-Acknowledgements-

In the first place, I would like to thank the committee for the discussion and observations, which helped to improve this work and stimulated future contributions.

Many thanks to Siegfried Siegesmund and Pedro Oyhantçabal for giving me the chance to come to Germany and for accepting to supervise my PhD. Thanks for the guidance, patience, knowledge generosity and all advices about geology, science and life. I am especially indebted for the good times in the field and the shared *asados/Grills* and wines, also together with Klaus Wemmer. Special thanks go to Klaus Wemmer for his invaluable help in the laboratory and the field, especially concerning K-Ar data measurement and interpretation, and also for his critical suggestions and discussions regarding isotope geology.

I am greatly indebted to the Iglesias family and Enrique Domínguez for the hospitality and logistic support in the field. The Department of Geology of the Universidad de la República (Uruguay) and the DINAMIGE are acknowledged for the support during two research stays in Montevideo and for granting access to the geological database of Uruguay, respectively. I would also like to thank Jorge Spoturno and Pablo Lara for discussions regarding the geology of Uruguay.

Florian Heidelbach is greatly acknowledged for the help with quartz CPO measurements and data interpretation. Many thanks to him, his family and the Bayerisches Geoinstitut for the hospitality during a short research stay in Bayreuth.

I would like to thank Miguel Basei for the guidance during U-Pb and Lu-Hf data processing and interpretation. I would also like to acknowledge him for several discussions concerning the Precambrian geology of South America and the evolution of Gondwana.

Jeff Benowitz, Jörg Pfänder, Felix Hannich and Blanka Sperner are acknowledged for Ar/Ar measurements and the help with data processing and interpretation, whereas Dirk Frei is thanked for U-Pb measurements of detrital zircons. Harald Tonn and Daniel Picchi are thanked for the help

with thin section preparation and Kerstin Techmer, for REM assistance. Brigitte Dietrich, Franziska Wilsky, Klaus Simon and Nicole Nolte are acknowledged for the support and advices during preparation, measurement and interpretation of the Rb-Sr samples.

All members of the Department of Structural Geology and Geodynamics are acknowledged for discussions and critical observations related to this work. Thanks to Craig Robertson for the interesting discussion about the origin of the term “Gondwana”.

To Graciela Sosa and Alfons van den Kerkhof go special thanks for the hospitality and the shared meals at their home. I would also like to acknowledge Graciela for the *pastafrola, dulce de membrillo* and, especially, for the shared *mates* every morning.

Filiz Afşar, Jan-Peter Duda, Mathias Hueck, Elco Luijendijk, Silke Meier and Victoria Shushakova are thanked for the (many) shared beers, coffees and talks. Special thanks to Filiz and Jan for their “always-open-house” and their continuous help and support. Thanks to Filiz for the help with the abstract translation and for tolerating our never-ending discussions about science and geology with Jan.

I would also like to acknowledge the D’Almeida-Cattaneo family, Hilario Espinosa and Santiago Finamore for the many *asados*, pizzas, beers and wines shared together.

I am deeply indebted to Silvia Japas for showing me the amazing world of rock deformation and for guiding me during my entire academic career since the very early beginning. I thank her for her selfless continuous support and help.

Last but not least, I would like to thank Ivana, my parents and my family for their continuous support. Also to my friends in Argentina, who accompanied me even in the distance.

I am also indebted to DAAD (Deutscher Akademischer Austausch Dienst) for a long-term PhD scholarship (A/12/75051), which made this work possible. DAAD is also acknowledged for financial support to print this thesis.

-PREFACE-

New data presented in this work are divided into different contributions, which are outlined below. These results as a whole comprise an integral approach to constrain the evolution of the study area. Chapter 1 and 2 are introductory, whereas results obtained in this thesis are included in Chapters 3 to 7. Chapter 8, in turn, presents a critical discussion of all new and available data, and Chapter 9 outlines the main conclusions of the work.

Chapter 1 presents the aim of the work as well as an overview of Gondwana evolution and regional geology of the study area. Chapter 2 reviews methodologies applied in this work, including all methods and analytical procedures.

Chapter 3 (Oriolo et al., 2016, *Precambrian Research*) presents new U-Pb and Hf zircon data from the basement of the study area, which comprise the Nico Pérez and Piedra Alta terranes. These results are integrated with available data from these blocks as well as from adjacent units in order to establish regional correlations and the allochthony/autochthony of the Nico Pérez Terrane regarding the Río de la Plata Craton.

Chapter 4 (Oyhantçabal et al., submitted to *Precambrian Research*) includes U-Pb and Hf detrital zircon data from the metasedimentary cover of the Dom Feliciano Belt, which overlains the basement units studied in Chapter 3. Age, provenance and tectonic setting of these units are thus discussed. In the corresponding manuscript, these results are integrated with geochemical and Sm-Nd whole-rock data from the same units, which were mostly analysed by the first author.

Chapter 5 (Oriolo et al., 2015, *International Journal of Earth Sciences*) presents kinematic, structural and microstructural data from the Sarandí del Yí Shear Zone and adjacent blocks. Quartz CPO data and strain analysis of the mylonites of the shear zone are integrated with these data in order to constrain the structural evolution of the Sarandí del Yí Shear Zone.

Chapter 6 (Oriolo et al., 2016, Tectonics) complements data from Chapter 5, as it incorporates geochronological data from the Sarandí del Yí Shear Zone. Hence, integration of structural, microstructural and geochronological data allows assessing the timing of deformation of the shear zone. Additionally, implications for dating the age of deformation in mylonitic rocks are discussed as well.

Chapter 7 (Oriolo et al., submitted to Journal of Structural Geology) presents structural, microstructural and geochronological data from the Dom Feliciano Belt. The timing of deformation and metamorphism and structural evolution of the belt are thus constrained.

Chapter 8 integrates all available data and results obtained in this work into an evolutionary model for the study area. As a corollary, the history of Western Gondwana assembly is reassessed, evaluating the role of major crustal blocks and Neoproterozoic orogenic belts (Oriolo et al., submitted to Geoscience Frontiers). Chapter 9 summarizes the main results of the work.

-ABSTRACT-

The Sarandí del Yí Shear Zone (Uruguay) is a crustal-scale structure that separates the Río de la Plata Craton from the Nico Pérez Terrane and Dom Feliciano Belt. Nevertheless, its evolution is poorly constrained, even though it represents a key structural feature of Western Gondwana. A multidisciplinary study was thus carried out, in order to assess the tectonic evolution of the Sarandí del Yí Shear Zone and adjacent blocks and the crustal affinity of the latter. Likewise, new and available data were integrated to provide a unified tectonic model for the history of amalgamation of Gondwana and the evolution of major mobile belts during the Neoproterozoic.

Geological, geochronological and isotopic data indicate that the Nico Pérez Terrane originated mostly from Archean episodic crustal growth and underwent dominantly crustal reworking during several Proterozoic events, whereas the Piedra Alta Terrane is made up of juvenile Paleoproterozoic continental crust. Hence, the Nico Pérez Terrane was allochthonous to the Río de la Plata Craton. In contrast, it shows an African crustal affinity and probably derived from the southwestern margin of the Congo Craton. Similarities of Archean and Proterozoic events recorded in the Nico Pérez Terrane basement and the overlying metasedimentary cover of the southwestern Dom Feliciano Belt further support an African derivation.

The onset of the deformation along the Sarandí del Yí Shear Zone is recorded at 630-625 Ma, giving rise to dextral shearing, and is coeval with the onset of deformation, metamorphism and exhumation of the Dom Feliciano Belt. This is related to the collision of the Río de la Plata and Congo Craton and the consequent juxtaposition of the Nico Pérez Terrane to the Río de la Plata Craton margin. Subsequent post-collisional exhumation, deformation and magmatism are ubiquitously recorded in the Dom Feliciano Belt up to 600 Ma. Sinistral shearing at ca. 600-580 Ma took place along the Sarandí del Yí Shear Zone as well as along NNE-striking shear zones of the Dom Feliciano Belt, and resulted from the onset of the Kalahari convergence with the already

amalgamated Río de la Plata and Congo cratons. The input of Kalahari-derived sediments is restricted to the late Ediacaran southeastern post-collisional sequences of the Dom Feliciano Belt, which further indicates that the Congo-Río de la Plata amalgamation predates the accretion of the Kalahari Craton.

As in the case of the Sarandí del Yí Shear Zone, collisional events up to 600 Ma along crustal-scale shear zones can be further traced to the north along the Transbrasiliiano-Kandi Lineament, which gave rise to the birth of Western Gondwana. The late stages of Rodinia break-up associated with the opening of the Iapetus Ocean between Laurentia, Baltica and Amazonas occurred contemporaneously and were succeeded by collisional events at 580-550 Ma of the East African/Antartic Orogen. The latter gave rise to the amalgamation of Eastern and Western Gondwana and predated the incorporation of the Kalahari Craton into Gondwana during the late Ediacaran-early Cambrian.

Hence, the assembly of Gondwana comprised a protracted history of amalgamation of crustal blocks between ca. 630 and 530 Ma. Likewise, the existence of the Pannotia supercontinent can be ruled out, as the final configuration of Gondwana was attained during the early Cambrian and took place after rifting between Laurentia and Amazonas.

-ZUSAMMENFASSUNG-

Die zu untersuchende Sarandí del Yí Scherzone trennt den Río de la Plata Kraton von dem Nico Pérez Terran und dem Dom Feliciano Gürtel. Obwohl diese Scherzone entscheidende Kenntnisse hinsichtlich der genauen Verschmelzung Gondwanas bringen könnte, ist die Entwicklung dieser Struktur unbekannt. Diese multidisziplinäre Studie beschäftigt sich nicht nur mit der tektonischen Entwicklung der Sarandí del Yí Scherzone, sondern auch der benachbarten Terrane und ihren Krustensignaturen. Dabei wurden neue und vorhandene Daten verwendet und in ein tektonisches Gesamtmodell integriert, welches nähere Erkenntnisse über die Zusammenführung Gondwanas und die Entwicklung der neoproterozoischen tektonischen Gürtel liefern soll.

Geologische, geochronologische und isotopengeochemische Untersuchungen des Nico Pérez Terrans weisen zum größten Teil auf ein episodisches Krustenwachstum im Archaikum hin, wobei die Kruste während mehrerer Ereignisse im Proterozoikum wiederaufgearbeitet wurde. Im Gegensatz dazu besteht das Piedra Alta Terran aus jüngerer, paläoproterozoischer kontinentaler Kruste. Das Nico Pérez Terran ist somit allochthon zum Río de la Plata Kraton. Die Krustensignatur des Nico Pérez Terrans ähnelt der afrikanischen sehr und wäre ein weiteres Indiz für eine Provenienz aus dem südwestlichen Congo Kraton. Die Ähnlichkeit zwischen archaischen und proterozoischen Ereignissen, die sich im Grundgebirge des Nico Pérez Terrans und den darüber liegenden Metasedimenten des südwestlichen Dom Feliciano Gürtels abzeichnen, ist ein weiterer Beleg für eine afrikanische Provenienz.

Der Verformungsbeginn der Sarandí del Yí Scherzone, die zu dextraler Scherung führte, kann in dieser Studie auf den Zeitraum 630-625 Ma eingegrenzt werden und fand somit zeitgleich mit dem Beginn der Deformation, Metamorphose und Exhumation des Dom Feliciano Gürtels statt. Diese Prozesse sind auf die Folgen der Kollision des Río de la Plata und Congo Kratons und

der darauffolgenden Verlagerung des Nico Pérez Terrans zum Rand des Río de la Plata Kratons zurückzuführen. Hinweise auf postkollisionale Prozesse (Exhumation, Deformation, Magmatismus) reichen im Dom Feliciano Gürtel bis zu 600 Ma zurück. Um ca. 600-580 Ma trat eine sinistrale Scherung entlang der Sarandí del Yí Scherzone sowie der NNO-streichenden Scherzonen des Dom Feliciano Gürtels auf, welche aus dem konvergierenden Kalahari Kratons mit den bereits verschmolzenen Río de la Plata und Congo Kratonen resultierte. Die von dem Kalahari Kraton eingetragenen Sedimente beschränken sich auf das obere Ediacarium des südöstlichen Dom Feliciano Gürtels. Dies weist auf eine der Akkretion des Kalahari Kratons vorhergehende Verschmelzung der Congo - Río de la Plata Kratone hin.

Wie im Fall der Sarandí del Yí Scherzone sind Kollisionsphasen bis 600 Ma entlang transregionaler Scherzonen, die entlang des Transbrasiliano-Kandi Lineaments nach Norden zu verfolgen sind, erkennbar. Diese Phasen führten zur initialen Bildung West-Gondwanas. Gleichzeitig fanden mit der Öffnung des Iapetus Ozeans zwischen Laurentia, Baltica und Amazonas die letzten Züge des Zerbrechens Rodinias statt. Anschließend fand eine Kollisionsphase des Ostafrikanisch-Antarktischen Orogens um 580-550 Ma statt. Durch diese letzte Kollision wurden West- und Ost-Gondwana zusammengeführt, obwohl der Kalahari Kraton anschließend im oberen Ediacarium-unterem Kambrium zu Gondwana verschmolzen wurde.

Somit ist festzustellen, dass mit der Entstehung Gondwanas eine langwierige Verschmelzung von Krustenblöcken zwischen ca. 630 und 530 Ma einhergeht. Ebenso wird die Existenz des Superkontinents Pannotia ausgeschlossen, da Gondwana erst im unteren Kambrium die finale Konfiguration erreichte, die dem Laurentia-Amazonas Rifting nachfolgte.

-CHAPTER 1-**General Introduction****1.1. Aim of the thesis**

The goal of this work is to characterize the tectonic evolution of the Sarandí del Yí Shear Zone and adjacent blocks (Uruguay), namely the Piedra Alta and Nico Pérez terranes and the Dom Feliciano Belt, and to establish their role during Gondwana evolution. A multidisciplinary study was thus carried out, considering several specific objectives that can be summed up in the following:

-To define the age and isotopic signature of the Piedra Alta and Nico Pérez terranes. The autochthonous/allochthonous nature of the Nico Pérez Terrane regarding the Río de la Plata Craton and its crustal affinity are thus evaluated.

-To determine the detrital zircon pattern and provenance of the metasedimentary sequences of the southwestern Dom Feliciano Belt.

-To constrain the tectonothermal evolution of the Sarandí del Yí Shear Zone: structure, kinematics, deformation mechanisms and conditions, and timing of deformation. Based on this thorough analysis, strain localization processes during shear zone nucleation and evolution as well as the application of multiple geochronometers in mylonitic rocks are also discussed.

-To characterize the structural architecture and timing of deformation and metamorphism of the Dom Feliciano Belt. The role of shear zones is emphasized and, consequently, temporal and spatial strain variations at the orogen scale are analysed.

-To provide a unified tectonic model for the history of amalgamation of the main crustal blocks of Western Gondwana and the evolution of major mobile belts during the Neoproterozoic.

1.2. From Rodinia break-up to Gondwana amalgamation

The term *Gondwana* was first used by Medlicott (1872, apud Feistmantel, 1876) to refer to a plant-bearing series in India and was afterwards extended to the Gondwana system (Feistmantel, 1876; Medlicott and Blanford, 1879). Based on similarities in the Paleozoic-Mesozoic geological and fossiliferous record of India and other continental masses, Suess (1885) proposed the existence of a supercontinent and coined the name *Gondwanaland*, which was extended to South America, Australia and Antarctica by Wegener (1915).

The evolution of Gondwana was strongly linked to Rodinia break-up, although the participation of some African and South American blocks in Rodinia is controversial (Kröner and Cordani, 2003; Tohver et al., 2006; Evans, 2009). After amalgamation during the late Mesoproterozoic, Rodinia break-up occurred diachronously during the Cryogenian and Ediacaran (Li et al., 2008; Johansson, 2014). Rifting started at ca. 800-700 Ma at the margin of Laurentia and the Kalahari Craton with the Australia-East Antarctica and South China cratons, and was succeeded by rifting at ca. 600 Ma at the Laurentia-Amazonas Craton margin (Fig. 1.1; Jacobs et al., 2008; Li et al., 2008). This late extensional event was almost coeval with the amalgamation of Western Gondwana, which includes most of the South American and African crustal blocks (e.g., Brito Neves et al., 1999; Cordani et al., 2003). However, the Kalahari Craton and the Eastern Gondwana blocks were not amalgamated with the rest of Gondwana till the early Cambrian (Fig. 1.2; Meert, 2003; Jacobs and Thomas, 2004; Collins and Pisarevsky, 2005; Li et al., 2008).

