bullet])$ vs time trace for mesohemin-(MPEG₅₀₀)-imidazole in 50 wt% H₂O/PEGMA at 20 °C. The curvature in the early time regime indicates the significant contribution of radical-radical termination. A straight line has been fitted to the later time regime when ATRP deactivation controls the decay in radical concentration.

Listed in Table 5.2 are the determined k_{deact} values for mesohemin-MPEG-imidazole and mesohemin-MPEG-thioether. In case of the mesohemin-MPEG-imidazole and the mesohemin-MPEG-thioether, one MPEG side arm is substituted by an amide side chain with an imidazole or thioether endgroup (see Figure 5.1). The mesohemin-(MPEG₅₀₀)-imidazole complex exhibits a higher $k_{\text{deact}} = 11.2 \cdot 10^4 \text{ L} \cdot \text{mol}^{-1} \cdot \text{s}^{-1}$ than the mesohemin-(MPEG₅₀₀)₂, whereas k_{deact} of the mesohemin-(MPEG₅₀₀)-thioether $k_{\text{deact}} = 4.3 \cdot 10^4 \text{ L} \cdot \text{mol}^{-1} \cdot \text{s}^{-1}$ is slightly lower.

The coordinated side arms may influence the reactivity of the complex in a positive manner since the coordination of imidazole favors a low spin complex. Due to the smaller metal atom radius in low spin complexes and to the more symmetric electron distribution, the metal ion is better contained within the porphyrin plane in the low spin configuration. According to literature this may enhance the axial ligand exchange.^[161] It is not yet fully clear why the thioether complex shows a slightly smaller k_{deact} .

The stronger coordination ability of imidazole and thioether may stabilize the complex and make it more robust against the coordination

of solvent and monomers with an acid functionality. For future applications it may be of interest that the strongly coordinated “protective” imidazole complex provides a high k_{deact} that might be associated with a better control over polymerization.

Table 5.2: Deactivation rate coefficient, k_{deact} , for mesohemin-(MPEG₅₀₀)₂, mesohemin-(MPEG)-imidazole and mesohemin-(MPEG)-thioether at 70 wt% H₂O/PEGMA at 20 °C.

Ligand in 70 wt% H ₂ O/PEGMA	$k_{\text{deact}} / 10^4 \text{ L} \cdot \text{mol}^{-1} \cdot \text{s}^{-1}$
Mesohemin-(MPEG ₅₀₀) ₂	7.1 ± 1.0
Mesohemin-(MPEG)-imidazole	11.2 ± 2.1
Mesohemin-(MPEG)-thioether	4.3 ± 1.5

5.3 Rate coefficients via Stopped-Flow – UV/Vis spectroscopy

The SP–PLP–EPR technique was used to measure k_{deact} . Furthermore it is desirable to additionally determine the associated activation rate coefficient, k_{act} , and thus the overall equilibrium constant, K_{ATRP} , at different water concentrations. The measurement of k_{act} , k_{deact} and thus K_{ATRP} may be achieved by using UV/Vis spectroscopy in conjunction with stopped-flow injection.

5.3.1 Determination of K_{model} , k_{deact} and $k_{\text{add,Fe}}$

This subchapter deals with the measurement of the activation and deactivation rate coefficients, and thus of the ATRP equilibrium constant for the monomer-free model system mesohemin-(MPEG₅₀₀)₂ catalyst at various solvent compositions. The rate coefficients are estimated via PREDICI[®]. By an extended analysis of the experimental

data, also the rate coefficient for the addition of radicals to the $\text{Fe}^{\text{II}}/\text{L}$ complex may be estimated. The experiments were performed at solvent compositions of H_2O /polyethylene glycol (M_n 500, PEO) with water contents from 50 to 70 wt% at 20 °C.

The conditions for measuring the ATRP-specific coefficients k_{act} and k_{deact} should be carefully selected to avoid the interference of OM reactions. Thus, according to Scheme 5.1, sub-stoichiometric amounts of $\text{Fe}^{\text{II}}/\text{L}$ with respect to R-Br are favorable to avoid significant contributions of OM reactions, whereas stoichiometric amounts of $\text{Fe}^{\text{II}}/\text{L}$ and R-Br may induce significant OM reactions.

The determination of k_{act} and k_{deact} , and thus K_{ATRP} , with an excess of R-Br with respect to Fe^{II} , is more feasible with the monomer-free model system. The ATRP activation-deactivation equilibrium for a monomer-free model system is referred to as K_{model} in what follows.

The reaction scheme for a monomer-free Fe-mediated RDRP-type model system is illustrated in Scheme 5.3. The absence of monomer simplifies the reaction kinetics, as chain-length-dependent termination and concentration-dependent propagation are excluded. The starting materials $\text{Fe}^{\text{II}}/\text{L}$ and R-Br are marked red. The reaction of $\text{Fe}^{\text{II}}/\text{L}$ with, e.g., HEMA-Br acting as the alkyl halide initiator, R-Br, results in the oxidation to $\text{Fe}^{\text{III}}/\text{L-Br}$. The accumulation of $\text{Fe}^{\text{III}}/\text{L-Br}$, which is concurrent with termination of transient radicals according to Scheme 5.3, is referred to as the *persistent radical effect* (PRE) and may be monitored via the d-d transition of the $\text{Fe}^{\text{III}}/\text{L-Br}$ complex at 640 nm without interference of the OM species (cf. 5.1 and Figure A7).

The accumulation of $\text{Fe}^{\text{III}}/\text{L-Br}$ is expected to be particularly fast in case of the investigated mesohemin-(MPEG₅₀₀)₂-complex based on the results reported for polymerizations of PEGMA.^[1] Complete conversion of $\text{Fe}^{\text{II}}/\text{L}$ will occur in less than one minute. Therefore, the analysis of K_{model} for such fast reaction has been performed using stopped-flow injection in conjunction with UV/Vis spectroscopy to measure the change in absorption.

A stopped flow setup is built of a syringe driver which holds two syringes with the reactants, and a mixing chamber which allows for UV/Vis monitoring. Temperature control is achieved by a cryostat. The stopped-flow injection technique allows for times being as low as a few milliseconds and high time resolution during the course of the experiment. The disadvantage of the stopped-flow technique is the

Scheme 5.3: Reaction scheme for the Fe-mediated RDRP-type reaction of the monomer-free model system; R-Br refers to the dormant alkyl halide species, R• to the radical species, k_t to the termination rate coefficient. k_{act} and k_{deact} are the ATRP rate coefficients for activation and deactivation, respectively. $k_{\text{add,Fe}}$ refers to the addition of a radical to the Fe^{II}/L complex via an OM reaction. The starting materials are marked red.

limitation to monomer-free model systems, as polymer would clog the low diameter tubing of the stopped-flow setup. Moreover, the higher viscosity of a polymerization system does not provide an efficient mixing.

To ensure efficient mixing even of the monomer-free model system, both mixing syringes were filled with identical solvent composition and identical amounts of added NaBr to prevent halide dissociation. As solvents, mixtures of 50 and 70 wt% H₂O/PEO were used. PEO serves as a saturated analogue of PEGMA (cf. chapter 4). A typical stopped-flow experiment was carried out in the relevant solvent mixture with 0.9 mM of the mesohemin-(MPEG₅₀₀)₂ catalyst with 0.50 equivalents of Na₂S₂O₄, in the first stopped flow syringe. Na₂S₂O₄ was directly added to the catalyst solution for in situ reduction without prior dissolution in water, to avoid the decomposition of [SO₂]⁻ radicals. The second syringe contained 20 mM of HEMA-Br.