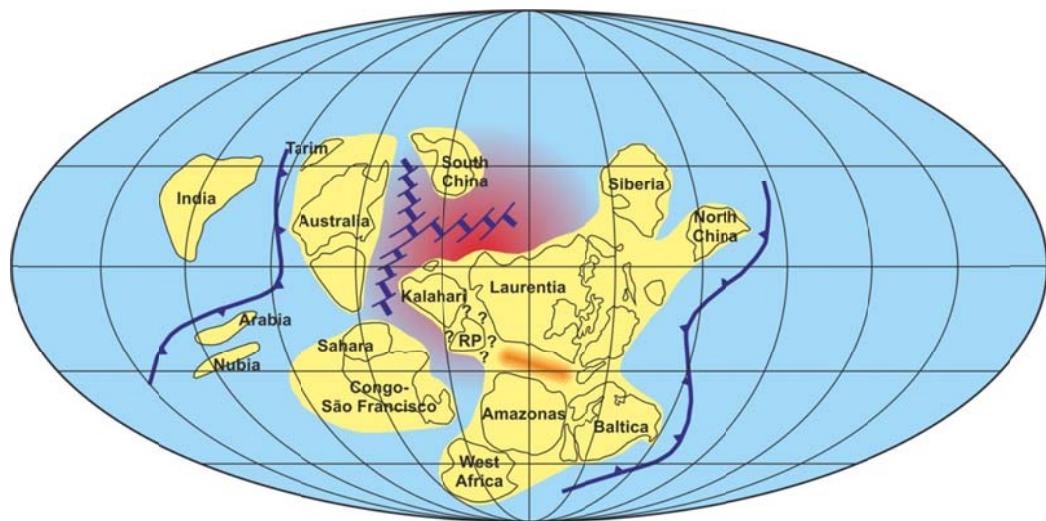

Fig. 1.1: Schematic paleogeography showing main crustal block distribution during Rodinia break-up at ca. 720 Ma (modified after Li et al., 2008). Subduction zones and spreading ridges are indicated in blue, whereas the red area indicates the possible location of a mantle plume. The rifting zone at ca. 600 Ma between Laurentia and Amazonas is shown in orange. Question marks indicate the uncertain location of the Río de la Plata (RP) in Rodinia, as outlined by Kröner and Cordani (2003) and Tohver et al. (2006).

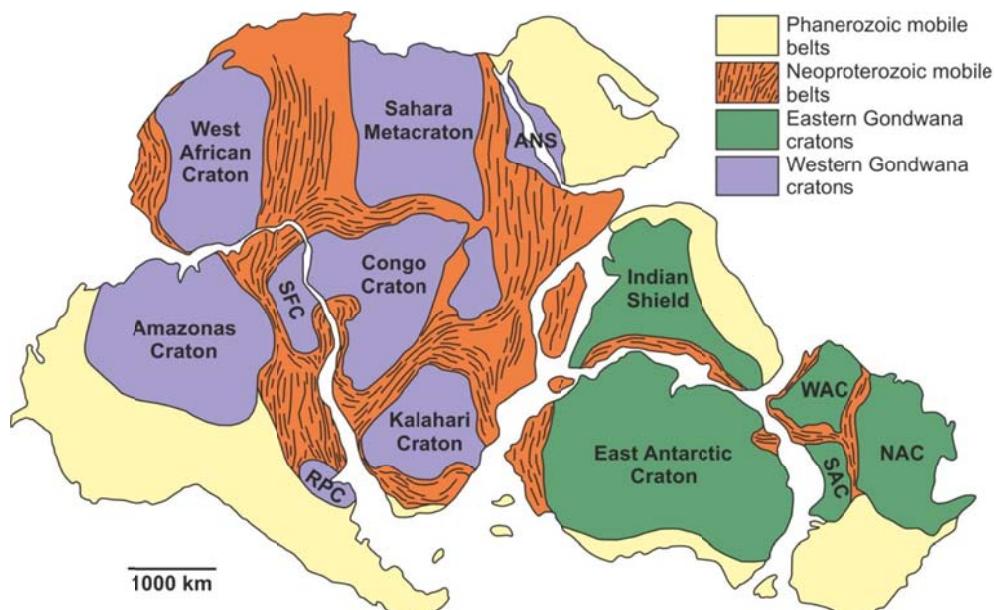

Fig. 1.2: Gondwana map showing main crustal fragments and orogenic belts during the late Neoproterozoic–early Paleozoic (modified after Gray et al., 2008). RPC: Río de la Plata Craton, SFC: São Francisco Craton, ANS: Arabian-Nubian Shield, WAC: West Australian Craton, NAC: North Australian Craton, SAC: South Australian Craton.

1.2. The Brasiliano–Pan-African Orogeny

The Neoproterozoic Brasiliano–Pan-African Orogeny is ubiquitous in South America and Africa and represents a protracted amalgamation of major crustal blocks along several mobile belts, giving rise to the accretion of Gondwana after Rodinia break-up (Almeida et al., 1973; Brito Neves et al., 1999; Cordani et al., 2003; Kröner and Stern, 2004). Particularly, the juxtaposition of the Río de la Plata, Kalahari and Congo cratons together with other minor continental fragments such as the Nico Pérez Terrane took place in Western Gondwana (Basei et al., 2005; Goscombe et al., 2005a; Gray et al., 2008; Foster et al., 2009; Frimmel et al., 2011; Oyhantçabal et al., 2011a, 2011b; Rapela et al., 2011).

The Río de la Plata Craton comprises the Piedra Alta Terrane in Uruguay and the Tandilia Belt in Argentina (Cingolani, 2011, Oyhantçabal et al., 2011a). This Paleoproterozoic block is bounded to the west by the late Ediacaran-Cambrian Pampean Orogen (e.g., Rapela et al., 1998, 2007; Siegesmund et al., 2010), whereas the Sarandí del Yí Shear Zone represents its eastern margin (Oyhantçabal et al., 2011a). The Dom Feliciano Belt is located to the east of this crustal-scale shear zone and reworks several Archean and Paleoproterozoic minor crustal blocks (Oyhantçabal et al., 2011a; Rapela et al., 2011). On the other hand, both Congo and Kalahari cratons comprise mostly Archean and Paleoproterozoic rocks, although Mesoproterozoic rocks are widespread in the Kalahari Craton as well (Fig. 1.3; e.g., Hanson, 2003; McCourt et al., 2013). The western Congo and Kalahari cratons are bounded by the Kaoko and Gariep belts, respectively (Fig. 1.3; Hälbich and Alchin, 1995; Dürr and Dingeldey, 1996; Frimmel and Frank, 1998; Goscombe et al., 2003a, 2003b, 2005a, 2005b; Konopásek et al., 2005; Goscombe and Gray, 2008, 2009; Foster et al., 2009), whereas the Damara Belt represents the boundary between both cratons (Gray et al., 2006, 2008; Foster et al., 2015; Lehmann et al., 2015).

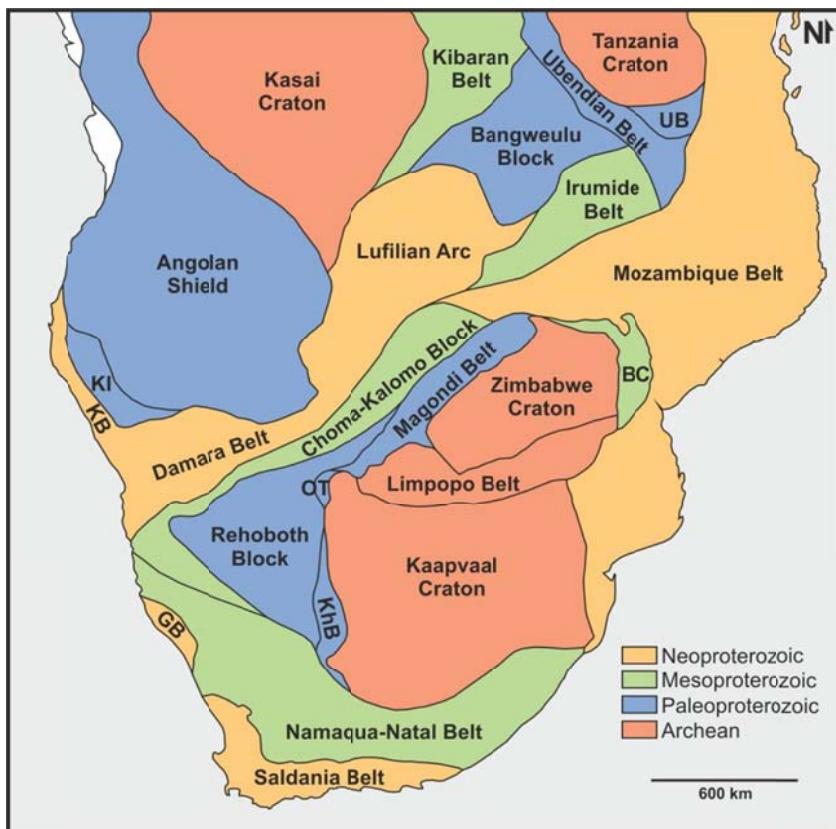

Fig. 1.3: Geological map of the Precambrian of Africa modified after Hanson (2003) and McCourt et al. (2013). UB: Usagaran Belt, KhB: Kheis Belt, OT: Okwa Terrane, KI: Kamanjab Inlier, BC: Bárue Complex, KB: Kaoko Belt, GB: Gariep Belt.

1.4. Geological setting

1.4.1. Tectonostratigraphic units

The Piedra Alta and the Nico Pérez terranes as well as the Dom Feliciano Belt represent the main tectonostratigraphic units that can be recognized in the Precambrian of Uruguay (Fig. 1.4; Oyhantçabal et al., 2011a). The Piedra Alta Terrane is located in western Uruguay and represents a part of the Paleoproterozoic Río de la Plata Craton (Almeida et al., 1973; Dalla Salda et al., 1988), which also includes the Buenos Aires Complex of the Tandilia Belt in Argentina (Cingolani, 2011 and references therein). The craton boundaries are dominantly covered by younger sediments and were thus only recognized through borehole and geophysical information (Booker et al., 2004; Rapela et al. 2007, 2011; Pángaro and Ramos, 2012).

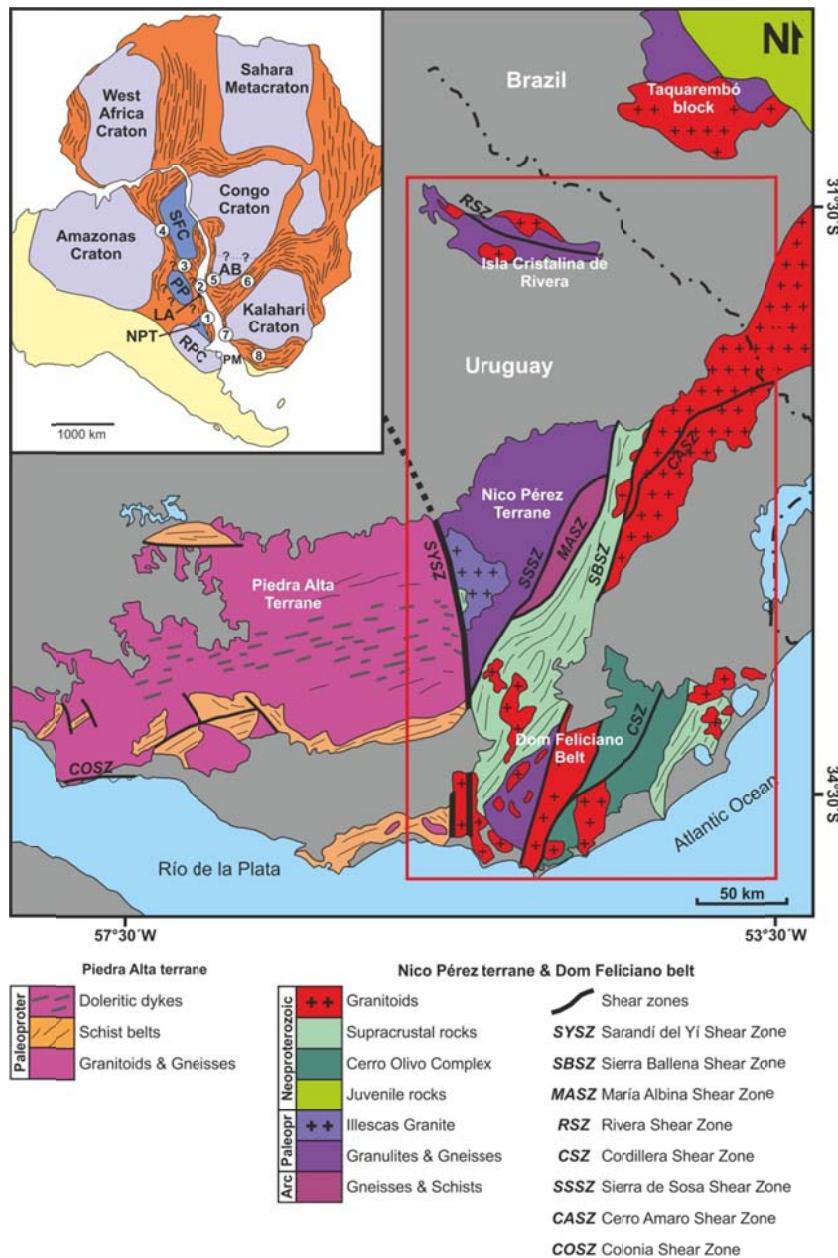

Fig. 1.4: Geological map of the Precambrian of Uruguay modified after Oyhantçabal et al. (2011a) and references therein. The inset shows the distribution of main crustal fragments and Neoproterozoic orogenic belts in South America and Africa, modified after Gray et al. (2008). The study area is indicated in red. African blocks in South America are shown in blue (NPT: Nico Pérez Terrane, PP: Paranapanema Block, SFC: São Francisco Craton). RPC: Río de la Plata Craton, AB: Angola Block. 1: Dom Feliciano Belt, 2: Ribeira Belt, 3: Brasilia Belt, 4: Araçuaí Belt, 5: Kaoko Belt, 6: Damara Belt, 7: Gariep Belt, 8: Saldania Belt. The location of the Punta Mogotes borehole (PM), which represents the southeastern margin of the Río de la Plata Craton, is also indicated (Rapela et al., 2011).

The Nico Pérez Terrane crops out in central Uruguay. It is an Archean-Paleoproterozoic block that shows strong Neoproterozoic reworking (Ellis, 1998; Oyhantçabal et al., 2011a, 2012). It also includes the Isla Cristalina de Rivera in northern Uruguay (Ellis, 1998) and the Taquarembó block in southern Brazil (Oyhantçabal et al., 2011a). The basement of the Nico Pérez Terrane is made up of the Pavas Block, the Valentines-Rivera Granulitic Complex and the Campanero Unit. The Pavas Block comprises Archean orthogneisses, mafic and ultramafic rocks and metasediments (Preciozzi et al., 1979; Hartmann et al., 2001), whereas the Valentines-Rivera Granulitic Complex is constituted by 2.2-2.0 Ga granulites and orthogneisses (Oyhantçabal et al., 2011a, 2012), which are intruded in the west by the 1.7 Ga Illescas rapakivi granite (Campal and Schipilov, 1995). The Campanero Unit comprises migmatites, amphibolites, BIFs, micaschists and orthogneisses with zircon ages of 1.7 Ga and is exposed as a basement inlier of the Dom Feliciano Belt (Sánchez Bettucci et al., 2003, 2004; Oyhantçabal, 2005; Mallmann et al., 2007). Likewise, Neoproterozoic granitoids and metasediments are widespread and indicate a significant reworking related to the evolution of the Dom Feliciano Belt (Oyhantçabal et al., 2011a, 2012).

The Dom Feliciano Belt represents a Neoproterozoic transpressional orogen, which is located in eastern Uruguay and south-eastern Brazil. It can be divided into three main geotectonic units: the granite belt, the schist belt and foreland basins (Basei et al., 2000). The granite belt is made up of the Pelotas and Florianópolis Batholith in Brazil and the Aigúa Batholith in Uruguay (Basei et al., 2000). On the other hand, the schist belt comprises deformed metavolcano-sedimentary sequences such as the Lavalleja, Porongos and Brusque groups, whereas the foreland belt includes post-collisional volcano-sedimentary successions (Basei et al., 2000, 2008). Likewise, it includes a series of pre-Brasiliano basement inliers (Sánchez Bettucci, 1998; Preciozzi et al., 1999; Mallmann et al., 2007; Basei et al., 2011a; Rapela et al., 2011; Saalmann et al., 2011). Due to similarities in the tectonomagmatic evolution, the Dom Feliciano Belt was alternatively correlated

with the Kaoko and Gariep belts in Africa (e.g., Basei et al., 2005, 2008, 2011a; Gross et al., 2009; Oyhantçabal et al., 2009a, 2009b, 2011b; Lenz et al., 2011; Rapela et al., 2011).

1.4.2. Shear zones

The main tectonostratigraphic units of the basement of Uruguay are bound and cross-cut by several major shear zones (Fig. 1.4). In particular, the Sarandí del Yí and the Sierra Ballena shear zones represent the main structural features.

The Sarandí del Yí Shear Zone separates the Paleoproterozoic Piedra Alta Terrane from the adjacent Nico Pérez Terrane and Dom Feliciano Belt (Oyhantçabal et al., 2011a; Rapela et al., 2011) and was proposed as the easternmost boundary of the Río de la Plata Craton (Oyhantçabal et al., 2011a). Due to the lack of structural studies of this shear zone, its evolution is still controversial (Oyhantçabal et al., 1993, 2011a; Gaucher et al., 2011a), even though it represents a key element for the understanding of the amalgamation of Western Gondwana.

On the other hand, the Sierra Ballena Shear Zone represents the boundary between the Nico Pérez Terrane and the Cerro Olivo Complex, i.e., the Punta del Este Terrane (Basei et al., 2011a; Oyhantçabal et al., 2011a; Rapela et al., 2011). Further to the north, the Sierra Ballena was correlated with the Dorsal de Canguú/Cordilheira and Major Gercino shear zones from southern Brazil (Fernandes et al., 1992; Fernandes and Koester, 1999; Oyhantçabal et al., 2009b, 2011b; Passarelli et al., 2010, 2011) as well as with the Purros Shear Zone of the Kaoko Belt in Namibia (Oyhantçabal et al., 2011b).

Shear zones of the Piedra Alta Terrane present typically E-ENE strike and strike-slip sinistral shearing (Fig. 1.4). Among them, the Colonia and Mosquitos shear zones yield K-Ar muscovite ages of 2.05-1.78 Ga (Oyhantçabal et al., 2006; Gianotti et al., 2010), indicating tectonic activity related to the Paleoproterozoic evolution of the Río de la Plata Craton. The same E-ENE

structural grain can be recognized elsewhere within the Piedra Alta Terrane due to the distribution of gneissic-granitic and metavolcano-sedimentary belts and the Florida dyke swarm (Fig. 1.4; Oyhantçabal et al., 2011a). Furthermore, comparable E-striking Paleoproterozoic shear zones such as the Azul Shear Zone crop out in the Tandilia Belt (Frisicale et al., 2005, 2012).

Between the Sarandí del Yí and Sierra Ballena shear zones, several mylonitic belts are present within the basement of the Nico Pérez Terrane and the southwestern Dom Feliciano Belt (Fig. 1.4). The Rivera Shear Zone cross-cuts the Valentines-Rivera Granulitic Complex, whereas the Sierra de Sosa and María Albina shear zones separate different lithostratigraphical units (Oyhantçabal et al., 2011a, 2012). Likewise, several NE-striking shear zones such as the Cerro Amaro and Cordillera shear zones are present to the east of the Sierra Ballena Shear Zone (Oyhantçabal, 2005; Oyhantçabal et al., 2011a).

-CHAPTER 2-

Methodology

2.1. Geological mapping

The starting point of this research was the geological mapping of the study area (Fig. 1.4), which was based on field work, available geological maps, aerial photographs and satellite images. A total of four months of field work was divided into several campaigns between 2011 and 2014. Geological and structural data were collected thorough the study area and key areas were mapped in detail (ca. 1:20000). Field data were integrated with all available maps from publications, data from the Geological Survey of Uruguay (DINAMIGE), Landsat images and 1:20000 aerial photographs from the Servicio Geográfico Militar, Uruguay.

Based on the mapping, key units were sampled for laboratory analyses (thin sections, quartz crystallographic preferred orientation analyses, geochronological and isotopic studies). In turn, preliminary laboratory results were checked during subsequent field work.

2.2. Petrography

About 160 thin sections were analysed using classical optical microscopy. Petrographic observations included lithological and modal characterization, determination of critical parageneses to constrain metamorphic conditions and microstructural analysis. Microstructural analysis was carried out in order to assess deformation mechanisms and conditions, and was integrated with quartz crystallographic preferred orientation data in the case of mylonitic rocks.

2.3. Quartz crystallographic preferred orientation patterns

Samples of mylonites were collected to analyse the crystallographic preferred orientation (CPO) of quartz (Appendix 1). Sections parallel to the lineation and perpendicular to the foliation

were studied with electron backscatter diffraction (EBSD). The reference structural frame is presented in all pole figures. The sections were polished additionally with a high pH silica solution (40 nm particle size) in order to remove damage from the previous polishing steps. The SEM was a Leo (now Zeiss) Gemini 1530 with a Schottky emitter run at 30 keV accelerating voltage and a beam current of about 8 nA, and is located at the Bayerisches Geoinstitut of the Universität Bayreuth. EBSD patterns were recorded with a Nordlys 2 camera and indexed with the Channel software package, both from Oxford Instruments. Areas of about 40 mm² were mapped with a step size of 10 µm yielding between 20000 and 70000 indexed points for quartz depending on the sample. The discrete orientation points were clustered with a 5° circle and then smoothed with a 10° FWHM for representation in the pole figures.

2.4. Geochronology

2.4.1. U-Pb geochronology

Samples were crushed and sieved and, afterwards, the mineral fractions were separated using conventional heavy liquid and isodynamic techniques. Sample locations are presented in Appendix 2. For several samples, not only zircons but also other mineral phases were also concentrated for geochronology (Appendix 2). Measurements were carried out at the Geochronological Research Centre of the University of São Paulo, Brazil (U-Pb SHRIMP and LA-ICP-MS) and the Central Analytical Facility of the Stellenbosch University, South Africa (U-Pb LA-ICP-MS).

Age determinations by SHRIMP were performed at the Geochronological Research Centre of the University of São Paulo, according to standard procedures (Compston et al., 1984; Stern, 1998; Williams, 1998; Sircombe, 2000). Zircons from each sample were arranged in rows with Temora 2 zircon reference standard, cast into epoxy resin grain mounts with a diameter of 2.54

cm, and polished to reveal grain centers. Prior to analysis, cathodoluminescence (CL) and transmitted images were obtained so that sites for analysis could be chosen. The SHRIMP IIe setup is described below:

- Primary beam analytical conditions: Kohler aperture = 120 μm , spot size = 30 μm , and O_2^- beam density = ~2.5-7 nA (depending on brightness aperture).
- Secondary beam analytical conditions: source slit = 80 μm ; mass resolutions for $^{196}(\text{Zr}_2\text{O})$, ^{206}Pb , ^{207}Pb , ^{208}Pb , ^{238}U , $^{248}(\text{ThO})$ and $^{254}(\text{UO})$ ranging between 5,000 and 5,500 (1%), and residues < 0.025; energy slit = open.

During acquisition, raster time was 2-3 minutes with spot size = 50 μm , plus 0.5 minutes of burning time fixed at the center. Analytical rate among standard and sample is 1 standard to 4 zircon samples.

The Pb^+ ionization efficiency is about a factor of two higher than U^+ , and so the $^{206}\text{Pb}^+/\text{U}^+$ ratio must be calibrated using a standard material (Williams, 1998). Measured $^{206}\text{Pb}^+/\text{U}^+$ varies with the measured UO^+/U^+ to define a calibration line of known age, in this case 416.78 Ma for the Temora 2 zircon. The age of an unknown sample can then be determined by the ratio of $^{206}\text{Pb}^+/\text{U}^+$ in the unknown to that ratio in the standard at the common UO/U value. For additional information, see Williams (1998). SHRIMP softwares are LabVIEW 8.5 and SHRIMP SW 2.90. Data was reduced using SQUID 1.06. Common lead corrections use ^{204}Pb according to Stacey and Kramer (1975). Temora 2 is used as $^{206}\text{Pb}/\text{U}$ age reference (416.78 Ma; Black et al., 2004), and SL13 (238 ppm) is used as U composition reference. More details about analytical procedures and data acquisition and processing are presented by Sato et al. (2014).

On the other hand, zircon and titanite LA-ICP-MS analyses performed at the Geochronological Research Centre of the University of São Paulo were carried out using a Neptune inductively coupled plasma-mass spectrometer (ICP-MS) and an excimer laser ablation (LA)

system. Table 2.1 provides the cup and ICP-MS configuration as well as the laser parameters used during the analysis. The U-Pb analysis was used to measure the materials in the following order: two blanks, two NIST standard glasses, three external standards, 13 unknown samples, two external standards and two blanks. Each experiment consisted of 40 cycles with 1 s/cycle. The ^{204}Hg interference for ^{204}Pb was corrected using ^{202}Hg , as $^{204}\text{Hg}/^{202}\text{Hg} = 4.350360$. The $^{207}\text{Pb}/^{206}\text{Pb}$ ratio was used to normalize both the NIST and external standards, whereas the $^{238}\text{U}/^{206}\text{Pb}$ ratio was used to normalize the external standard. The standard GJ-1 was used for the zircon analyses (Elhlou et al., 2006). Zircon typically contains low concentrations of common Pb. Thus, the reliability of the measured $^{207}\text{Pb}/^{206}\text{Pb}$ and $^{238}\text{U}/^{206}\text{Pb}$ ratios critically depends on accurately assessing the common Pb component. The residual common Pb was corrected based on the measured ^{204}Pb concentration using the known terrestrial composition (Stacey and Kramers, 1975). The uncertainty introduced by laser-induced fractionation of elements and mass instrumental discrimination was corrected using a reference zircon standard (GJ-1; Jackson et al., 2004). The isotope ratios and interelement fractionation of data collected using the ICP-MS instrument were evaluated by interspersing the GJ-1 zircon standard in each set of thirteen zircon spots. The GJ-1 standard meets the requirements for the methods used in the laboratory, and the ratios $^{238}\text{U}/^{206}\text{Pb}^*$, $^{207}\text{Pb}^*/^{206}\text{Pb}^*$ and $^{232}\text{Th}/^{238}\text{U}$ were homogeneous throughout application of the bracket technique. External errors were calculated using error propagation for the individual measurements of the standard GJ-1 and the individual zircon sample measurements (spots).

Most of the data plot close to concordant ages. Results are represented in concordia and Tera-Wasserburg plots generated by the program Isoplot/Ex (Ludwig, 2003). Data were filtered prior to plotting, to remove analyses with the most disturbed radiogenic Pb and with higher ^{206}Pb of common origin, calculated from measured ^{204}Pb using Cumming and Richards (1975) Pb evolution curves for common Pb compositions.

U–Pb age data obtained at the Central Analytical Facility of the Stellenbosch University were, in turn, acquired by laser ablation-single collector-magnetic sector field-inductively coupled plasma-mass spectrometry (LA-SF-ICP-MS) employing a ThermoFinnigan Element2 mass spectrometer coupled to a NewWave UP213 laser ablation system. All age data were obtained by single spot analyses with a spot diameter of 30 µm and a crater depth of approximately 15–20 µm. The methods employed for analysis and data processing are described in detail by Gerdes and Zeh (2006) and Frei and Gerdes (2009). For quality control, the Plešovice (Sláma et al., 2008) and M127 (Nasdala et al., 2008; Mattinson, 2010) zircon reference materials were analysed, and the results were consistently in excellent agreement with the published ID-TIMS ages. The calculation of concordia ages and plotting of concordia diagrams were performed using Isoplot 3.0 (Ludwig, 2003). Results are presented in relative probability curves recalculated from the number of zircon analyses for each age class.

2.4.2. $^{40}\text{Ar}/^{39}\text{Ar}$

$^{40}\text{Ar}/^{39}\text{Ar}$ step-heat analyses were carried out in hornblende and mica separates (Appendix 2). Measurements were carried out at the Geochronology Laboratory of the University of Alaska Fairbanks and the Argonlab Freiberg.

In the case of $^{40}\text{Ar}/^{39}\text{Ar}$ determinations conducted at the Geochronology Laboratory of the University of Alaska Fairbanks, the mineral MMhb-1 (Samson and Alexander, 1987) with an age of 513.9 Ma (Lanphere and Dalrymple, 2000) was used to monitor neutron flux and to calculate the irradiation parameter (J). The samples and standards were wrapped in aluminium foil and loaded into aluminium cans of 2.5 cm in diameter and 6 cm in height. The samples were irradiated in position 5c of the uranium enriched research reactor of the McMaster University in Hamilton, Ontario, Canada for 20 MW h.

Upon their return from the reactor, the samples and monitors were loaded into 2 mm diameter holes in a copper tray that was then loaded in an ultra-high vacuum extraction line. The monitors were fused and the samples heated, using a 6 W argon-ion laser following the technique described in York et al. (1981), Layer et al. (1987) and Layer (2000). Argon purification was achieved using a liquid nitrogen cold trap and a SAES Zr-Al getter at 400°C. The samples were analysed in a VG-3600 mass spectrometer at the Geophysical Institute, University of Alaska, Fairbanks. The measured argon isotopes were corrected for system blank and mass discrimination, as well as calcium, potassium, and chlorine interference reactions following procedures outlined in McDougall and Harrison (1999). System blanks generally were 2×10^{-16} mol ^{40}Ar and 2×10^{-18} mol ^{36}Ar , which are 10 to 50 times smaller than fraction volumes. Mass discrimination was monitored by running both calibrated air shots and a zero-age glass sample. These measurements were made on a weekly to monthly basis to check for changes in mass discrimination.

Ages are quoted to the $\pm 1\sigma$ level and calculated using the constants of Steiger and Jaeger (1977). The integrated age is given by the total gas measured and is equivalent to a K-Ar age. The

spectrum provides a plateau age if three or more consecutive fractions represent at least 50% of the total gas release and are within two standard deviations of each other ($\text{MSWD} < 2.5$).

On the other hand, $^{40}\text{Ar}/^{39}\text{Ar}$ step-heat analyses were conducted at the Argonlab in Freiberg Germany as well. Sample packets (2-3 mg multigrain) were placed along with fluence monitors on Al discs, and irradiated for 6.5 hours in the LVR-15 research reactor of the Nuclear Research Institute in Řež, Czech Republic. The thermal neutron fluence was $\sim 5 \times 10^{13} \text{ n/cm}^2\text{s}$ and the thermal-to-fast neutron ratio was ~ 2.2 . Step heating was performed using an energy-controlled floating 30W CO₂ laser system at 10.6 μm wavelength and a defocused beam of 3 mm diameter. Gas purification was achieved by two AP10N getter pumps, one operated at room temperature and the other at 400°C. Laser-heating time was 5 minutes per step. Cleaning time per step was 10 minutes. Argon isotope compositions were measured in static mode on a GV instruments ARGUS noble gas-mass spectrometer equipped with five Faraday cups. Typical blank levels are $2.5 \times 10^{-16} \text{ mol } ^{40}\text{Ar}$ and $8.1 \times 10^{-18} \text{ mol } ^{36}\text{Ar}$. Measurement time was 7.5 minutes per step comprising 45 scans of 10 seconds integration time. Mass bias was corrected assuming a linear mass-dependent isotope fractionation and an atmospheric $^{40}\text{Ar}/^{36}\text{Ar}$ ratio of 295.5. Raw-data reduction and time-zero intercept calculations were carried out with an in-house developed Matlab® software. Isochron, inverse isochron, and plateau ages were calculated with ISOPLOT 3.7 (Ludwig, 2008). All ages are based on Fish Canyon sanidine as flux monitor ($28.305 \pm 0.036 \text{ Ma}$) and the decay constant ($\lambda_{\text{tot}} = (5.5492 \pm 0.0093) \times 10^{-10} \text{ a}^{-1}$) reported by Renne et al. (2010). The age uncertainties are reported at the $\pm 1\sigma$ confidence level. Interfering Ar isotopes were corrected using $(^{36}\text{Ar}/^{37}\text{Ar})_{\text{Ca}} = 0.000227 \pm 0.000002$, $(^{39}\text{Ar}/^{37}\text{Ar})_{\text{Ca}} = 0.000602 \pm 0.000006$, $(^{38}\text{Ar}/^{39}\text{Ar})_{\text{K}} = 0.01211 \pm 0.00061$, $(^{40}\text{Ar}/^{39}\text{Ar})_{\text{K}} = 0.00183 \pm 0.00009$.

2.4.3. K-Ar

The mica minerals were enriched by a mica-jet as described by Wemmer (1991) and other standard techniques like magnetic separation and hand picking. Purified micas were ground in pure alcohol to remove alteration rims that might have suffered a loss of Ar or K. The argon isotopic composition was measured in a pyrex glass extraction and purification line coupled to a Thermo Scientific ARGUS VI noble gas mass spectrometer operating in static mode at the Geoscience Centre of the Georg-August-Universität Göttingen. The amount of radiogenic ^{40}Ar was determined by isotope dilution method using a highly enriched ^{38}Ar spike from Schumacher (1975). The spike is calibrated against the biotite standard HD-B1 (Fuhrmann et al., 1987). The age calculations are based on the constants recommended by the IUGS quoted in Steiger and Jäger (1977).

Potassium was determined in duplicate by flame photometry using a BWB-XP flame photometer. The samples were dissolved in a mixture of HF and HNO_3 according to the technique of Heinrichs and Herrmann (1990). The analytical error for the K-Ar age calculations is given on a 95% confidence level ($\pm 2\sigma$). Further details of argon and potassium analyses for the laboratory in Göttingen are given in Wemmer (1991).

2.4.4. Rb-Sr

Rb-Sr analyses were carried out at the Geoscience Centre of the Georg-August-Universität Göttingen (Appendix 2). Whole-rock (WR) and muscovite separates (~50 mg) were transferred into Savillex beakers and mixed with a calibrated ^{87}Rb - ^{84}Sr spike. Samples were mixed with 2.0 ml of 40% HF and 2.0 ml of 65% HNO_3 . After a period of cold reaction, the solution was evaporated to dryness. A second HF- HNO_3 digestion step was carried out, which was followed by addition of 5.0 ml of 6N HCl, initiating another hot reaction. Afterwards, cooled solutions were heated up for

evaporation. In a last step, 1.5 ml of 2.5 N HCl was added and the solutions were centrifuged for 10 minutes.