Depicted in Figure 5.9 are the spectra for the reaction of 0.4 mM mesohemin-(MPEG₅₀₀)₂ catalyst with 10 mM HEMA-Br in 50 wt% H₂O/PEO mixture at 20 °C, injected with an injection flow rate of 7 mL · s⁻¹. The red line represents the Fe^{II}/L spectrum at the beginning of the reaction (cf. chapter 5.1). The black line is associated with the Fe^{III}/L-Br species formed at the end of the reaction (see chapter 5.1). The spectra are identical to the ones from the UV/Vis measurements without

Figure 5.9: UV/Vis spectra via stopped-flow injection recorded for 0.4 mM mesohemin-(MPEG₅₀₀)₂ in 50 wt% H₂O/PEO at 20 °C. The red spectrum refers to the Fe^{II} catalyst before the reaction with HEMA-Br. The black spectrum refers to the Fe^{III}/L-Br species at the end of the reaction with 10 mM HEMA-Br. The arrows at 535 and 640 nm indicate the changes in absorption with the time. The absorbance at around 640 nm has been used to record the concentration time profiles.

stopped-flow injection (see Figure A7 and Figure 5.2). The d-d absorbance at 640 nm, which does not interfere with the absorption of Fe^{III}-R (see chapter 5.1) has been used to analyze the [Fe^{III}/L-Br] vs time traces.

Shown in Figure 5.10 is a graph of the Fe^{III}/L-Br concentration vs time trace for the reaction of 0.59 mM Fe^{II}-mesohemin-(MPEG₅₀₀)₂ and 18 mM HEMA-Br in 70 wt% H₂O/PEO with an injection flowrate of 3 mL · s⁻¹ at 20 °C. The experimental data (black line) have been fitted with PREDICI[®] (magenta line) as described below.

For fitting the experimental data, the reaction equations shown in Table 5.3 were implemented into the software package PREDICI[®]. Due to the above-mentioned simplifications, the PREDICI[®] model consists of the

four reactions: ATRP activation Eq 5.2 and deactivation Eq 5.3, radical-radical termination Eq 5.4 and addition of radicals to the $\text{Fe}^{\text{II}}/\text{L}$ complex Eq 5.5. The rate coefficient k_{t} is estimated via the diffusion limit as described in chapter 4.1.1.

The estimation of k_{act} , k_{deact} and $k_{\text{add,Fe}}$ is based on three steps. Within the first two steps, it is assumed that the recorded $[\text{Fe}^{\text{III}}/\text{L-Br}]$ vs time trace in Figure 5.10 is predominantly controlled by k_{act} and k_{deact} , and that the reaction kinetics may be divided into two parts: the initial pre-equilibrium state and the equilibrium state towards the end of the reaction.^[68]

First, the activation-deactivation equilibrium constant, K_{model} , was estimated via the F[Y]-function for the equilibrium state.^[68] The F[Y]-function does however not consider the potential formation of $\text{Fe}^{\text{III}}/\text{L-R}$. The so-obtained K_{model} values thus are systematically below the actual number. For the system under investigation, the initial discrepancy later turns out to be below a factor of 2. The initial value derived via the F[Y]-function for system in Figure 5.10 is $K_{\text{model}} = 7 \cdot 10^{-5}$ and will be corrected via the modeling procedure within the subsequent evaluation steps. However, the first estimate of K_{model} confirms the high activity of the mesohemin-(MPEG₅₀₀)₂ catalyst.

In the second step, k_{deact} is estimated from the equilibrium state. Since $K_{\text{model}} = k_{\text{act}}/k_{\text{deact}}$, the F[Y]-function provides a useful starting point for estimating k_{deact} from the pre-equilibrium state of the $[\text{Fe}^{\text{III}}/\text{L-Br}]$ vs time traces. k_{act} may be substituted by $K_{\text{model}} \cdot k_{\text{deact}}$, such that k_{deact} remains the only parameter to be fitted from the pre-equilibrium data. k_{deact} was estimated to $3 \cdot 10^5 \text{ L mol}^{-1} \text{ s}^{-1}$.

In the third step, after determination of K_{model} and k_{deact} , the experimental data may be used for an estimate of $k_{\text{add,Fe}}$ from the equilibrium state. Within the final modeling procedure of the $[\text{Fe}^{\text{III}}/\text{L-Br}]$ vs time data, both K_{model} (and thus k_{act}) and k_{deact} will be refined along with the analysis of $k_{\text{add,Fe}}$.

According to Scheme 5.3, the ATRP mechanism is the dominant reaction pathway and the formation of $\text{Fe}^{\text{III}}/\text{L-R}$ may be neglected in the pre-equilibrium state. If these reactions were entirely ATRP-controlled, $\text{Fe}^{\text{II}}/\text{L}$ would be transformed almost entirely to $\text{Fe}^{\text{III}}/\text{L-Br}$, because of the high K_{model} value for this system. As illustrated in Figure 5.10 the $\text{Fe}^{\text{III}}/\text{L-Br}$ concentration reaches a maximum concentration of 0.50 mM, which differs from the overall Fe/L concentration of 0.59 mM. The discrepancy

Table 5.3: Reaction scheme used for the PREDICI® modeling of the Fe^{III}/L-Br concentration vs time traces.

$\text{Fe}^{\text{II}}/\text{L} + \text{R-Br} \xrightarrow{k_{\text{act}}} \text{Fe}^{\text{III}}/\text{L-Br} + \text{R}^\bullet$	(5.2)
$\text{Fe}^{\text{III}}/\text{L-Br} + \text{R}^\bullet \xrightarrow{k_{\text{deact}}} \text{Fe}^{\text{II}}/\text{L} + \text{R-Br}$	(5.3)
$\text{R}^\bullet + \text{R}^\bullet \xrightarrow{k_{\text{t}}} \text{R-R}$	(5.4)
$\text{Fe}^{\text{II}}/\text{L} + \text{R}^\bullet \xrightarrow{k_{\text{add,Fe}}} \text{Fe}^{\text{III}}/\text{L-R}$	(5.5)

Figure 5.10: Recorded Fe^{III}/L-Br concentration vs time profile via stopped-flow UV/Vis spectroscopy at 640 nm for the reaction of 0.59 mM Fe^{II}-mesohemin-(MPEG₅₀₀)₂ complex with 18 mM HEMA-Br in 70 wt% H₂O/PEO at 20 °C. The black line represents the experimental data and the magenta line the PREDICI® fit.

of ca. 20% is assigned to the formation of Fe^{III}/L-R. This additional piece information about the relative amounts of Fe species may be used to estimate $k_{\text{add,Fe}}$ during the final modeling of the [Fe^{III}/L-Br] versus time trace.

A set of PREDICI[®] modelings were performed in which $k_{\text{add,Fe}}$ was estimated and k_{deact} and K_{model} were kept constant. As illustrated in Figure 5.11, the variation of $k_{\text{add,Fe}}$ affects the [Fe^{III}/L-Br] vs time traces only in the equilibrium state and allows for the correct fit of this Fe^{III}/L-Br concentration versus time trace under equilibrium conditions. After fitting $k_{\text{add,Fe}}$, the value for K_{model} and k_{deact} may be finally refined by fitting them to both reaction parts simultaneously while $k_{\text{add,Fe}}$ is kept constant. K_{model} and k_{deact} are then determined to be $1 \cdot 10^{-4}$ and $2.1 \cdot 10^5 \text{ L mol}^{-1} \text{ s}^{-1}$, respectively, at 70 wt% water concentration and 20 °C.

To illustrate the quality of the estimated values and of the fitting of the Fe^{III}/L-Br concentration vs time profiles, a set of PREDICI[®] simulations adopting various K_{model} and k_{deact} values were performed.

Shown in Figure 5.12A are simulated [Fe^{III}/L-Br] vs time traces for the experimental composition of 0.59 mM Fe^{II}-mesohemin-(MPEG₅₀₀)₂ complex with 18 mM HEMA-Br in 70 wt% H₂O/PEO at 20 °C. K_{model} has been varied between $0.5 \cdot 10^{-4}$ and $3.0 \cdot 10^{-4}$, whereas k_{deact} and $k_{\text{add,Fe}}$ are kept constant at $2.0 \cdot 10^5 \text{ L mol}^{-1} \text{ s}^{-1}$ and $5.0 \cdot 10^4 \text{ L mol}^{-1} \text{ s}^{-1}$, respectively. Illustrated in Figure 5.12B are simulated [Fe^{III}/L-Br] vs time traces for the experimental composition with k_{deact} being varied between $0.5 \cdot 10^5$ and $10.0 \cdot 10^5 \text{ L mol}^{-1} \text{ s}^{-1}$, and K_{model} and $k_{\text{add,Fe}}$ being kept constant at $1.0 \cdot 10^{-4}$ and $5.0 \cdot 10^4 \text{ L mol}^{-1} \text{ s}^{-1}$, respectively.

As illustrated in Figure 5.12, the modeling process is very sensitive toward K_{model} and k_{deact} . A variation of K_{model} by 20% from the optimum value results into strong deviations from the recorded Fe^{III}/L-Br concentration vs time trace. A similar precision is achieved for the modeling that has been carried out adopting several values for k_{deact} . Although, the precision of the modelling process is very good, a higher error is adopted in Table 5.4, which takes the uncertainties due to calibration and mixing into account.

As illustrated by Figure 5.12, the modeled concentration vs time traces are influenced in different ways. With increasing K_{model} the final Fe^{III}/L-Br concentration is reached earlier and the concentration of the formed Fe^{III}/L-Br reaches a higher level due to the more dominant

Figure 5.11: PREDICI® modeling of the $[\text{Fe}^{\text{III}}/\text{L-Br}]$ time profiles for different values of $k_{\text{add,Fe}}$, whereas k_{deact} and K_{model} were kept constant. The concentrations of $\text{Fe}^{\text{II}}/\text{L}$ and HEMA-Br are identical to the ones in Figure 5.10.

ATRP pathway. With increasing k_{deact} , the final $\text{Fe}^{\text{III}}/\text{L-Br}$ concentration is also reached earlier, but the final concentration of $[\text{Fe}^{\text{III}}/\text{L-Br}]$ is less affected. Only minor variations of the combination of K_{model} and k_{deact} yield a matching fit to the experimental data.

Listed in Table 5.4 are the K_{model} , k_{deact} and $k_{\text{add,Fe}}$ values estimated for mixtures with 50 and 70 wt% $\text{H}_2\text{O}/\text{PEO}$ at 20 °C. k_{deact} increases with water content from $6.2 \cdot 10^4 \text{ L mol}^{-1} \text{ s}^{-1}$ at 50 wt% H_2O to $2.1 \cdot 10^5 \text{ L mol}^{-1} \text{ s}^{-1}$ at 70 wt% H_2O . This effect is consistent with the measured k_{deact} values from SP-PLP-EPR. Also the relative increase in k_{deact} from 50 wt% to 70 wt% H_2O , by almost a factor of 3.5, is found in perfect agreement via both methods.

Absolute k_{deact} values for the monomer-free model systems, $6.2 \cdot 10^4 \text{ L mol}^{-1} \text{ s}^{-1}$ at 50 wt% H_2O and $2.1 \cdot 10^5 \text{ L mol}^{-1} \text{ s}^{-1}$ at 70 wt% H_2O exceeds the associated numbers for the polymerization system, as obtained via SP-PLP-EPR, by a factor of 4. Such a discrepancy between

Figure 5.12: (A) PREDICI® simulation for the $[\text{Fe}^{\text{III}}/\text{L-Br}]$ time profiles with variation of K_{model} , whereas k_{deact} and $k_{\text{add,Fe}}$ were held constant. (B) PREDICI® simulation for the $[\text{Fe}^{\text{III}}/\text{L-Br}]$ time profiles with variation of k_{deact} , whereas K_{model} and $k_{\text{add,Fe}}$ were held constant. For both simulations concentrations of $\text{Fe}^{\text{II}}/\text{L}$ and HEMA-Br are identical to the ones in Figure 5.10.

Table 5.4: Values for K_{model} , k_{deact} and $k_{\text{add,Fe}}$ estimated for the mesohemin-(MPEG₅₀₀)₂ at 20 °C via PREDICI® modeling.

	50 wt% H ₂ O/PEO	70 wt% H ₂ O/PEO
K_{model}	$(1.2 \pm 0.5) \cdot 10^{-4}$	$(1.0 \pm 0.3) \cdot 10^{-4}$
$k_{\text{deact}} / \text{L mol}^{-1} \text{ s}^{-1}$	$(6.2 \pm 1.7) \cdot 10^4$	$(2.1 \pm 0.6) \cdot 10^5$
$k_{\text{add,Fe}} / \text{L mol}^{-1} \text{ s}^{-1}$	$(1.3 \pm 0.9) \cdot 10^4$	$(4.9 \pm 1.2) \cdot 10^4$

model system and polymerization system is known from Cu-mediated ATRP.^[126] The higher k_{deact} values for the model system are explained by the backstrain effect.^[139] As a consequence of the penultimate α -methyl group on the polymeric backbone, a steric strain is induced that hinders the addition of bromide to the radical, and thus reduces k_{deact} . In the model system, the methacrylate ATRP initiator has no penultimate unit to induce such steric strain.

The K_{model} values $1.2 \cdot 10^{-4}$ for 50 wt% H₂O and $1.0 \cdot 10^{-4}$ for

70 wt% H₂O are almost the same. They are above the values reported for the other Fe-catalysts. The K_{model} value for FeBr₂ in *N*-methyl-2-pyrrolidone is at least by two orders of magnitude lower.^[69] Even the active Fe-amine-(*bis*)phenolates exhibit smaller K_{model} values around 10^{-6} .^[57]

The high activation-deactivation-equilibrium constants for the mesohemin-(MPEG₅₀₀)₂ catalyst are to be preferred in regenerative ATRP's, e.g., ARGET ATRP, due to the possibility of using Fe concentrations onto a ppm level. Moreover, the high activity and low Fe concentration is also favorable for the predominated ATRP pathway without interference by OM reactions.

The product of K_{model} and k_{deact} yields k_{act} . The increase in k_{deact} and a nearly constant K_{model} indicate that the increase of k_{act} is identical to the one of k_{deact} . It has been reported for Cu-mediated ATRP that k_{act} increases with water content due to a better stabilization of the Cu^{II}.^[178] For Fe-mediated ATRP, there seems to be an additional effect that increases k_{deact} , i.e., a better axial ligand exchange in water, as discussed in the chapter 5.2.1.