Rb and Sr were separated using standard cation exchange procedures. The cation exchange columns were conditioned with 15 ml of 2.5 N HCl. The samples were diluted in 1.5 ml 2.5 N HCl and the resulting sample solutions were loaded into the columns and washed with 1.5 ml of 2.5 N HCl. The separated elements were dissolved in 2.5 N HCl and homogenized using an ultrasonic bath for 2 minutes. From each sample, 200 ng were transferred to the center of a rhenium filament with a loading bed of 2 μ l of 0.4N H₃PO₄ in order to suppress ionization and to enable measurement with a stable signal. The prepared sample filaments and additional standard filaments were put onto a sample wheel, which was mounted into the sample chamber. Samples were ionized and measured under vacuum using a ThermoFinnigan Triton TI mass spectrometer (TIMS).

2.5. Hf isotopy

All Lu-Hf zircon analyses were carried out at the Geochronological Research Centre of the University of São Paulo on a Neptune multicollector inductively coupled plasma mass spectrometer equipped with a laser-ablation Photon system. Analyses were performed in the same zircon grains that were previously dated by LA-ICP-MS (Appendix 2). The ablation time was 60 s; repetition rate of 7 Hz, and He was used as carrier gas. $^{176}\text{Hf}/^{177}\text{Hf}$ ratios were normalized to $^{179}\text{Hf}/^{177}\text{Hf} = 0.7325$. Cup configuration and instrument operating parameters are presented in Table 2.2. The isotopes ^{172}Yb , ^{173}Yb , ^{175}Lu , ^{177}Hf , ^{178}Hf , ^{179}Hf , ^{180}Hf and $^{176}\text{(Hf+Yb+Lu)}$ were collected simultaneously on Faraday cups. $^{176}\text{Lu}/^{175}\text{Lu}$ ratio of 0.02669 was used to calculate $^{176}\text{Lu}/^{177}\text{Hf}$. Mass bias corrections of Lu-Hf isotopic ratios were calculated using the variations of GJ-1 standard. A decay constant for ^{176}Lu of $1.867 \times 10^{-11} \text{ a}^{-1}$ (Söderlund et al., 2004), the present-day chondritic

ratios of $^{176}\text{Hf}/^{177}\text{Hf} = 0.282772$ and $^{176}\text{Lu}/^{177}\text{Hf}=0.0332$ (Blichert-Toft and Albarède, 1997) were adopted to calculate ε_{Hf} values. A two-stage continental model (T_{DM2}) was calculated using the initial $^{176}\text{Hf}/^{177}\text{Hf}$ of zircon and the $^{176}\text{Lu}/^{177}\text{Hf}=0.022$ ratio for the lower continental crust (Griffin et al., 2004).

-CHAPTER 3-**The Nico Pérez Terrane****3.1. Introduction**

The recognition of terranes as fault-bounded crustal blocks with a geological history that differs significantly from the adjacent blocks is fundamental to understand crustal accretion processes during supercontinent amalgamation (Howell et al., 1985). This was early recognized for the South American Platform, particularly during the Precambrian collisional orogenies that gave rise to the consolidation of this part of Western Gondwana (Almeida et al., 1973; Cordani and Brito Neves, 1982; Ramos, 1988).

The Nico Pérez Terrane of Uruguay was first defined by Bossi and Campal (1992) as a Paleoproterozoic block with Neoproterozoic magmatism and deformation. Archean basement inliers were afterwards recognised (Hartmann et al., 2001), whereas Mesoproterozoic reworking during the Grenville Orogeny was also suggested but not confirmed (Campal and Schipilov, 1999; Bossi and Cingolani, 2009; Gaucher et al., 2011a). Nevertheless, the Nico Pérez Terrane was always understood as the easternmost part of the Paleoproterozoic Río de la Plata Craton (Bossi and Campal, 1992; Mallmann et al., 2007; Gaucher et al., 2011a; Frimmel et al., 2011). In contrast, Oyhantçabal et al. (2011a) separated the Nico Pérez Terrane from the Río de la Plata Craton and considered it an Archean-Paleoproterozoic crustal block with a significant Neoproterozoic reworking related to the Brasiliano Orogeny. Rapela et al. (2011) compared it with the Encantadas, Punta del Este and Mar del Plata terranes, indicating that they all comprise African blocks that were rifted away from the African major cratons during the opening of the Adamastor Ocean at 780-760 Ma.

3.2. Geological setting

The Nico Pérez Terrane is bounded to the west by the Sarandí del Yí Shear Zone, whereas the Sierra Ballena Shear Zone separates it from the Cerro Olivo Complex, which comprises a Neoproterozoic basement inlier within the Dom Feliciano Belt, and the Aiguá Batholith (Fig. 3.1;

Oyhantçabal, 2005; Oyhantçabal et al., 2009b, 2011b). The basement of the Nico Pérez Terrane includes the Archean Pavas Block (Preciozzi et al., 1979) as well as two Paleoproterozoic units, namely the Valentines-Rivera Granulitic Complex and the Campanero Unit (Sánchez Bettucci, 1998; Oyhantçabal et al., 2011a), which are intruded by the Paleoproterozoic Illescas granite and several Neoproterozoic intrusions (Campal and Schipilov, 1995; Oyhantçabal et al., 2011a, 2012). A summary of the available geochronological data for the Nico Pérez Terrane is presented in Table 3.1.

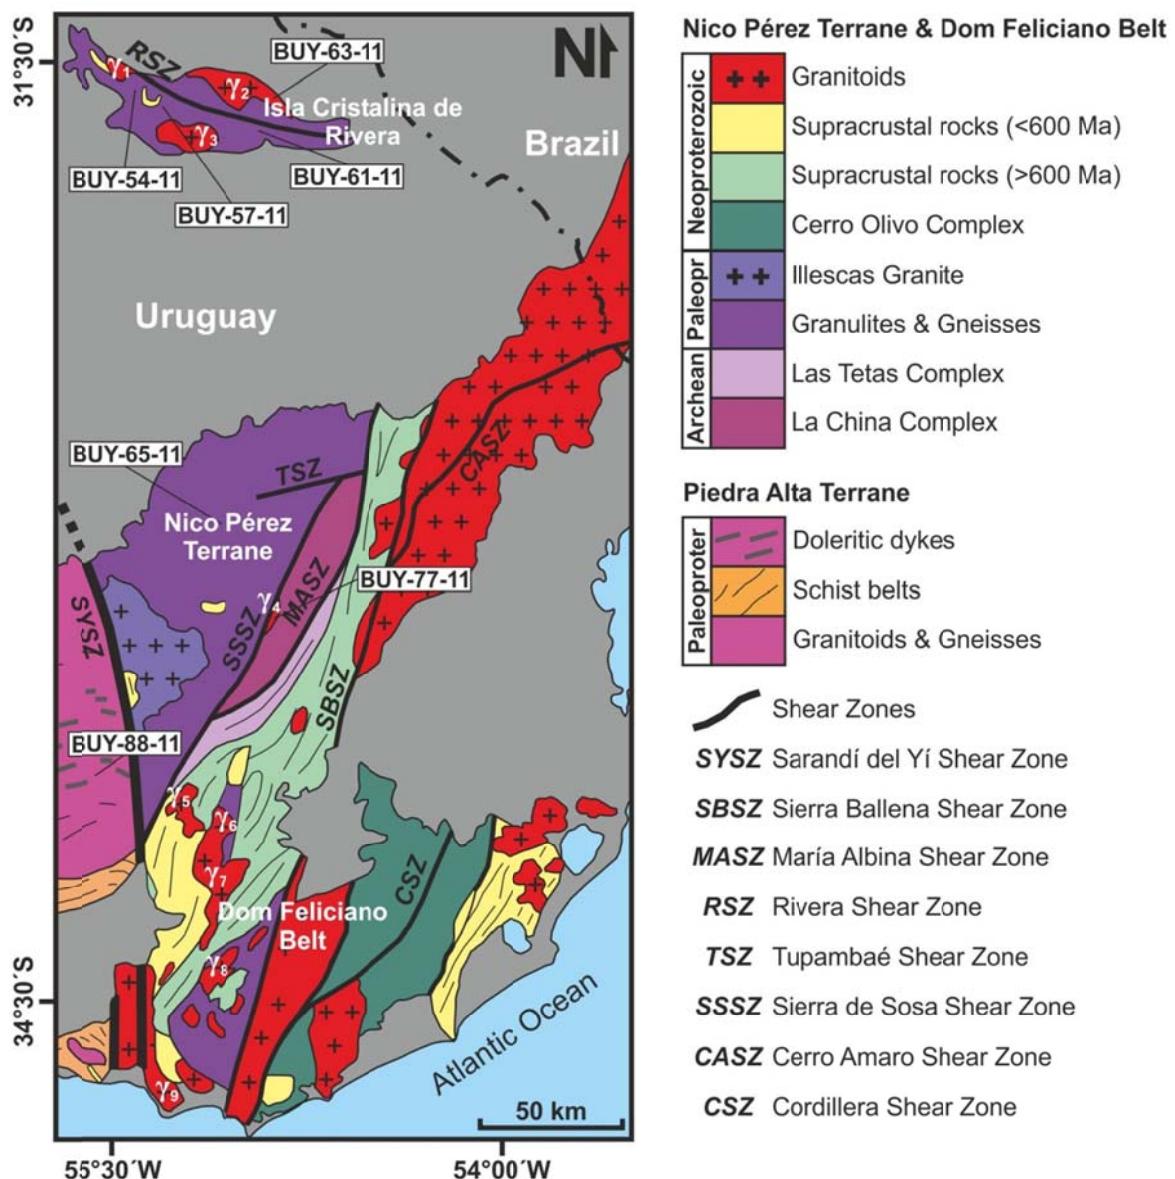

Fig. 3.1: Geological map of the Nico Pérez Terrane and adjacent blocks (modified after Oyhantçabal et al., 2011a, and references therein). Sample locations and Neoproterozoic intrusions (γ_1 : Sobresaliente granite, γ_2 : Amarillo granite, γ_3 : Las Flores granite, γ_4 : Zapicán granodiorite, γ_5 : Lavaderos granite, γ_6 : Arroyo Mangacha granite, γ_7 : Puntas del Santa Lucía monzogranite, γ_8 : Puntas de Mataojo granodiorite, γ_9 : Pan de Azúcar intrusion) are shown.

Table 3.1: Summary of available geochronological data of the Nico Pérez Terrane (Zrn: zircon, Hbl: hornblende, WR: whole-rock, Ttn: titanite, Mnz: monazite, Ms: muscovite).

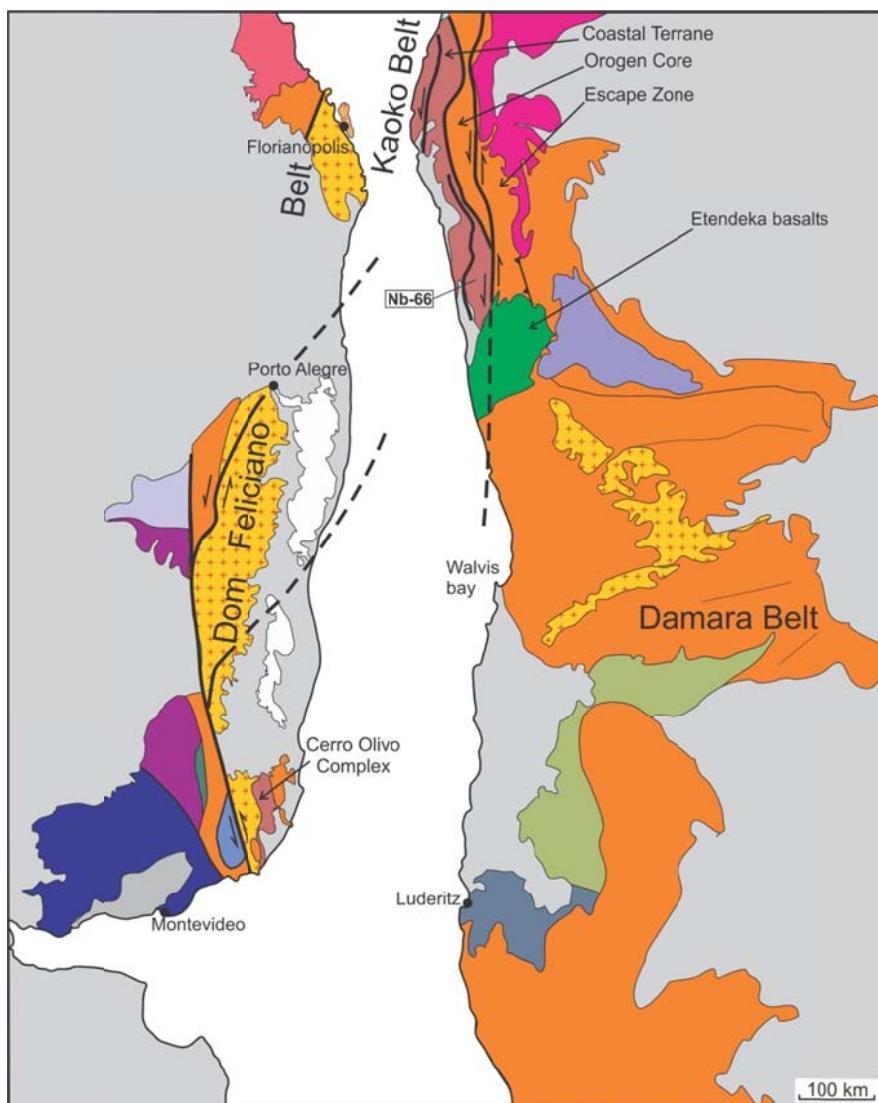

The Pavas Block is dominantly characterized by orthogneisses, amphibolites, migmatites, mafic-ultramafic igneous rocks and metasediments with ages between 3.0 and 2.7 Ga (Preciozzi et al., 1979; Hartmann et al., 2001; Gaucher et al., 2011a). Hartmann et al. (2001) separated the Pavas Block into the La China and Las Tetas complexes, which are constituted by amphibolite facies metaigneous and metasedimentary rocks, respectively. The Valentines-Rivera Granulitic Complex is made up of felsic and subordinated mafic granulites with a metasedimentary succession including BIFs, pyroxene fels, micaschists and marbles (Ellis, 1998). On the other hand, the Campanero Unit comprises orthogneisses, scapolite gneisses, amphibolites, micaschists, BIFs and migmatites (Oyhantçabal, 2005).

The Illescas granite represents a rapakivi igneous body that intruded the Valentines-Rivera Granulitic Complex at ca. 1.7 Ga (Campal and Schipilov, 1995). Likewise, Neoproterozoic granitoids are widespread and show ages with a range of ca. 650-570 Ma (Table 3.1).

3.3. Sample description

Eight samples were analysed using U-Pb LA-ICP-MS zircon geochronology, which was carried out at the Geochronological Research Centre of the University of São Paulo (Appendix 2, Appendix 3). Samples BUY-54-11, BUY-57-11, BUY-61-11, BUY-63-11, BUY-65-11 and BUY-77-11 were collected from the Nico Pérez Terrane. On the other hand, BUY-88-11 corresponds to the Cerro Colorado granite in the Piedra Alta Terrane, whereas Nb-66 was obtained from the basement of the Congo Craton in the Kaoko Belt (Fig. 3.2). Sample locations are presented in Appendix 2 and Figure 3.1.

Sample BUY-54-11 corresponds to a mafic granulite of the Valentines-Rivera Granulitic Complex (Fig. 3.3a; Appendix 2). It is mostly made up of plagioclase, orthopyroxene and clinopyroxene, which exhibit granoblastic texture. Garnet and, occasionally, hornblende are present as well. Zircons are prismatic and show homogeneous dark cores with homogeneous bright rims, although oscillatory zoning is sometimes observed in cores (Fig. 3.4).

Neoproterozoic		Archean-Proterozoic Basement	
		South America	Africa
Phanerozoic cover			
Metasediments		Campanero Unit	Epupa Complex
Granitoids		Piedra Alta Terrane	Kamanjab Inlier
Basement		Valentines-Rivera Cx	Sinclair & Rehoboth seq.
Sao Gabriel Block		Luis Alves Microplate	Namaqua Complex
Main shear zones		Pavas Block	

Sample BUY-57-11 comprises a tonalitic-dioritic orthogneiss of the Valentines-Rivera Granulitic Complex (Appendix 2). Zircons are anhedral and fragmented, and show cores that are either homogeneous or zoned. Homogeneous bright rims are typically observed (Fig. 3.4).

Likewise, samples BUY-61-11 and BUY-65-11 were collected from felsic orthogneisses of the Valentines-Rivera Granulitic Complex (Appendix 2). The orthogneisses are made up of granoblastic K-feldspar and plagioclase, and also exhibit monocrystalline quartz ribbons (Fig. 3.3b). In both samples,

Fig. 3.2: Map of Brasiliano-Pan-African orogens in South America and Africa, respectively (modified after Oyhantçabal et al., 2011b, and references therein). Location of sample Nb-66 is indicated as well.

zircons are dominantly prismatic, although rounded crystals are also observable. Both cores and rims dominantly exhibit oscillatory zoning (Fig. 3.4). In the case of BUY-61-11, homogenous dark cores and rims are occasionally observed, whereas homogeneous bright cores are sometimes present in zircons from BUY-65-11.

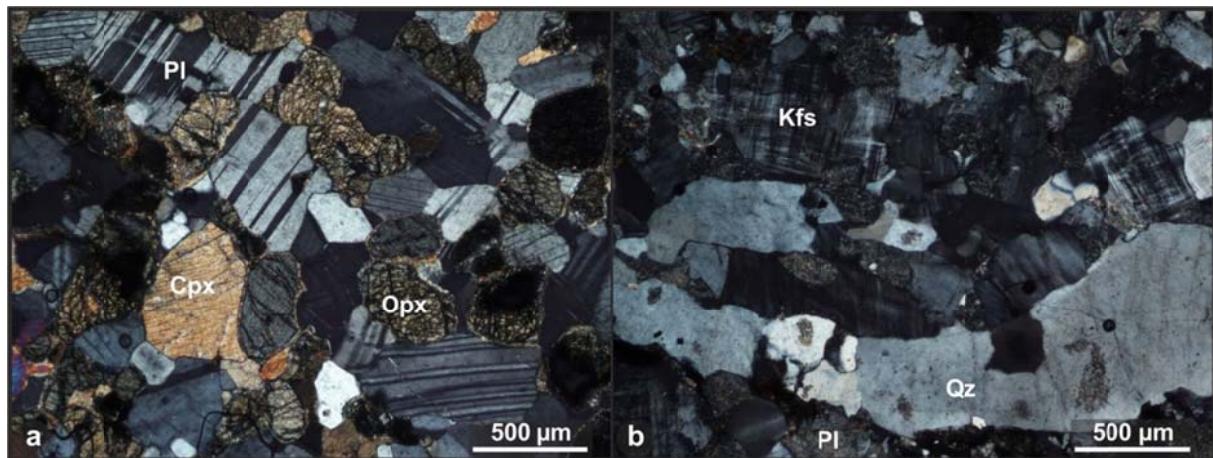

Fig. 3.3: Photomicrographs of studied units (cross-polarized light). a) Mafic granulites with granoblastic plagioclase, orthopyroxene and clinopyroxene. b) Felsic orthogneiss with quartz ribbon.

Sample BUY-63-11 corresponds to the Amarillo granite, which intrudes the basement of the Nico Pérez Terrane in the Isla Cristalina de Rivera (Appendix 2). This equigranular leucocratic granite is constituted by quartz, K-feldspar, plagioclase and scarce biotite. Zircons are prismatic and exhibit oscillatory zoning (Fig. 3.4). In some cases, cores with oscillatory or sector zoning are recognizable as well.

Sample BUY-77-11 was collected from the Zapicán intrusion, which comprises a porphyritic to equigranular tonalitic-granodioritic body (Appendix 2). It is made up of plagioclase, K-feldspar, quartz, hornblende and subordinated biotite. This intrusion is elongated in SW-NE direction and intrudes the orthogneisses of the Pavas Block near the Sierra de Sosa Shear Zone. Zircons are prismatic and exhibit oscillatory zoning (Fig. 3.4). Scarce zoned or homogenous cores are also present.

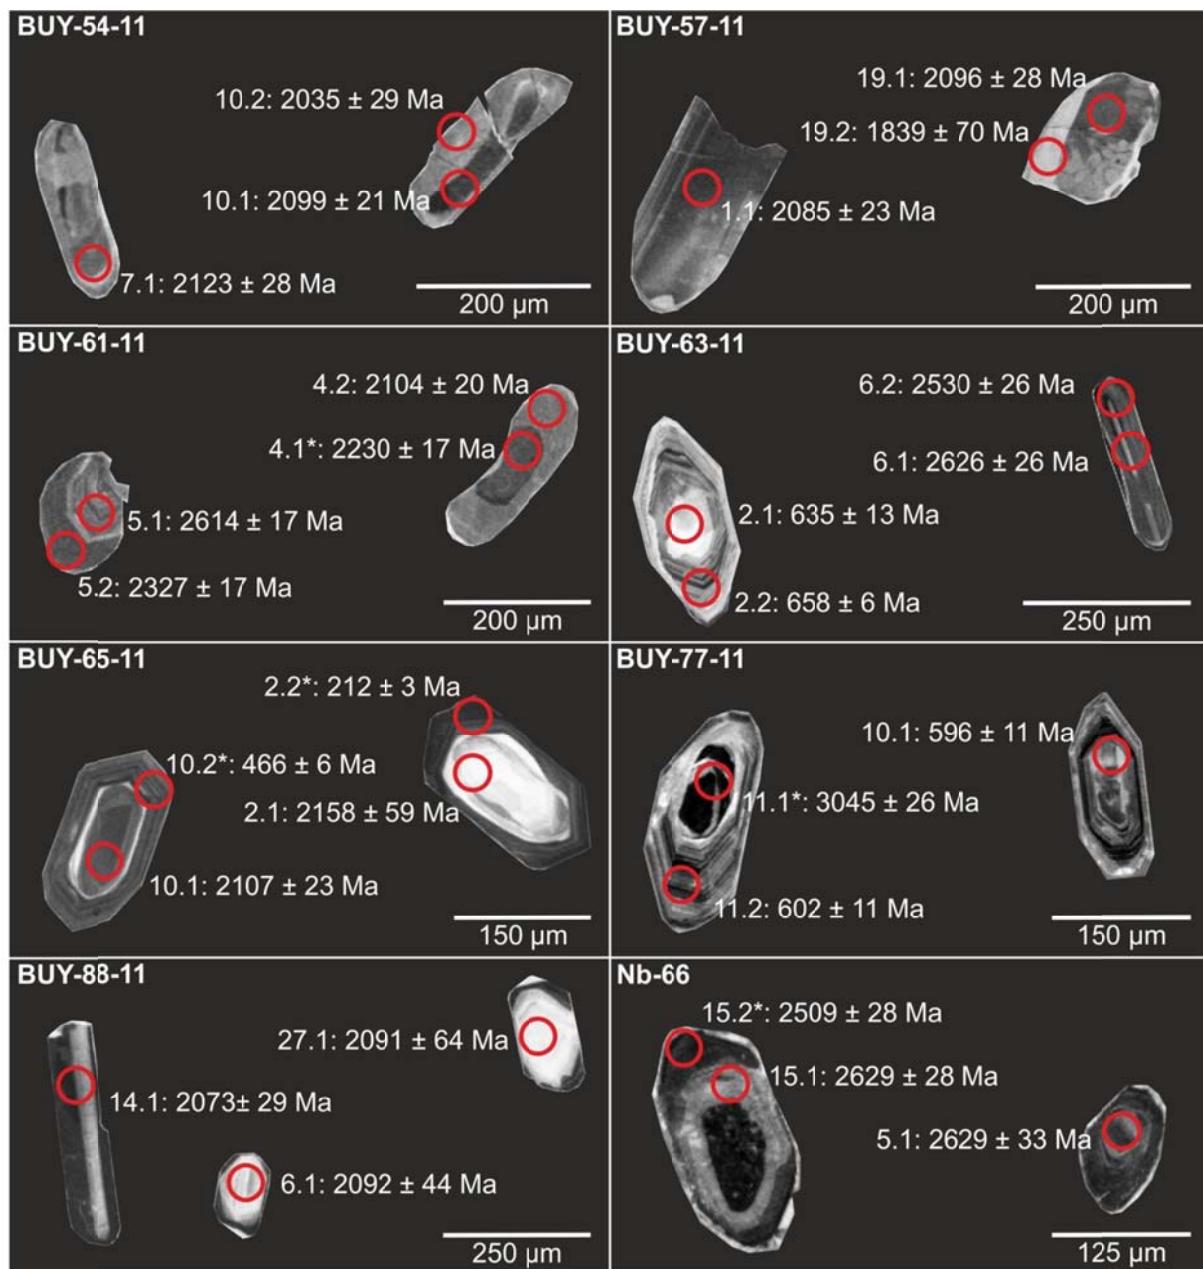

Fig. 3.4: Cathodoluminescence (CL) images of representative zircons. Individual U-Pb ages are shown. Asterisks indicate discordant ages.

One sample, BUY-88-11, was also collected from the Cerro Colorado granite, which comprises a porphyritic intrusion from the Piedra Alta Terrane (Appendix 2). It is made up of K-feldspar, quartz, plagioclase and biotite. Zircons are prismatic and exhibit either oscillatory or sector zoning (Fig. 3.4).

On the other hand, Nb-66 corresponds to an augen gneiss from the basement of the Congo Craton in the Kaoko Belt (Appendix 2). It is made up by quartz, plagioclase, muscovite and biotite.

Zircons are prismatic to round and exhibit oscillatory zoning, although homogeneous or zoned cores are occasionally observable (Fig. 3.4).

3.4. Results

3.4.1. U-Pb geochronology

Two weighted mean $^{207}\text{Pb}/^{206}\text{Pb}$ ages of 2095 ± 15 Ma (12 out of 26 points) and 2041 ± 24 Ma (4 out of 26 points) were obtained for BUY-54-11 and all concordant data spread between these two values (Fig. 3.5). Highly discordant data were discarded and most of the data show Pb loss. Although youngest ages are observed in rims, they are sometimes present in grain cores as well.

Despite most of the data show Pb loss, a concordia age of 2087.0 ± 7.3 Ma was calculated considering 4 out of 26 points for the sample BUY-57-11 (Fig. 3.5). Additionally, a weighted mean $^{207}\text{Pb}/^{206}\text{Pb}$ age of 1857 ± 45 Ma (5 out of 26 points) was determined for the rims.

BUY-61-11 presents a weighted mean $^{207}\text{Pb}/^{206}\text{Pb}$ age of 2069 ± 16 Ma (7 out of 25 points, highly discordant data discarded), while BUY-65-11 shows a concordant age of 2106 ± 21 Ma (3 out of 26 points, discordant data discarded). Both samples present Archean inheritance (Fig. 3.5), being Paleoproterozoic and Archean ages recorded in cores and rims.

In the case of BUY-63-11, a concordia age of 596.0 ± 2.3 Ma was calculated considering 12 out of 26 points (discordant data discarded). Nevertheless, zircons with Archean and Paleoproterozoic ages were also identified (Fig. 3.5). Likewise, a concordant age of 610.4 ± 2.5 Ma was calculated for the Zapicán intrusion (21 out of 26 points), which occasionally shows Paleoproterozoic and Archean ages in cores (Fig. 3.5).

Zircons from the sample BUY-88-11 show a concordia age of 2078.3 ± 4.7 Ma, which was obtained considering 15 out of 39 points (Fig. 3.5; discordant data and older Paleoproterozoic grains discarded). For the sample Nb-66, a concordant age of 2600.2 ± 14.0 Ma was obtained (10 out of 26 points, discordant data discarded). However, one discordant grain may indicate Mesoarchean inheritance (Fig. 3.5).

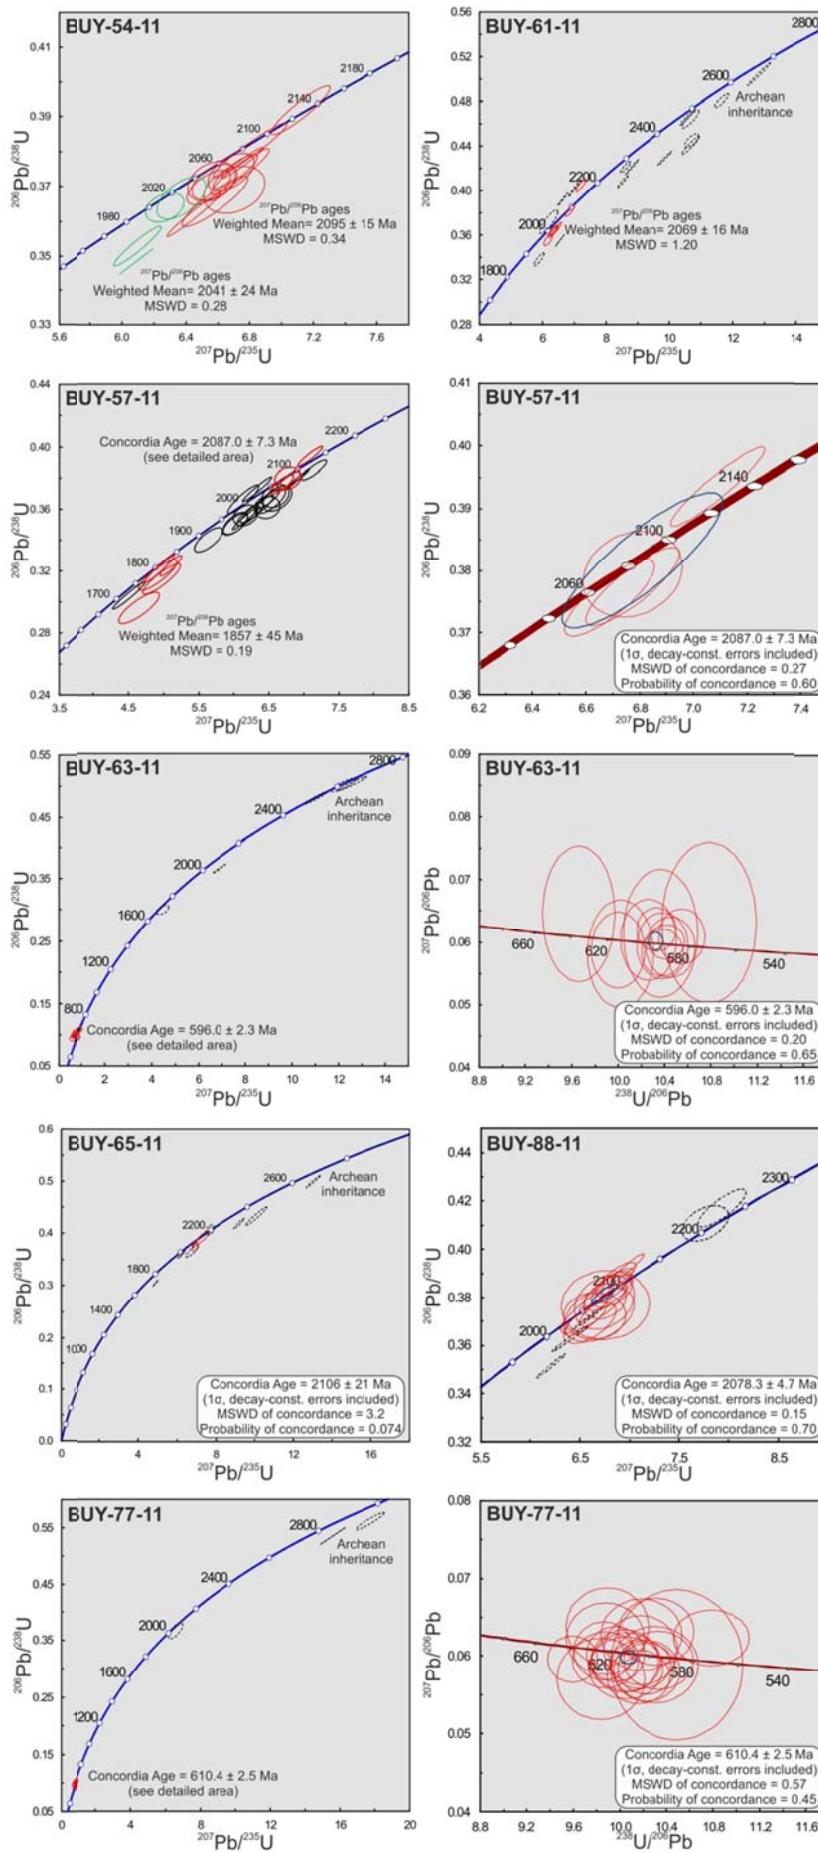

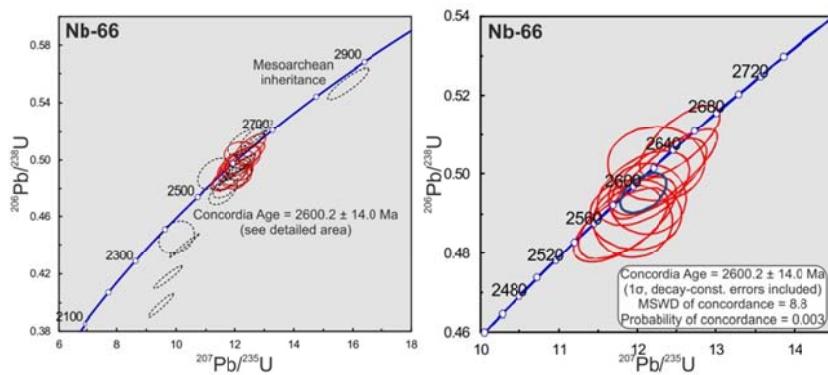

Fig. 3.5: U-Pb diagrams. Red and green ellipses indicate data used for age calculations, whereas black ellipses represent data that were not considered. Blue ellipses show concordia ages. Errors depicted at the 2 σ level.