Toward higher water content, $k_{\text{add,Fe}}$ increases from $1.3 \cdot 10^4 \text{ L mol}^{-1} \text{ s}^{-1}$ at 50 wt% to $4.9 \cdot 10^4 \text{ L mol}^{-1} \text{ s}^{-1}$ 70 wt% H₂O. Despite this increase in $k_{\text{add,Fe}}$ with the water content, these values are by a factor 5 below the competing deactivation rate coefficients. $k_{\text{add,Fe}}$ is not sufficiently large, to make the OM reactions competitive to ATRP techniques with the advantage of ATRP being further enhanced by using ppm levels of Fe^{II} and regenerative concepts, e.g., ARGET ATRP.

Although Na₂S₂O₄ is an effective reducing agent for Fe^{III}/L-Br, the very slow reduction of ascorbic acid may be favorable for highly active catalysts in an actual polymerization. For example, in the reported ARGET ATRP polymerization with the mesohemin-(MPEG₅₀₀)₂-complex, in which ascorbic acid acts as the reducing agent, the resulting polymer provides narrow MMDs with a dispersity of 1.28.^[1] Such dispersity would not be reached at a significant contribution of OM reactions.

As shown in chapter 5.1, the reduction of ascorbic acid during polymerization is very slow such that only trace amounts of Fe^{II}/L are produced. It may be assumed that the ratio of Fe^{III}/L-Br to Fe^{II}/L is around 100:1. Based on the obtained k_{deact} , k_{act} and $k_{\text{add,Fe}}$ values, the probability that radicals react in the ATRP pathway is 500 times larger

than is the formation of the $\text{Fe}^{\text{III}}/\text{L-R}$ species. The simultaneous increase of the ATRP-relevant parameters, k_{deact} and $k_{\text{add,Fe}}$, toward higher water content indicates that the polymerization is most likely controlled by ATRP.

The measurement of k_{deact} , k_{act} and $k_{\text{add,Fe}}$ is very important for the understanding of the kinetics of Fe-mediated RDRP. It turned out that, despite the possibility of OM reactions, polymerizations are predominantly ATRP controlled with the mesohemin-(MPEG₅₀₀)₂ catalyst. This is particularly true, when an excess of R-Br with respect to $\text{Fe}^{\text{II}}/\text{L}$ is used. The same is holds for ARGET ATRPs, e.g., with ascorbic acid as a reducing agent, where only ppm levels of $\text{Fe}^{\text{II}}/\text{L}$ are produced.

Once the kinetics and mechanism of the reduction process is known, the set of rate coefficients from the present study allows for the simulation of the ATRP kinetics and polymer molar mass.

5.4 Impact on polymerization

The mechanistic and kinetic analysis suggests that the PEGMA ARGET ATRP with mesohemin-(MPEG₅₀₀)₂ operates exclusively via an ATRP mechanism. This situation is advantageous for polymerization since the formation of the stable $\text{Fe}^{\text{III}}/\text{L-R}$ species is inhibited. Thus the polymerization may be faster and may provide higher chain-end functionality, which is advantageous for further modifications, e.g., for the synthesis of block copolymers.

Moreover, it has been shown that k_{deact} increases toward higher water content and that K_{model} is almost independent of water concentration. Since higher k_{deact} is associated with better control, it is to be expected that a higher water concentration may be favorable for ATRP.

To check for the influence of water content on dispersity, a set of PEGMA ARGET ATRPs with ascorbic acid and mesohemin-(MPEG₅₀₀)₂ were carried out. Analogous to the procedure reported by Simakova *et. al.*, the polymerization system contained 2 mM Mesohemin-(MPEG₅₀₀)₂, 2 mM ethyl α -bromophenylacetate and 4 mM ascorbic acid in various

mixtures of PEGMA/H₂O at 25 °C.^[1] The resulting polymer was analyzed via size exclusion chromatography (SEC).

Shown in the lower part of Figure 5.13 are the measured dispersities of the resulting PEGMA polymer. The upper part of Figure 5.13 correlates the dispersity with the ratio of $k_p[M]/k_{\text{deact}}[\text{Fe}^{\text{III}}/\text{L-Br}]$, i.e., the number of propagation steps prior to the deactivation step. The k_{deact} and k_p values used for the estimates are reported in Chapter 5.2.1 and 3.1, respectively.

As shown in Figure 5.13, the dispersity decreases with water content from 1.85 in 70 wt% PEGMA toward 1.25 in 20 wt% PEGMA. This effect is consistent with the findings of an increasing k_{deact} and a decreasing ratio of $k_p[M]/k_{\text{deact}}[\text{Fe}^{\text{III}}/\text{L-Br}]$. The ratio of $k_p[M]/k_{\text{deact}}[\text{Fe}^{\text{III}}/\text{L-Br}]$ is lowered from 80 at 30 wt% H₂O to about unity in 80 wt% H₂O, which latter value indicates efficient control.

The findings show that an efficient control for an ARGET ATRP is achieved by the addition of at least 60 wt% H₂O. The majority of PEGMA solution polymerization are performed in this concentration range because of the high viscosity and the swelling of the polymer.

The good control of polymerization at higher water content is achieved by the combination of a high k_{deact} and the slow reducing rate of ascorbic acid, which yields an almost constant high Fe^{III}/-Br concentration with only small traces of Fe^{II}/L being present in the solution.

Moreover, the mesohemin-(MPEG₅₀₀)₂ catalyst exhibits a high equilibrium constant of $1 \cdot 10^{-4}$ for the model system. It is known that the equilibrium constant of the model system is by one to two orders of magnitude above the equilibrium constant of the methacrylate polymerization system, the catalyst has also the potential of being used with the ATRP of acrylates – which usually provide a small K_{ATRP} than methacrylates – and should even sufficiently stable for ATRP of acidic monomers. In all these cases, ARGET ATRP with low levels of Fe^{II} and with water concentration above 60 wt% should be best suited.

Figure 5.13: The upper part illustrates the ratio of $k_p[M]/k_{\text{deact}}[\text{Fe}^{\text{III}}/\text{L-Br}]$ as a function of the water content. The lower part shows the variation with water content of dispersity for mesohemin-(MPEG₅₀₀)₂ PEGMA ARGET ATRP. The polymerization system contained 2 mM mesohemin-(MPEG₅₀₀)₂, 2 mM ethyl α -bromophenylacetate and 4 mM ascorbic acid in various mixtures of PEGMA/H₂O at 25 °C.

6

Closing Remarks

ATRP equilibrium constants, activation rate and deactivation rate coefficients were determined for Cu- and Fe-mediated ATRP in aqueous solution for monomer-free model systems, and polymerization systems with PEGMA.

For the Cu-mediated ATRP with CuBr/2,2'-bipyridine catalyst, it has been shown that K_{ATRP} increases by above three orders of magnitude in passing from bulk PEGMA solution to a pure water environment. The enhancement of K_{ATRP} is essentially due to the increase in k_{act} , whereas k_{deact} is independent of water content. A higher K_{ATRP} is associated with a faster polymerization. This faster polymerization rate in water, however, may be at the cost of a slight loss of control and of higher dispersity for the polymerization. This loss of control is induced by the halide dissociation of the Cu catalyst. Moreover the constant k_{deact} does not counteract the higher radical concentration which is associated with a higher polymerization rate.