3.4.2. Hf isotopes

All samples from the basement of the Nico Pérez Terrane (BUY-54-11, BUY-57-11, BUY-61-11 and BUY-65-11) show T_{DM} model ages from 2.62 to 3.81 Ga with associated negative to positive ϵ_{Hf} values between -25.85 and +0.23 (Fig. 3.6; Appendix 4). Likewise, Neoproterozoic intrusions (BUY-63-11 and BUY-77-11) present Archean model ages (2.53-3.56 Ga) and negative ϵ_{Hf} values between -33.5 and -15.5 as well (Fig. 3.6; Appendix 4). These results represent the first Hf data from the Nico Pérez Terrane.

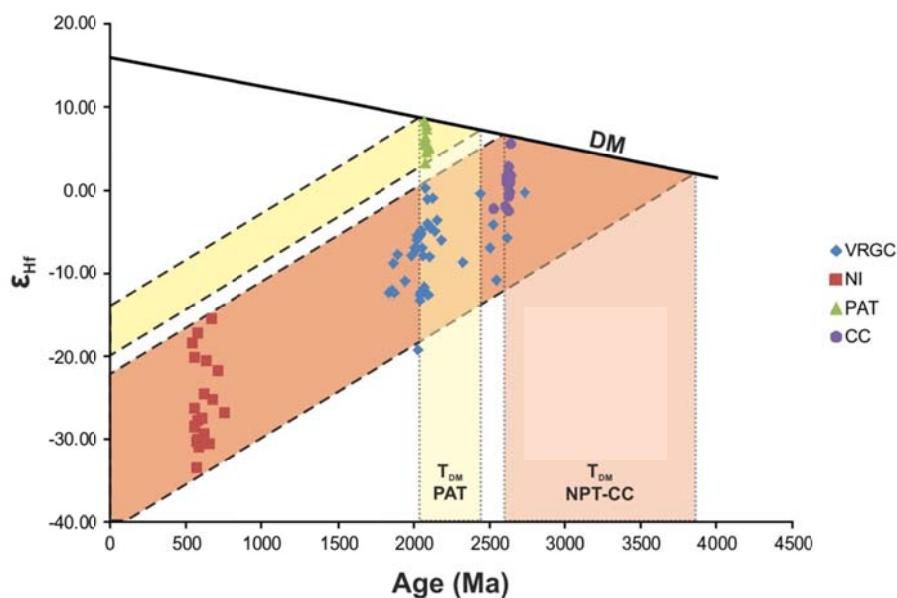

Fig. 3.6: ϵ_{Hf} vs. zircon age. Model ages (T_{DM}) are also shown. VRGC: Valentines-Rivera Granulitic Complex, NI: Neoproterozoic intrusions of the Nico Pérez Terrane (NPT), PAT: Piedra Alta Terrane, CC: Congo Craton.

In the case of the Congo Craton (sample Nb-66), zircons yield T_{DM} values between 2.71 and 3.22 Ga, and ϵ_{Hf} values between -2.62 and +5.59 (Fig. 3.6; Appendix 4). In contrast, model ages from

2.10 to 2.43 Ga and positive ϵ_{Hf} values (+3.22 to +8.30) were obtained for the Cerro Colorado granite zircons (sample BUY-88-11, Fig. 3.6; Appendix 4), which constitute the first reported Hf data for the Piedra Alta Terrane.

3.5. Discussion

3.5.1. Paleo- and Neoproterozoic reworking of Archean crust

Complex textures and U-Pb zircon ages in high-grade metamorphic rocks can result from multiple episodes of recrystallization, presence of a melt, solid-state processes and fluids, among others (Corfu et al., 2003; Kröner et al., 2014; Zhao et al., 2015). In the case of the Valentines-Rivera Granulitic Complex, Santos et al. (2003) and Oyhantçabal et al. (2012) reported ages of magmatism of ca. 2.18-2.11 Ga (Table 3.1). However, ages between 2.10 and 2.05 Ga were alternatively interpreted as the result of high-grade metamorphism (Santos et al., 2003) or multistage magmatism (Oyhantçabal et al., 2012). Similar U-Pb zircon ages were obtained in this work, further supporting Paleoproterozoic ages for the Valentines-Rivera Granulitic Complex, although Archean inheritance is also recorded.

Samples BUY-61-11 and BUY-65-11 show a dominance of prismatic zircon crystals with oscillatory zoning and Th/U > 0.1 (Fig. 4, 5; Appendix 3), allowing to interpret the weighted mean $^{207}\text{Pb}/^{206}\text{Pb}$ age of 2069 ± 16 Ma and the concordant age of 2106 ± 21 Ma, respectively, as magmatic ages (Hoskin and Schaltegger, 2003, and references therein). On the other hand, ages recorded in mafic granulites (weighted mean $^{207}\text{Pb}/^{206}\text{Pb}$ ages of 2095 ± 15 Ma and 2041 ± 24 Ma, BUY-54-11) and mesocratic gneisses (concordia age of 2087.0 ± 7.3 Ma, BUY-57-11) show more complex textures, including homogeneous cores rims, evidences of dissolution-precipitation and anhedral crystals with rounded boundaries, particularly in the case of BUY-57-11. These textures could indicate that these zircons record high-grade metamorphism (Corfu et al., 2003; Zhao et al., 2015), although the presence of prismatic zircon crystals with oscillatory zoning and Th/U > 0.1 may indicate

a magmatic origin (Hoskin and Schaltegger, 2003, and references therein). However, Th/U > 0.1 were also reported for zircons in high-grade metamorphic rocks (Santosh et al., 2007; Zhang et al., 2016).

Hence, integration of all geochronological data from the Valentines-Rivera Granulitic Complex reveals multistage magmatism at ca. 2.18-2.10 Ga, as previously indicated by Oyhantçabal et al. (2012). Despite not being conclusive, the event recorded at ca. 2.10-2.02 Ga might be related to granulite facies metamorphism and associated melt presence, accounting for coeval metamorphic and magmatic ages reported by Santos et al. (2003) and Oyhantçabal et al. (2012), respectively. Several authors indicated the role of anatexis during high-grade metamorphism, which is recorded by U-Pb zircon ages (Roberts and Finger, 1997; Schaltegger et al., 1999; Vavra et al., 1999; Rubatto et al., 2001; Hermann and Rubatto, 2003), thus explaining the observed ages. However, U-Pb zircon ages may not necessarily record the age when peak metamorphic conditions were attained but the timing of certain metamorphic reactions that occur due to changes in environmental conditions during high-grade metamorphism (Fraser et al., 1997; Roberts and Finger, 1997; Whitehouse and Platt, 2003; Harley et al., 2007). On the other hand, the high-grade event seems to be also recorded by titanite and monazite ages at ca. 2.1-2.0 Ga (Table 3.1; Oyhantçabal et al., 2012).

In a similar way, concordant ages of 596.0 ± 2.3 Ma (BUY-63-11) and 610.4 ± 2.5 Ma (BUY-77-11) present further evidences of Neoproterozoic magmatism, which is associated with the Dom Feliciano Belt. These results agree with previous ages obtained in the Puntas del Santa Lucía monzogranite (633 ± 8 Ma, U-Pb SHRIMP zircon; Hartmann et al., 2002), the Puntas de Mataojo granodiorite (627 ± 23 Ma, U-Pb SHRIMP zircon, Oyhantçabal et al., 2009a), the Lavaderos granite (610 ± 3 Ma, U-Pb LA-ICP-MS zircon, Gaucher et al., 2014a), the Arroyo Mangacha granite (583 ± 7 Ma, U-Pb SIMS zircon, Gaucher et al., 2008a), the Sobresaliente granite (585 ± 2.5 Ma, U-Pb SHRIMP zircon, Oyhantçabal et al., 2012), the Las Flores granite (586 ± 2.7 Ma, U-Pb SHRIMP zircon, Oyhantçabal et al., 2012) and the Pan de Azucar pluton (579 ± 1.5 Ma, Ar/Ar hornblende, Oyhantçabal et al., 2007; 581.8 ± 3.4 Ma, 574.5 ± 8.1 Ma, U-Pb SHRIMP zircon, Rapalini et al., 2015) (Fig. 3.1).

On the other hand, the Valentines-Rivera Granulitic Complex and the Neoproterozoic intrusions yield negative ϵ_{Hf} values and Archean model ages (Appendix 4; Fig. 3.6). Similar Archean Sm-Nd model ages were also reported for the Nico Pérez Terrane (Oyhantçabal et al., 2011a). Furthermore, inheritance of Archean zircons is recorded in both the Valentines-Rivera Granulitic Complex and Neoproterozoic intrusions (Fig. 3.5; Santos et al., 2003; Oyhantçabal et al., 2009a), whereas Archean crystallization ages were reported for the La China Complex (Hartmann et al., 2001; Gaucher et al., 2011a).

Despite of the recognition of two distinct Paleo- and Neoproterozoic magmatic events, data reveal that the crust of the Nico Pérez Terrane was mostly generated during the Archean (Fig. 3.6). Likewise, T_{DM} distribution reveals Archean episodic crustal growth with main peaks of crustal generation during the Paleo- and Mesoarchean (Fig. 3.7; Nebel-Jacobsen et al., 2010), indicating that the Nico Pérez Terrane underwent mostly crustal reworking during the Proterozoic. Complete resetting of the U-Pb ages implies total dissolution and reprecipitation of zircons (Mezger and Krogstad, 1997), which is mostly controlled by temperature and composition (Boehnke et al., 2013). Even though the Nico Pérez Terrane underwent high-grade metamorphism during the Paleoproterozoic (Oyhantçabal et al., 2011a, 2012), Paleoproterozoic protoliths of the Valentines-Rivera Granulitic Complex record inheritance. Consequently, relative saturation of zircon in the Proterozoic melts can be inferred (Watson and Harrison, 1983; Miller et al., 2003).

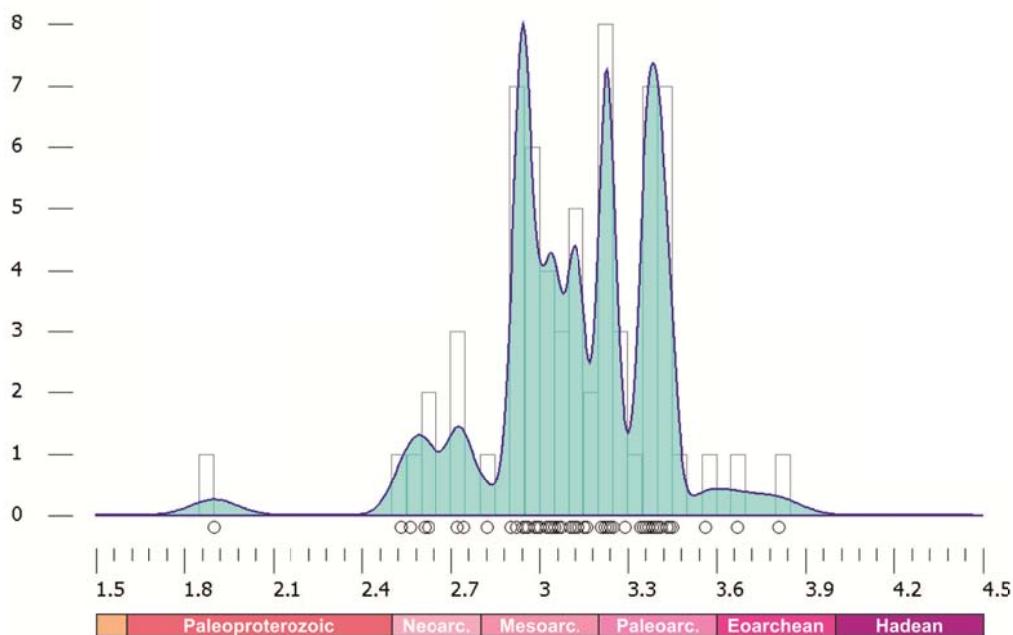

Fig. 3.7: Kernel density estimation curve and histogram of Hf model ages (Ga) of the Nico Pérez Terrane (n=66) plotted using DensityPlotter (Vermeesch, 2012).

3.5.2. Main tectonic events

Ages of orthogneisses of the La China Complex (Hartmann et al., 2001; Gaucher et al., 2011a) together with inherited zircons and Hf model ages in Paleo- and Neoproterozoic units point to Archean episodic crustal growth of the Nico Pérez Terrane. Archean crust was subsequently reworked by Paleoproterozoic multistage magmatism recorded in the Valentines-Rivera Granulitic Complex at 2.18-2.10 Ga, as previously reported by Oyhantçabal et al. (2012). Based on geochemical data (Ellis, 1998; Oyhantçabal et al., 2012), a magmatic arc setting was suggested for this magmatism. This could be further supported by the presence of inheritance-rich magmas and crustal reworking revealed by zircon data, which are frequently related to crustal thickening processes (Watson and Harrison, 1983; Miller et al., 2003). High-grade metamorphism and associated crustal anatexis are subsequently recorded at ca. 2.10-2.02 Ga. Oyhantçabal et al. (2012) reported Th-U-Pb CHIME-EPMA monazite ages of 1.98-1.94 Ga, which were interpreted as evidences of amphibolite facies metamorphism, whereas zircon overgrowths record a weighted mean $^{207}\text{Pb}/^{206}\text{Pb}$ age of 1857 \pm 45 Ma in sample BUY-57-11. Although not conclusive, retrograde metamorphism could be thus constrained at ca. 1.98-1.80 Ga, predating the late Paleoproterozoic magmatism recorded at 1.7 Ga

in the Illescas rapakivi granite and the calc-alkaline Campanero Unit (Bossi and Campal, 1992; Oyhantçabal, 2005; Mallmann et al., 2007).

Mesoproterozoic events are also present but so far restricted to metavolcano-sedimentary units such as the Parque UTE and Mina Verdún groups (Poiré et al., 2003; Chiglino et al., 2008). Metavolcanic intercalations yield U-Pb zircon ages of ca. 1.4-1.5 Ga (Oyhantçabal et al., 2005; Gaucher et al., 2011a).

Widespread Neoproterozoic magmatism is recorded between ca. 650-570 Ma, which is related to subduction and collisional processes in the Dom Feliciano Belt (Oyhantçabal et al., 2007, 2009a, 2011a). The collision between the Río de la Plata Craton and the Nico Pérez Terrane is constrained at 630-625 Ma, based on geochronological data of the Sarandí del Yí Shear Zone (Chapter 6).

3.5.3. The Nico Pérez Terrane and its crustal affinity

Despite being traditionally considered as part of the Río de la Plata Craton (Bossi and Campal, 1992; Mallmann et al., 2007; Gaucher et al., 2011a; Frimmel et al., 2011), recent contributions indicated the allochthony of the Nico Pérez Terrane and its docking to the Río de la Plata Craton during the Neoproterozoic (Oyhantçabal et al., 2011a; Rapela et al., 2011). The stabilization of the Río de la Plata was attained during the late Paleoproterozoic (Cingolani, 2011; Oyhantçabal et al., 2011a), whereas the Nico Pérez Terrane shows a much more complex evolution till the Neoproterozoic.

The main characteristic of cratons is their stability through time, which basically implies lack of large-scale pervasive deformation and magmatism (Bates and Jackson, 1980; Pollack, 1986). As craton stability is fundamentally related to the presence of a thick lithospheric mantle (Black and Liégeois, 1993), destabilization is most likely to occur during collisional or post-collisional events (Liégeois et al., 2013). Based on K-Ar muscovite ages, Oyhantçabal et al. (2011a) revealed thermal overprinting of the Nico Pérez Terrane during the Brasiliano–Pan-African Orogeny, which is further

supported by the existence of several Neoproterozoic intrusions (Table 3.1). Coeval deformation and metamorphism reworking basement units were also identified (Rossini and Legrand, 2003; Sánchez Bettucci et al., 2003; Mallmann et al., 2007; Oyhantçabal et al., 2009a, 2012). Hence, the Nico Pérez Terrane achieved stability after cessation of the Brasiliano–Pan-African Orogeny, thus contrasting with Paleoproterozoic cratonisation achieved by the Río de la Plata Craton.

Isotopic data from the Paleoproterozoic Cerro Colorado shows dominant Paleoproterozoic Hf model ages (Fig. 3.5, 3.6; Appendix 4), which are similar to Hf and Sm-Nd model ages from other units of the Río de la Plata Craton (Cingolani, 2011; Oyhantçabal et al., 2011a), and positive ε_{Hf} values. In contrast, the Nico Pérez Terrane shows main crustal growth during the Paleo- and Mesoarchean (Fig. 3.6, 3.7) and only underwent crustal reworking during the Paleo- and Neoproterozoic. Post-collisional underformed intrusions of the Piedra Alta Terrane, such as the Cerro Colorado or Isla Mala granites (Hartmann et al., 2000a), are contemporaneous with metamorphosed intrusions of the Nico Pérez Terrane, providing further evidences of a different evolution of both blocks. On the other hand, Hf model ages from the Nico Pérez Terrane match Hf model ages from Nb-66 from the Congo Craton (Fig. 3.6), and both areas also show Archean basement inliers (Hartmann et al., 2001; McCourt et al., 2013), thus supporting derivation of the Nico Pérez Terrane from the Congo Craton. Moreover, the southwestern Congo Craton presents Paleoproterozoic gneisses of ca. 2.2-2.0 and 1.8-1.7 Ga as well as 1.5-1.4 Ga old igneous rocks in the Kunene Complex (Seth et al., 1998; Kröner et al., 2004; Drüppel et al., 2007; Luft Jr et al., 2011; Ernst et al., 2013; McCourt et al., 2013; Kröner et al., 2015), which in many cases reworked Archean crust (Seth et al., 1998; McCourt et al., 2013). These units would be thus comparable to the gneisses of the Valentines-Rivera Complex and Campanero Unit and Mesoproterozoic metavolcanic rocks of the Nico Pérez Terrane, respectively. These evidences further support previous correlations between the Angolan Shield and the Nico Pérez Terrane (Rapela et al., 2011), as the former comprise the southwestern portion of the Congo Craton (e.g., McCourt et al., 2013).