In highly diluted polymerization systems at 80 wt% H₂O, K_{ATRP} yields $2 \cdot 10^{-4}$. Such high K_{ATRP} value has so far only been reported for the very active CuBr/Me₆TREN catalyst in organic solvents.^[60] This enhancement of K_{ATRP} toward higher water content is a feature of the Cu-mediated ATRP in aqueous solution, which allows for reducing the Cu-catalyst concentration without compromising the polymerization

rate.

A different behavior has found for the Fe-mediated ATRP of the mesohemin-(MPEG₅₀₀)₂ catalyst. In contrast to the Cu-mediated ATRP, K_{ATRP} is almost independent of water content between 50 and 70 wt% H₂O. Nevertheless, this catalyst is the most active Fe-catalyst so far. K_{ATRP} for monomer-free model systems is with $1 \cdot 10^{-4}$ by almost one order of magnitude higher as the also very active [FeBr₄]⁻ catalyst and by almost two orders of magnitude as the Fe-amine-(*bis*)phenolates.

Besides the high K_{ATRP} , k_{deact} increases strongly by one order of magnitude with water content to be $2 \cdot 10^5 \text{ L} \cdot \text{mol}^{-1} \cdot \text{s}^{-1}$ and is almost as large as the k_{deact} of the [FeBr₄]⁻ and of the Fe-amine-(*bis*)phenolate systems at temperatures above 60 °C. As a consequence, the investigated Fe/mesohemin catalysts are very efficient even at low temperature to achieve well-controlled polymerizations.

It could be shown that the above-described findings with the water content for the Cu- and Fe-mediated ATRP have a different impact on the polymerization rate, the dispersity and the chain-end functionality. For a successful Cu-mediated ATRP, there is always the compromise between polymerization rate and efficient control. ATRP techniques with regenerative concepts, e.g., ARGET ATRP, may help to achieve a better control even at higher water content. In contrast to Cu-mediated ATRP, the Fe-mediated ATRP strongly benefits from higher water content and it may be absolutely necessary to polymerize at higher water content.

Besides the described advantages of both ATRP systems in water, in future applications it has to be considered that on the one hand Cu-ATRP in water may be accompanied by a loss of control. On the other hand, the good accessibility of different Cu-ligands for a great variety of monomers may still be an advantage over the Fe-mediated ATRP at the moment. Moreover, most of the ligands for the Cu-mediated ATRP are commercially available and cheap.

The Fe/heme systems are however difficult to synthesize and more expensive as the Cu-ligands. Nevertheless, these bio-inspired catalysts are the next generation of ATRP catalysts due to their bio-compatibility and very good polymerization behavior at ambient temperature and pressure. The mechanistic and kinetic analysis in this work for both systems provides an essential framework for further catalyst development. Especially the development of more efficient and cheaper

Fe-catalyst with higher deactivation rate at lower water content and with slower organometallic reactions seems to be rewarding.

7

Experimental

7.1 Chemicals

Metal salts, solids and ligands. FeBr₂ (ABCR, ultra dry, 99.995 % metal basis), FeBr₃ (ABCR, anhydrous, 99 %), FeCl₂ (Aldrich, anhydrous, 99.998 % metal basis), CuBr (Aldrich, 99.999 % metal basis), CuBr₂ (Aldrich, 99.99 % metal basis), copper(II) trifluoromethanesulfonate (Aldrich, 98 %), NaBr (Aldrich, ≥ 99 %), and 4-hydroxy-2,2,6,6-tetramethylpiperidine 1-oxyl (TEMPOL, Aldrich, 97 %), 2,2'-Bipyridyl (bpy, Aldrich, ≥ 99%), L-Ascorbic acid (AsAc, Aldrich, reagent grade), sodium dithionite (ABCR, technical grade, > 85 %), tris[2-(2-methoxyethoxy)ethyl]amine (TDA-1, Aldrich, 95 %) were used as received. Fe^{III}/Br-mesohemin-(MPEG₅₀₀)₂, Fe^{III}/Br-mesohemin-(MPEG₅₀₀)-thioether, Fe^{III}/Br-mesohemin-(MPEG₅₀₀)-imidazole and Fe^{III}/Cl-mesohemin-(MPEG₅₀₀)₂ were kindly provided by Antonina Simakova and Krzysztof Matyjaszewski at the Carnegie Mellon University of

Pittsburgh.^[1]

Initiators. 2-hydroxyethyl 2-bromoisobutyrate (HEMA-Br, Aldrich, 95 %), Ethyl α -bromophenylacetat (EBrPA, ABCR, 97 %), methyl 2-bromo-*iso*-butyrate (MBriB, Fluka, ≥ 99 %), ethyl α -chlorophenylacetate (ECIPA, Aldrich, 97 %), α -methyl-4-(methylmercapto-)- α -morpholinopropiophenone (MMMP, Aldrich, 98 %), 2,2'-azobis[2-(2-imidazolin-2-yl)propane] dihydrochloride (VA-44, Wako), 2,2'-azobis(4-methoxy-2,4-dimethyl valeronitrile) (V-70, Wako) were used as received. 2,2'-Azobis(2-methylpropionitrile) (AIBN, Aldrich, 98 %) was recrystallized from cold ethanol (Aldrich, p.a.) and dried under vacuum prior to use.

Monomer and Solvents. Poly(ethylene glycol) dimethyl ether Mn ~500 (PEO, Merck), poly(ethylene glycol) methyl ether methacrylate were purified by passing through a flash column with neutral aluminum oxide (Type CG-20, Aldrich). 1-Vinylpyrrolidin-2-one (NVP, Fluka, purum, ≥ 97 %) was purified by distillation under reduced pressure and stored at -21 °C. Tetrahydrofuran (THF, Aldrich, for HPLC, inhibitor-free), *n*-dodecane (Aldrich, anhydrous, ≥ 99 %) were used as received. Ultrapure (type I) water (resistivity 18.2 M Ω cm at 25 °C, total organic carbon < 5ppb) from a Millipore water purification system was used.

General information. Monomers, solvents and other liquid substances were degassed by several freeze-pump-thaw cycles. The solutions for all experiments were prepared under an argon atmosphere.

7.2 PLP–SEC measurements³

7.2.1 Pulsed-Laser-Polymerization (PLP)

Monomer, solvent and the photoinitiator Darocur 1173 were mixed,

³ All PLP–SEC measurements were carried out by Stella Weber during her bachelor thesis.

poured into a double-walled cylindrical cuvette (Starna, 65.14/Q/10, Spectrosil-fused quartz, path length 10 mm) and degassed with argon for 5 minutes. The samples were tempered with a heat-transfer fluid (ethylene glycol:water = 4:1) using a thermostat (Haake K, Haake F3). After tempering the sample for 15 min, the PLP experiment was performed with an ATLEX-I laser (ATL Lasertechnik GmbH, pulse width: 20 nm, maximum pulse energy: 7 mJ, maximum pulse repetition rate: 1000 Hz) operating on the XeF-line at 351 nm. A further detailed setup is described elsewhere.^[113] PLP was performed at pulse repetition rate from 1 to 100 Hz. After laser irradiation, the polymer/monomer mixture was given into a flask containing hydroquinone (HQ). Residual monomer was removed by dialysis with pre-wetted dialysis tubing (Spectra/Por 6, Spectrum Laboratories Inc., standard grade, regenerated cellulose, flat width of 18 mm, 11.5 mm in diameter with an MWCO of 2 kDa or 1 kDa) closed with Spectra/Por closures (Spectrum Laboratories, Inc., polypropylene, sealing width of 12 or 23 mm)

7.2.2 Size-Exclusion Chromatography (SEC)

The SEC analysis of poly(PEGMA) was performed at 35 °C with tetrahydrofurane as the eluent (1 mL · min⁻¹ flow rate) and with toluene as the flow-rate marker on an SEC system consisting of a Waters HPLC pump (Model 515), a JASCO As-2055-plus autosampler, three PSS SDV columns (5 µm particle size; 10⁵, 10³ and 10² Å pore sizes) and a Waters refractive index detector (Model 2410). The SEC was calibrated against narrowly distributed poly(MMA) and poly(Styrene) standards ($M = 800$ to $2 \cdot 10^6$ g · mol⁻¹, PSS). The MMDs of poly(PEGMA) were determined by the Mark-Houwink-constants from literature.^[33]

7.2.3 Density measurements

The density of various PEGMA-water mixtures was measured between 22 and 60 °C. The density meter is based on the oscillating U-tube principle and consists of a data acquisition unit (Anton Paar, DMA 60), a measuring unit (Anton Paar, DMA 602TP), and a high temperature cell (Anton Paar, DMA 602 H, Duran® 50, $-10 \leq \Theta \leq 150$ °C).

The temperature inside the U-tube was monitored via a digital thermometer.

The density was calculated by the following equation:

$$\rho = \frac{1}{A}(T^2 - B) \quad (7.1)$$

Where T is period, A and B are device specific constants of the oscillating U-tube and are calculated by the following equations.

$$A = \frac{T_{\text{H}_2\text{O}}^2 - T_{\text{Air}}^2}{\rho_{\text{H}_2\text{O}} - \rho_{\text{Air}}} \quad (7.2)$$

$$B = T_{\text{Air}}^2 - (A \cdot \rho_{\text{Air}}) \quad (7.3)$$

The density of water and air were taken from literature.^[179]

7.2.4 Viscosity measurements

The viscosity was measured by an AMVnTM instrument (Anton Paar GmbH) using RheoplusTM (Anton Paar GmbH) as the analysis software. The viscosimeter is a falling ball viscosimeter, which uses four different capillaries to cover a range between 0.3 and 20 000 mPa s.

7.3 Spectroscopic measurements

7.3.1 Online FT-Vis/NIR spectroscopy

Prior to the experiment, PEO or PEGMA and water were degassed by several freeze-pump-thaw cycles and stored under an argon atmosphere at $-33\text{ }^{\circ}\text{C}$. Each solvent mixture (7 mL) was separately prepared under argon. To the solvent mixture, Cu^IBr, 2,2'-bipyridine and 500 to 1000 equivalents of NaBr were added to obtain a $7\text{ mmol} \cdot \text{L}^{-1}$ Cu^Ibpy₂ solution for the model system and 3 to 8 mM Cu^Ibpy₂ for the

polymerization system. For the measurements at ambient pressure, 2 mL of the solution were filled into a quartz cuvette (117.100-QS, Hellma Analytics) of 5 and 10 mm optical path length, which was closed by a screw cap thus fixing a rubber/PTFE septum. The quartz cuvette was subsequently placed into the sample compartment of an FT-Vis/NIR spectrometer (IFS 66/S, Bruker). After starting spectral data collection, HEMA-Br was added through the septum via a microliter syringe to achieve initiator concentrations between 50 and 90 mmol · L⁻¹ for the model system or to match the Cu^Ibpy₂ concentration in the polymerization system. The setup and procedure for the high-pressure measurements has been detailed elsewhere.^[59,61,69]

The [Cu^{II}(bpy)₂Br]⁺[Br]⁻ concentration was determined via the associated absorbance between 15 500 cm⁻¹ and 8000 cm⁻¹. The spectra were recorded and evaluated using the software package Opus (Bruker Optic, version 7.0 and 6.0). The integration of the d–d absorbance of Cu(II) complexes between 13 300 and 11 400 cm⁻¹ was performed via Opus within the wavenumber range indicated by the dashed lines in Figure 1. The absorbance due to other components has been eliminated by subtraction of the absorbance integral at *t* = 0, i.e., at zero Cu^{II}. The remaining absorption is entirely due the [Cu^{II}L_nX]⁺[X]⁻ complex. Each measurement of *K*_{model} was repeated at least three times.

For calibration, three solutions were prepared of each H₂O/PEO or H₂O/PEGMA mixture containing 1, 3 and 6 mmol · L⁻¹ of [Cu^{II}(bpy)₂]²⁺(TfO)₂, respectively, to which the same amount of NaBr as within the actual measurements was added.

The spectra were recorded and evaluated using the software package Opus (Bruker Optic, version 7.0 and 6.0).

7.3.2 UV/Vis measurements

The samples for the UV/Vis measurements (Cary 300, Agilent) were prepared under an argon atmosphere and were carried out in sealed quartz cells with 5 or 10 mm path length. The extinction coefficients at 640 nm for estimation of the catalyst concentration were determined with 3 different catalyst concentrations between 0.3 and 4.0 mM for each solvent mixture.

7.3.3 Mössbauer

The samples were prepared analogues to the UV/Vis measurements and were flash-frozen in liquid nitrogen after the desired reaction. The spectra were obtained with a ^{57}Co source embedded in a Rh matrix using an alternating constant acceleration Wissel Mössbauer spectrometer operated in the transmission mode and equipped with a closed-cycle helium cryostat (SHI 850, Janis). Isomer shifts are given relative to iron metal at ambient temperature. Symmetric Lorentzian doubles have been fitted to the zero-field spectra using the Mfit program.^[180]

7.4 SP–PLP–EPR measurements

7.4.1 Sample Preparation

For measurement of the composite-model parameter, the purified monomer PEGMA and the ultrapure water were degassed by several freeze–pump–thaw cycles. The required monomer–solvent mixtures with ca. 20 mM of the photoinitiator Darocur 1173 were prepared under an argon atmosphere in a glove box. The highly polar samples were filled in special EPR flat cells. For quantitative measurements, the volumes of all samples have to be the same. The EPR flat cells have been filled completely till the junction of the flat cell and the round neck.

For the measurement of the ATRP deactivation rate coefficient, k_{deact} , the solvent mixtures of water and PEGMA were prepared analogous to the above-described procedure. Additionally, the ATRP catalysts under investigation: $\text{Cu}^{\text{II}}(\text{bpy})_2\text{Br}$, Fe^{III} -mesohemin-(MPEG₅₀₀)₂, Fe^{III} -mesohemin-(MPEG)-imidazole and Fe^{III} -mesohemin-(MPEG)-thioether were been added in a concentration range between 1 to 3 mM. To prevent the halide dissociation an excess of ca. 500 equivalents of NaBr was added to the solution with high water content and 250 equivalents of NaBr for the measurements below 50 wt% H₂O.

7.4.2 SP–PLP–EPR setup

EPR spectra and $c_R(t)$ -curves were recorded on a Bruker Elexsys E 500 series CW EPR spectrometer consisting of a microwave bridge, microwave source, a detector, a cavity (ER 4122SHQE-LC, Version V1.1, Bruker), a console (spectrometer electronics) for electronic data processing and two tunable magnets. Temperature control was realized via an ER 4131VT unit (Bruker) by purging the sample cavity with nitrogen.

The sample was irradiated by a XeF laser (LPX 210 iCC, Lambda Physik) at 351 nm with about 80 mJ/pulse. The EPR spectrometer and the laser source were synchronized by a Quantum Composers 9314 pulse generator (Scientific Instruments).