In contrast, the westernmost Kalahari Craton shows dominance of igneous and metamorphic 1.2-1.0 Ga old rocks from the Namaqua-Natal Belt (Eglington, 2006; Jacobs et al., 2008; Hofmann et al., 2014), which are derived from older Meso- and Paleoproterozoic crust as indicated by Sm-Nd and Hf model ages (e.g., Pettersson et al., 2009; Cornell et al., 2012; Colliston et al., 2015). Even though some Paleoproterozoic basement inliers are present as well, they yield dominant Paleoproterozoic Sm-Nd T_{DM} model ages (Pettersson et al., 2009). Likewise, the Paleoproterozoic Rehoboth Block is located to the north of the western part of the Namaqua Belt and comprises intrusions of 1.7-1.8 Ga (Ziegler and Stoessel, 1991, 1993; Becker et al., 1996; van Schijndel et al., 2014). These intrusions yield Paleoproterozoic Sm-Nd and Hf model ages (Ziegler and Stoessel, 1991; Becker et al., 2000, 2004; van Schijndel et al., 2014). The Nico Pérez Terrane lacks in Namaqua-age rocks and is clearly dominated by Archean Hf model ages, thus allowing to rule out pre-Gondwana connections with the Kalahari Craton.

3.6. Conclusions

New U-Pb and Hf data allow to characterize the Nico Pérez Terrane as a crustal block that originated mostly from Archean episodic crustal growth and underwent crustal reworking during the Proterozoic. In contrast, the Piedra Alta Terrane records Paleoproterozoic crustal growth, indicating that the Nico Pérez Terrane was allochthonous regarding the Río de la Plata Craton. Based on similarities in terms of tectonostratigraphy, the Nico Pérez Terrane would be thus equivalent to the southwestern Congo Craton.

The Archean crust of the Nico Pérez Terrane underwent multistage magmatism at ca. 2.2-2.1 Ga. Afterwards, a high-grade metamorphic event took place at ca. 2.1-2.0 Ga, prior to magmatism at 1.7 Ga. Metavolcano-sedimentary units indicate the existence of Mesoproterozoic events that could be related to the coeval magmatism of the Kunene Complex. After Cryogenian rifting from the Congo Craton, the Nico Pérez was accreted to the eastern Río de la Plata Craton and underwent further crustal reworking during the evolution of the Dom Feliciano Belt.

-CHAPTER 4-

Provenance of metasedimentary rocks of the southwestern Dom Feliciano Belt

4.1. Introduction

Provenance analyses based on detrital zircon geochronology constitute key elements to understand large-scale tectonic processes (Fedó et al., 2003; Gehrels, 2014). Based on the fingerprint of zircon age populations, characterization of the source rock and maximum sedimentation ages are assessable. Consequently, the history of uplift and erosion can be unravelled and even terrane boundaries can be identified (Fedó et al., 2003; Gehrels, 2014; Lease et al., 2007). Whole-rock geochemistry as well as detrital zircon ages has been applied in metasediments of the Dom Feliciano Belt to support different tectonic models (Basei et al., 2005, 2008, 2011b; Gaucher et al., 2008a; Blanco et al., 2009; Zimmerman, 2011). However, data are still scarce, being the provenance and the tectonic setting of the metasedimentary cover a matter of ongoing debate.

As previously outlined (Section 1.4.1), the Dom Feliciano Belt comprises three tectonic domains, namely the foreland basin, the schist belt and the granite belt, which are developed from west to east (Basei et al., 2000). Nevertheless, the Dom Feliciano Belt in Uruguay shows a singularity, as a second supracrustal assemblage is present on the eastern side of the granite belt. The metasedimentary cover of the southern Dom Feliciano Belt can be thus divided into a western and an eastern domain (Table 4.1).

4.2. Geological setting

Several authors have studied the metasedimentary rocks from the western domain of the Dom Feliciano belt in Uruguay in the last years (e.g., Basei et al., 2008; Gaucher, 2000; Gaucher et al., 2003, 2008a; Frei et al., 2013; Pecoits et al., 2008; Aubet et al., 2014) and different lithostratigraphic units have been proposed for this metasedimentary cover. However, due to non-optimal field exposures, complex deformation structures and scarcity of detailed regional geological maps, there is still no consensus about distribution, correlations and age of most of them (Sánchez Bettucci et al.,

2010; Aubet et al., 2014). Due to this controversy, original definitions of sections and formations with geographic continuity are preferred in this contribution over lithostratigraphic units of higher hierarchy, such as the Arroyo del Soldado Group (Gaucher, 2000; Blanco et al., 2009) or the Maldonado Group (Pecoits et al., 2005, 2011). A synthesis of available information about these units is presented in Table 4.1.

In the western Dom Feliciano Belt, the Las Tetas Complex seems to be the only metasedimentary unit that belongs to the pre-Neoproterozoic basement (Hartmann et al., 2001). The Las Tetas Complex is an association of quartzites, micaschists, conglomerates and marbles, which are strongly deformed and affected by amphibolite facies metamorphism as evidenced by parageneses with garnet and sillimanite (Oyhantçabal and Vaz, 1990) and garnet and staurolite (Hartmann et al., 2001). It probably represents remnants of the oldest metasedimentary sequence due to its metamorphism and the absence of detrital zircons younger than ca. 2.7 Ga (Hartmann et al., 2001).

The schist belt in Uruguay includes Neoproterozoic units such as the Zanja del Tigre Complex and the Lavalleja Group (Basei et al., 2000, 2008), which exhibit lower amphibolite to greenschist facies metamorphism. Micaschists, phyllites, marbles and metabasalts are the most frequent lithologies, although criteria for unequivocal distinguishing between these two units are still lacking (Spoturno et al., 2012, and references therein). Some units such as the Yerbal (Gaucher et al., 2008a) and Minas de Corrales formations (Arrighetti et al., 1981; Preciozzi et al., 1985) were also considered by some authors as part of the schist belt (Sánchez Bettucci et al., 2010; Aubet et al., 2014).

Likewise, the metasedimentary association of the western Dom Feliciano Belt also includes several Ediacaran to Cambrian units, which are characterized by better-preserved sedimentary structures and subgreenschist metamorphic facies conditions. This metasedimentary cover comprises the Barriga Negra (Midot, 1984), Piedras de Afilar (Jones, 1956), Playa Hermosa (Masquelin and Sánchez Bettucci, 1993), Arroyo de la Pedrera (Montaña and Sprechmann, 1993) and Las Ventanas formations (Midot, 1984). Available information for these units is summarized in Table 4.1 and their location is presented in Figure 4.1.

Unit	Lithology	Age (fossil content)	Youngest detrital zircon age (Ma, $\pm 1\sigma$)	Other age constraints (Ma, $\pm 1\sigma$)
Western Dom Feliciano Belt				
Arroyo de la Pedrera Formation	Arenites, mudstones, stromatolitic carbonates; Montaña and Sprechmann (1993)	Ediacaran	665 \pm 5; Blanco et al. (2009)	
Barriga Negra Formation	Conglomerates, sandstones, pelites; Midot (1984)	Ediacaran	564 \pm 9; Blanco et al. (2009)	
Piedras de Afilar Formation	Arenites, pelites, carbonates; Bossi (1966) , Spoturno et al. (2004) , Pecoits et al. (2008)	Ediacaran	1006 \pm 31; Gaucher et al. (2008a)	
Las Ventanas Formation	Conglomerates, sandstones, pelites; Midot (1984) , Masquelin and Sánchez Bettucci (1993) , Pecoits et al. (2005, 2008)	Ediacaran		Volcaniclastic rocks 573 \pm 11; Oyhantçabal et al. (2009a)
Playa Hermosa Formation	Diamictites, rhythmites; Elizalde (1979) , Preciozzi et al. (1989) , Masquelin and Sánchez Bettucci (1993) , Pazos et al. (2011)	Ediacaran	594 \pm 8; Rapalini et al. (2015)	
Minas de Corrales Formation	Pelites, arenites, acid volcaniclastic rocks, dolostones, conglomerates; Arrighetti et al. (1981) , Preciozzi et al. (1985)	Ediacaran	664 \pm 8; this work	
Yerbal Formation	Sandstones, siltstones, cherts, BIFs; Gaucher et al. (2004)	Ediacaran	663 \pm 16; Blanco et al. (2009)	K-Ar diagenetic illite 600-570; Aubet et al. (2012)
Polanco Formation	Limestones, dolostones; Gaucher (2000) , Gaucher et al. (2004) , Aubet et al. (2012)			Sr/Sr and $\delta^{13}\text{C}$ Ediacaran; Aubet et al. (2012)
Lavalleja Group	Greenschists, marbles, dolomitic slates, phyllites; Bossi (1966) , Sánchez Bettucci (1998)		1080 \pm 23; this work 715 \pm 26; Basei et al. (2008)	
Zanja del Tigre Complex	Micaschists, marbles, felsic volcanic rocks; Sánchez Bettucci (1998)		606 \pm 6; this work 1707 \pm 68; Basei et al. (2008)	
Las Tetas Complex	Conglomerates, quartzites, micaschists, marbles; Hartmann et al. (2001)		2717 \pm 24; Hartmann et al. (2001) 2736 \pm 35; this work	
Eastern Dom Feliciano Belt				
San Carlos Formation	Conglomerates, sandstones, pelites, felsic lavas, pyroclastic rocks; Masquelin (1990) , Pecoits et al. (2008) , Oyhantcabal et al. (2013)		535 \pm 7; Gaucher et al. (2014b)	
Cerro Aguirre Formation	Felsic tuffs, ignimbrites, lavas, sandstones, pelites; Masquelin and Tabó (1988) , Campal and Schipilov (2005)			Volcaniclastic rocks 572 \pm 11; Hartmann et al. (2002)
Rocha Formation	Sandstones, pelites; Sánchez Bettucci and Burgeño (1993)		596 \pm 40; Basei et al. (2005)	

Table 4.1: Summary of available age constraints for metasedimentary sequences (simplified after Oyhantçabal et al., submitted).

On the other hand, the eastern metasedimentary belt comprises the Rocha, Cerros de Aguirre and San Carlos formations (Table 4.1, Fig. 4.1). The Rocha Formation is a folded turbidite sequence, including essentially slates and metaarenites, which were metamorphosed under greenschist facies conditions (Sánchez Bettucci and Burgueño, 1993). Age constraints on sedimentation of the Rocha Formation are the youngest detrital zircon (596 ± 40 Ma, U-Pb SHRIMP zircon, Basei et al., 2005) and the age of the Santa Teresa granite (543 ± 5 Ma U-Pb LA-ICP-MS zircon, Basei et al., 2013a), which intrudes these metasediments. The Cerros de Aguirre Formation consists of felsic volcaniclastic rocks, felsic lavas, sandstones and pelites (Masquelin and Tabó, 1988; Campal and Schipilov, 2005). Hartmann et al. (2002) dated a dacitic pyroclastic rock of this formation at 572 ± 8 Ma (U-Pb SHRIMP zircon). The San Carlos Formation, in turn, comprises fluvial-lacustrine conglomerates, sandstones, pelites and felsic volcanics and volcaniclastic rocks (Masquelin, 1990; Pecoits et al., 2008; Oyhantçabal et al., 2013) and is probably Cambrian, as the youngest detrital zircon presents an age of 535 ± 13 Ma (U-Pb LA-ICP-MS zircon, Gaucher et al., 2014b).

4.3. Sample description

Nine samples from metasedimentary units of the western Dom Feliciano Belt were analysed using U-Pb detrital zircon geochronology. Sample locations are presented in Appendix 2 and Figure 4.1. Two samples were analysed using U-Pb LA-ICP-MS zircon geochronology (BUY-55-11, BUY-76-11), which was carried out at the Geochronological Research Centre of the University of São Paulo (Appendix 2, Appendix 3), whereas seven samples were analysed using U-Pb LA-ICP-MS zircon geochronology at the Central Analytical Facility of the Stellenbosch University (UY-4-13, UY-6-13, UY-8-13, UY-9-13, UY-16-13, UY-22-13, UY-24-13).

Sample BUY-55-11 is a metapelite of the Minas de Corrales Formation. Zircons are 50-150 μm long and present dominance of prismatic crystal faces. Oscillatory zoning is frequent, whereas sector zoning and homogeneous dark rims are sometimes present (Fig. 4.2).

Sample BUY-76-11 is a deformed metaconglomerate from the Las Tetas Complex, which is made up of quartz, muscovite and scarce fuchsite. Zircons comprise typically 100-250 µm long anhedral fragments with bright luminescence (Fig. 4.2). Oscillatory zoning, though not very frequent, is also present in prismatic crystals.

Sample UY-4-13 corresponds to a metapelite of the Lavalleja Group. Prismatic to ovoid 50-150 µm long zircons are the most frequent and present oscillatory zoning (Fig. 4.2).

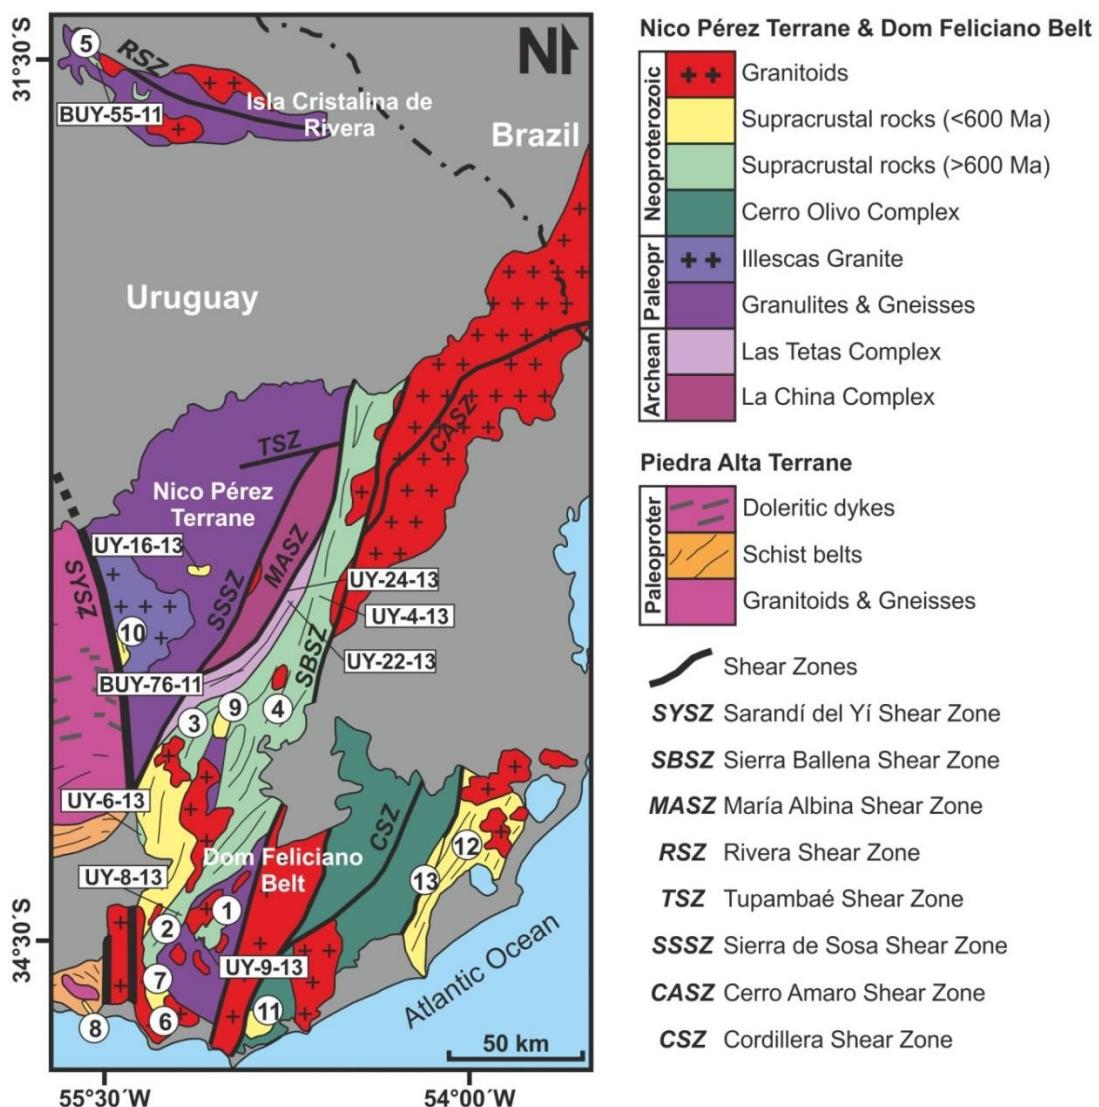

Fig. 4.1: Geological map of the Nico Pérez Terrane and adjacent blocks (modified after Oyhantçabal et al., 2011a, and references therein). Sample locations and metasedimentary sequences (1: Zanja del Tigre Complex, 2: Lavalleja Group, 3: Polanco Formation, 4: Yerbal Formation, 5: Minas de Corrales Formation, 6: Playa Hermosa Formation, 7: Las Ventanas Formation, 8: Piedras de Afilar Formation, 9: Barriga Negra Formation, 10: Arroyo de la Pedrera Formation, 11: San Carlos Formation, 12: Rocha Formation, 13: Cerros de Aguirre Formation) are shown.