The detailed setup is described and illustrated elsewhere.^[62]

7.4.3 SP–PLP–EPR experiment and calibration

The basic principle of an SP–PLP–EPR experiment is to measure a pseudo-stationary EPR spectrum for the investigated type of monomer radical to find the appropriate magnetic field position for the time resolved EPR measurement. The pseudo-stationary PLP conditions are achieved by periodic laser pulsing with 20 Hz. The time-resolved EPR spectra were measured at a magnetic field position with the maximum intensity. For an improved signal-to-noise quality, around 15 individual $c_R(t)$ traces were measured at time intervals up to 30 s and averaged. The EPR intensity has been converted into absolute radical concentration by a calibration against TEMPOL as detailed elsewhere.^[62] For the calibration, solvent mixtures of TEMPOL with following TEMPOL concentrations were used: $1 \cdot 10^{-4} \text{ mol} \cdot \text{L}^{-1}$, $1 \cdot 10^{-5} \text{ mol} \cdot \text{L}^{-1}$, $5 \cdot 10^{-5} \text{ mol} \cdot \text{L}^{-1}$, $1 \cdot 10^{-6} \text{ mol} \cdot \text{L}^{-1}$ and $5 \cdot 10^{-6} \text{ mol} \cdot \text{L}^{-1}$.

The concentration of monomer has been measured via online Fourier transform (FT) Vis/NIR spectroscopy (IFS 66/S and IFS 88, Bruker) using a broadband mercury cadmium telluride (MCT) detector.^[60,61] The concentration of Fe^{III} catalyst were measured via UV/Vis spectroscopy (Cary 300, Agilent).

7.5 Stopped-Flow injected measurements

The samples for the stopped-flow injected UV/Vis measurements were prepared under an argon atmosphere and were stored in gas tight syringes. Before using the stopped-flow setup, the inner tubes and reaction cell were purged with nitrogen gas.

The stopped-flow experiments were performed with a two syringe setup. Each syringe contains a different reaction solution: one with the ATRP initiator and the other one with the catalyst. The content of the syringes were injected by a syringe driver (Bio-Logic μ -SFM 20) into a ball mixer (Berger-Ball technology mixers) and then forwarded into the UV/Vis cell (10 mm path length) for the measurement. The reaction temperature in the UV/vis cell was controlled by an external cryostat (Huber CC-75 cryostat). The detection of the absorption signal was realized via a diode array UV/Vis spectrometer (J&M MCS-UVNIR500 diode array spectrometer, band width 190-1015 nm, resolution of about 1 nm) between 400 and 800 nm. A minimum integration time of 12 ms per spectrum was chosen. The whole setup was operated with the *Biokine* software, whereas data analysis was performed with the *Specfit* 32 global analysis software from *Bio-Logic*. All experiments were performed with different flowrates to check for potential mixing artefacts.

To archive efficient mixing in the monomer-free model system, both mixing syringes had the identical solvent composition with identical amounts of NaBr. As solvents, mixtures of 50 and 70 wt% H₂O/PEO were used. A typical stopped-flow experiment was carried out in the relevant solvent mixture with 0.9 mM of the mesohemin-(MPEG₅₀₀)₂ catalyst with 0.50 equivalents of Na₂S₂O₄, in the first stopped flow syringe. Na₂S₂O₄ was directly added to the catalyst solution for in situ reduction without prior dissolving in water, to avoid the decomposition of [SO₂]⁻ radicals. The second syringe contained ca. 20 mM of HEMA-Br.

Figure A3: Variation on k_p with the laser pulse repetition rate, v_{rep} , for PEGMA bulk at 20 °C. The red line refers to the arithmetic mean of k_p between 1 and 20 Hz.

Figure A4: Variation on k_p with the initiator concentration in PEGMA bulk at 40 °C.

Figure A5: SEC spectra for different PEGMA polymerization with CuBr/-2,2'-bipyridine at 20 °C. All polymerizations were carried out with an excess of 50 equivalents of NaBr with respect to the total Cu-catalyst concentration. The concentration of the Cu^I/L- and Cu^{II}/L-Br catalyst are shown in Table 4.6.

Figure A6: UV/Vis spectra for the PEGMA polymerization with the Fe^{II} -mesohemin-(MPEG₅₀₀)₂ catalyst and with VA-44 in 50 wt% H₂O at 60 °C. (A) Reaction of Fe^{II} /L with PEGMA radicals to the formation of the Fe^{III} /L-R species in a time scale of 10 min. The arrows indicate the direction of the absorbance change. The resulting Fe^{III} /L-R species is marked red. (B) Shows the dissociation of the Fe^{III} /L-R species during the continued polymerization after 30 min.

Figure A7: UV/Vis spectra of the participating mesohemin-(MPEG₅₀₀)₂ species in PEO/H₂O mixtures with 50 wt% water at 22 °C. The black line indicates the initial $\text{Fe}^{\text{III}}\text{-Br/L}$ species which was reduced with $\text{Na}_2\text{S}_2\text{O}_4$ to yield the $\text{Fe}^{\text{II}}/\text{L}$ spectrum (red line). The reaction of $\text{Fe}^{\text{II}}/\text{L}$ and the thermal initiator VA-44 at 65 °C lead to the $\text{Fe}^{\text{III}}/\text{L-R}$ species (green line).

Figure A8: ^{57}Fe Mössbauer spectra recorded at various temperatures on a flash-frozen solution of $\text{Fe}^{\text{III}}/\text{L-Cl}$ in substance. The asymmetric peak shape is typical for Fe^{III} complexes and is induced by intermediate spin relaxation.

Figure A9: ^{57}Fe Mössbauer spectra recorded on a flash-frozen solution of $\text{Fe}^{\text{III}}/\text{L-Cl}$ after different reactions. (A) $\text{Fe}^{\text{III}}/\text{L-Cl}$ in PEGMA with 50 wt% water. (B) $\text{Fe}^{\text{III}}/\text{L-Cl}$ after the reaction with 5 equivalents ascorbic acid in a 50 wt% PEGMA-water mixture. (C) PEGMA polymerization in 50 wt% water after the procedure described by Simakova *et al.*^[1] In all cases the $\text{Fe}^{\text{III}}/\text{L-Cl}$ species is Mössbauer silent and could not be detected due to intermediated spin relaxation.

Figure A10: SP-PLP-EPR experiment with 1 mM mesohemin-(MPEG₅₀₀)₂ in 50 wt% H₂O/PEGMA at 20 °C. PEGMA radical concentration vs time profiles measured by SP-PLP-EPR with a single laser pulse being applied at $t = 0.23$. The black line represents the radical decay after 8 laser pulses applied. The red line represents the radical decay after 70 laser pulses being applied. Due to the consumption of Fe^{III}/L-Br the decay in radical concentration decelerated. This finding suggests that the reaction of Fe^{II}/L with radicals is slower than the ATRP deactivation.