Sample UY-6-13 corresponds to a garnet-bearing micaschist from an outcrop located ca. 20 km north of the city of Minas. This outcrop area is assumed to correspond to the Zanja del Tigre Complex. Zircons are 50-100 μm long and prismatic, and exhibit oscillatory and subordinated sector zoning (Fig. 4.2).

Sample UY-8-13 is a calcareous schist from the locus typicus of the Lavalleja Group. Prismatic 50-150 μm long zircons with oscillatory zoning dominate (Fig. 4.2). Ovoid, round and fragmented crystals are also present.

Sample UY-9-13 is a fine-grained quartz-sericite schist sampled in the locus typicus of the Zanja del Tigre Complex. Zircons are 50-200 μm long and prismatic crystals with oscillatory zoning are the most frequent, though anhedral crystal fragments and sector zoning are also observable (Fig. 4.2).

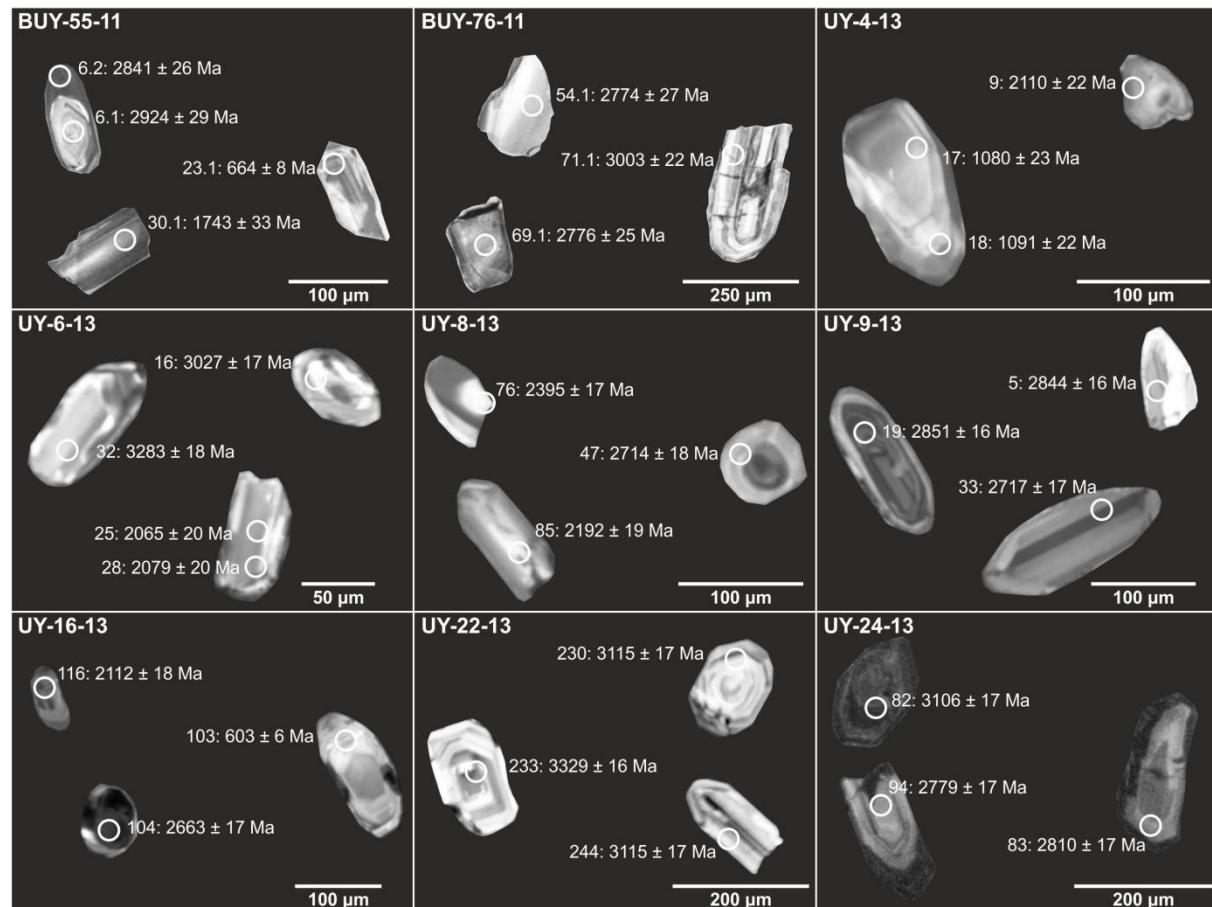

Fig. 4.2: Cathodoluminescence (CL) images of representative zircons. Individual U-Pb ages are shown. Asterisks indicates discordant ages.

Sample UY-16-13 corresponds to a metasandstone from one of the remnants of the foreland basin on the Nico Pérez Terrane. Zircons are up to 200 µm long and typically prismatic, whereas sector zoning is locally present (Fig. 4.2).

Sample UY-22-13 corresponds to a quartz-rich micaschist with muscovite from the Las Tetas Complex. Zircons are 100-200 µm long and present prismatic to ovoid habits with oscillatory zoning (Fig. 4.2).

Sample UY-24-13 is a mylonite of the María Albina Shear Zone constituted by quartz, feldspar and muscovite. The protolith of the mylonites are the metasediments of the Las Tetas Complex. Up to 300 µm long prismatic to ovoid zircons with oscillatory zoning are dominant, though dark overgrowths are recognizable as well (Fig. 4.2).

4.4. Results

4.4.1. *U-Pb geochronology*

Zircon age populations of the investigated samples are presented in Figure 4.3 as kernel density estimation plots and histograms plotted using DensityPlotter (Vermeesch, 2012). Samples from the Las Tetas Complex present only Archean zircons, which range in age between 3.8 and 2.7 Ga (Fig. 4.3). A main peak at 2.77 Ga is observed in two samples (BUY-76-11 and UY-24-13), whereas sample UY-22-13 shows a main peak at 3.3 Ga.

In comparison, samples from the Neoproterozoic cover (Zanja del Tigre, Lavalleja and Yerbal units) show a dominance of Archean and Paleoproterozoic zircons with scarce contribution of Meso- and Neoproterozoic grains (Fig. 4.3). The most abundant zircon populations are, however, restricted to 3.2-3.0, 2.8-2.6, 2.5-2.4 and 2.2-2.0 Ga. Mesoproterozoic and Statherian peaks are usually subordinated.

The sample of the Minas de Corrales Formation (BUY-55-11) stands out as it shows a main Mesoproterozoic contribution between 1.55 and 1.2 Ga as well as second major Paleoproterozoic peak at 1.8-1.7 Ga. Archean and Neoproterozoic zircons in this sample are subordinated (Fig. 4.3).

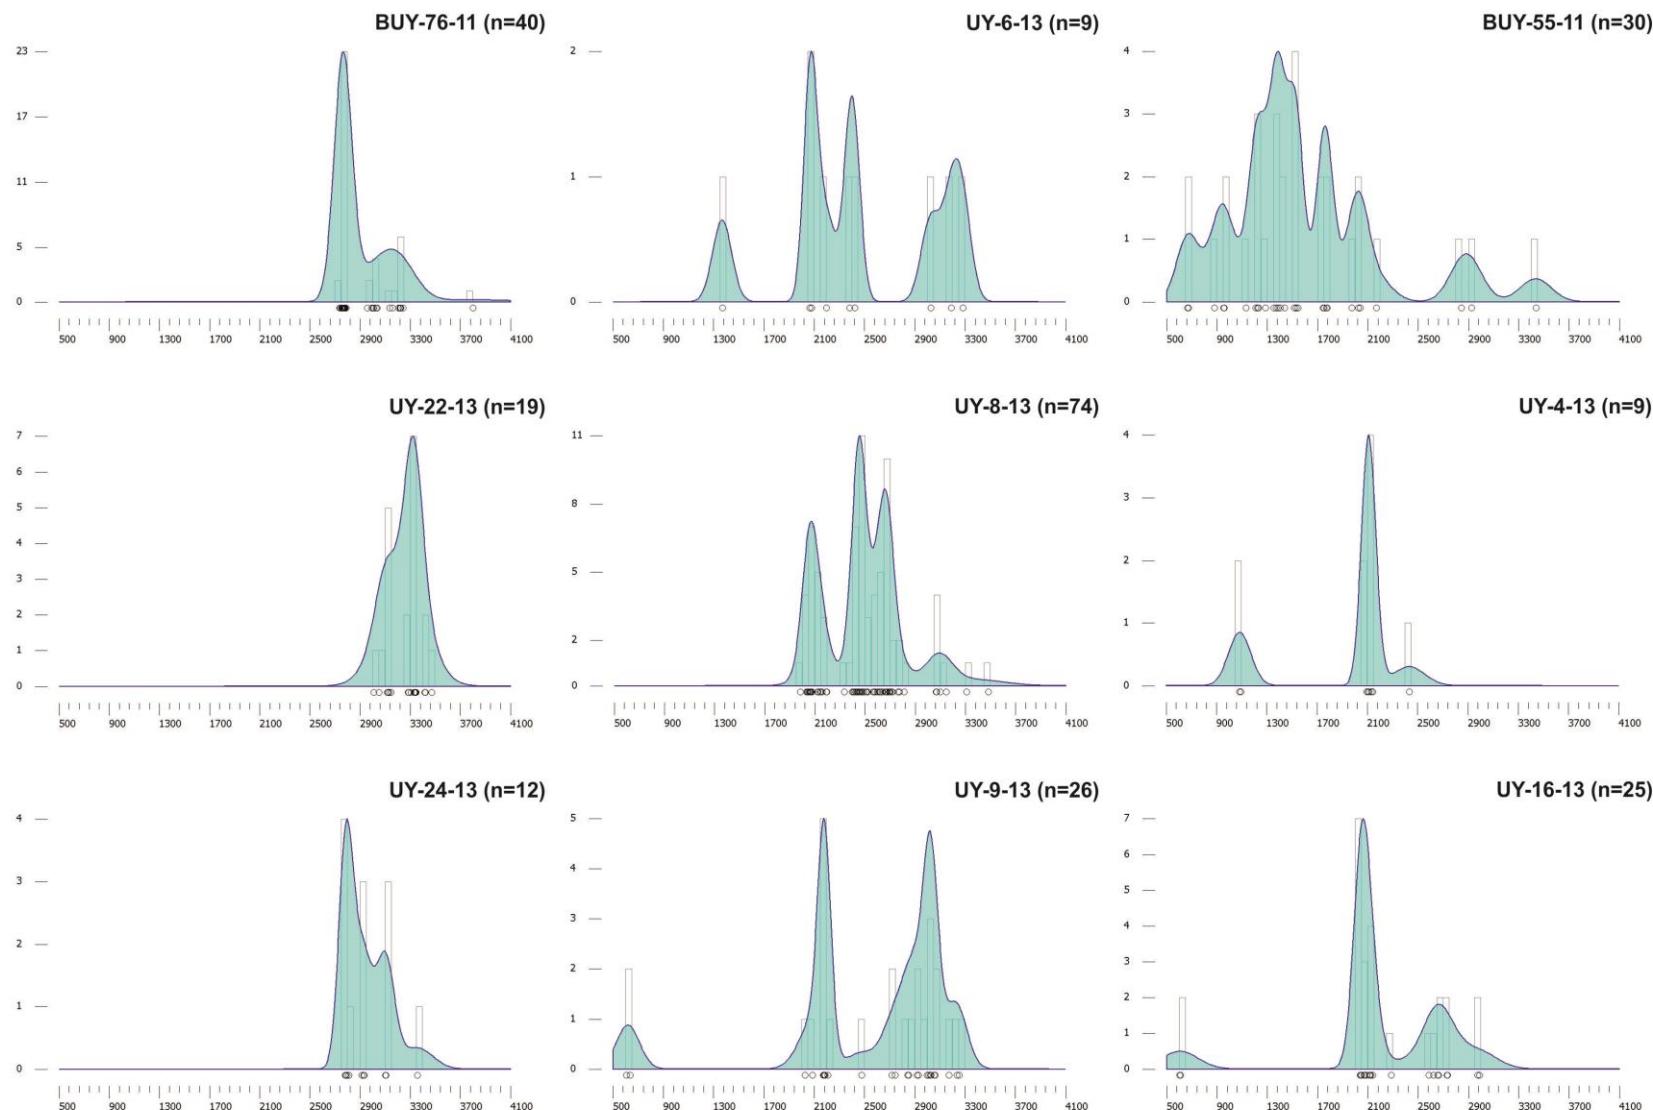

Fig. 4.3: Kernel density estimation plots and histograms plotted using DensityPlotter (Vermeesch, 2012). Plots only include data with $\pm 10\%$ concordance.

4.4.2. Hf isotopes

Archean grains in both samples show T_{DM} model ages from 3.47 to 2.96 Ga with associated ϵ_{Hf} values between -4.92 and +5.54 (Fig. 4.4; Appendix 4). In the case of Mesoproterozoic grains of sample BUY-55-11, Paleoproterozoic model ages (2.32-1.73 Ga) and dominantly positive ϵ_{Hf} values between -2.73 and -7.10 are recorded (Fig. 4.4; Appendix 4). Neoproterozoic grains show, in turn, Cryogenian model ages of 0.79-0.77 Ga and highly positive ϵ_{Hf} values of ca. 12.

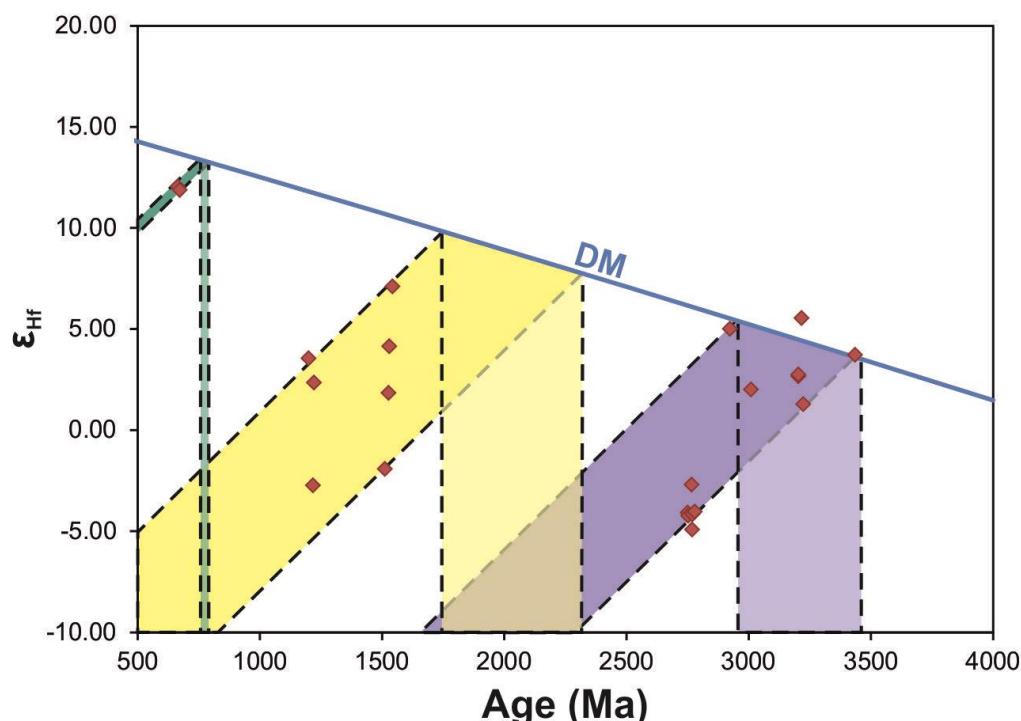

Fig. 4.4: ϵ_{Hf} vs. zircon age. Model groups are also shown.

4.5. Discussion

4.5.1. Maximum deposition ages

Table 4.1 shows the constraints for the deposition age of several lithostratigraphic units of the metasedimentary cover of the Dom Feliciano Belt in Uruguay, based on different age constraints. The first implication of these data is that only the Barriga Negra and Playa Hermosa formations show Ediacaran maximum deposition robust ages younger than ca. 600 Ma based on detrital zircon ages. A comparable age can be also interpreted for the Las Ventanas Formation based on intercalated volcaniclastic rocks of 573 ± 11 Ma (Oyhantçabal et al., 2009a). In the case of the Zanja del Tigre

Complex and the Yerbal, Minas de Corrales, Lavalleja and Piedras de Afilar formations, a Neoproterozoic deposition age probably older than ca. 600 