Abbreviations

A	absorbance
A_0	pre-exponential factor
AIBN	2,2'-azobis(2-methylpropionitrile)
α_s	composite-model exponent for the short chain regime
α_l	composite-model exponent for the long chain regime
AGET	Activator Generated by Electron Transfer
ARGET	Activator ReGenerated by Electron Transfer
ATRA	atom-transfer radical addition
ATRP	atom-transfer radical polymerization
BDE	bond-dissociation energy
bpy	2,2'-bipyridine
c	concentration
c'	Y-intercept of the linearized F[Y]-function for the non-equimolar case
c''	Y-intercept of the linearized F[Y]-function for the equimolar case
CCT	catalytic chain transfer
CRP	controlled radical polymerization
CRT	catalytic radical termination
d	optical pathway
ΔV^\ddagger	activation volume
$\Delta_r V$	reaction volume
DMF	dimethylformamide
DP	degree of polymerization
E_A	activation energy
EBrPA	ethyl α -bromophenylacetate
EPR	electron paramagnetic resonance

ε	molar decadic extinction coefficient
equiv	equivalents
<i>et al.</i>	<i>et alii</i>
$\eta(T,p)$	solvent viscosity at the given temperature and pressure
η	solvent viscosity
f	initiator efficiency
FT	Fourier transform
GC	gas chromatography
h	Planck constant
HEMA-Br	2-hydroxyethyl 2-bromoisobutyrate
HEMA	2-hydroxyethyl methacrylate
HMTETA	1,1,4,7,10,10-hexamethyltriethylenetramine
i	chain length
i_c	crossover chain length
k_{act}	rate coefficient for the activation
k_B	Boltzmann constant
K_{ATRP}	ATRP equilibrium constant
k_{deact}	rate coefficient for ATRP deactivation
K_{model}	ATRP equilibrium constant in case of model systems
k_p	propagation rate coefficient
k_t	termination rate coefficient
$k_{t,com}$	rate coefficient of the termination by combination
$k_{t,dis}$	rate coefficient of the termination by disproportionation
$k_t^{i,i}$	termination rate coefficient for monomers with chain-length i,i
$k_t^{1,1}$	termination rate coefficient for monomers with chain-length unity
LMCT	ligand to metal charge transfer
M	monomer molecule
MA	methyl acrylate

MBriB	methyl 2-bromoisobutyrate
MBrP	methyl 2-bromopropionate
MCT	mercury cadmium telluride
Me ₆ TREN	tris(2-dimethylaminoethyl)amine
MeCN	acetonitrile
MFA	modified fluoralkoxy
MMA	methyl methacrylate
M_n	number-average molar mass
M_w	weight-average molar mass
NIR	near-infrared
NMP	<i>N</i> -methyl-2-pyrrolidone
NMR	nuclear magnetic resonance
OMRP	organometallic-mediated radical polymerization
OM	organometallic
OSET	outer sphere electron transfer
p	pressure
<i>PDI</i>	dispersity
PE	polyethylene
PEGMA	poly (ethylene glycol) methyl ether methacrylate
PEEGMA	poly (ethylene glycol) ethyl ether methacrylate
PEBr	1-Phenylethyl bromide
PEO	poly (ethylene glycol) dimethyl ether
PID	proportional–integral–derivative controller
PLP	pulse-laser-induced polymerization
PMDETA	<i>N,N,N',N'',N''</i> -pentamethyldiethylenetriamine
P_{n+m}	polymer generated by combination
$P_n^=$	unsaturated polymer generated by disproportionation
P_m^H	saturated polymer generated by disproportionation
PRE	<i>persisten radical effect</i>
PS	polystyrene

R	ideal gas constant
RAFT	reversible addition-fragmentation chain-transfer
RDRP	reversible deactivation radical polymerization
RI	refractive index
R_n^\bullet	radical consisting of n monomer units
R_p	polymerization rate
SEC	size-exclusion chromatography
SP	single pulse
T	temperature
TEMPOL	4-hydroxy-2,2,6,6-tetramethylpiperidine 1-oxyl
UV	ultraviolet
Vis	visible
wt%	weight percent

Danksagung

Mein besonderer Dank gilt Herrn Prof. Dr. M. Buback für das interessante Thema und die herausfordernde Themenstellung dieser Arbeit. Seine Unterstützung und zahlreichen Diskussionen waren für mich besonders wertvoll. Weiterhin möchte ich Prof. Dr. P. Vana für die Übernahme des Korreferats danken.

Außerdem bedanke ich mich bei Herrn Prof. Dr. Franc Meyer, Prof. Dr. Burkhard Geil, PD Dr. Thomas Zeuch, Dr. Florian Ehlers für die Teilnahme am Prüfungskomitee.

Ein herzlicher Dank gebührt Prof. Dr. Krzysztof Matyjaszewski und Antonia Simakova für die thematische Kooperation und Bereitstellung der Eisenkatalysatoren.

Ebenso bedanke ich mich bei Stella Weber, die mit riesigem Fleiß alle PLP-SEC Messungen durchgeführt hat und dabei immer gut gelaunt und hoch motiviert war.

Ein herzlicher Dank geht auch an Prof. Dr. Franc Meyer für die Möglichkeit der Stopped-Flow Messungen in seinem Arbeitskreis. Außerdem danke ich Dr. Serhiy Demeshko für die Mössbauer Messungen und fachliche Beratung und Diskussion.

Herrn Hans-Peter Vögele danke ich für zahlreiche lustige Anekdoten und den vielen Hilfestellungen in Bezug zur Hochdruckpolymerisation und FT-NIR Spektroskopie.

Besonderer Dank gilt Hendrik Schröder, Patrick Drawe, Hendrik Kattner, Dennis Hübner und Alexander Groschopp für die Korrektur und hilfreichen Anmerkungen für diese Dissertation sowie die Diskussionsbereitschaft während der ganzen Promotion. Außerdem bedanke ich mich bei meinen ehemaligen und aktuellen Bürokollegen

Nicolai Sörensen, Jens Schrooten, Arne Wolpers, Nils Wittenberg, Sonja Schmidt und Martin Kassel für die zahlreichen Diskussion um die Promotion und um die Dinge des Alltags.

Außerdem möchte ich mich beim ganzen Arbeitskreis für die freundliche und lockere Atmosphäre, in der ich mich sehr wohl gefühlt habe, bedanken.

Ein ganz besonderer Dank gebührt meiner Mutter, die mich immer unterstützt hat und mir in ganz besonders schweren Zeiten geholfen und beigestanden hat. Genauso möchte ich auch meinem Vater danken, der diesen Moment leider nicht mehr miterleben kann. Er hat immer daran geglaubt, dass ich alles erreichen kann, was ich mir vornehme und er hat mir beigebracht nie aufzugeben. Ebenso bin ich meinen lieben Großeltern dankbar für die kleinen und großen Hilfen während des ganzen Studiums.

Einen ganz besonderer Dank gilt meiner Freundin Anne, die mich gerade in der kritischen Phase besonders unterstützt und mir immer wieder unerschütterlich Mut zugesprochen hat. Bei unserem kleinen Krümmelchen bedanke ich mich, dass es mir gerade am Ende der Promotion noch einmal einen riesigen Motivationsschub gegeben hat.

About the Author

Sebastian Smolne, * November 1, 1986 in Ludwigslust, Germany

Curriculum Vitae

12/ 2012 – 05/ 2016	Promotion an der Universität Göttingen bei Prof. Michael Buback Titel: Cu- and Fe-mediated Atom- transfer Radical Polymerization in Aqueous Solution
10/ 2010 – 10/ 2012	Masterstudium Chemie an der Universität Göttingen
10/ 2007 – 10/ 2012	Bachelorstudium Chemie an der Universität Göttingen
08/ 1999 – 07/ 2006	Abitur am Bernhard-Riemann- Gymnasium Scharnebeck

Publikationen

2015	Smolne S. , Buback M., Kinetic Investigations of Cu-Mediated ATRP in Aqueous Solution, <i>Macromolecular Chemistry and Physics</i> , 2015.
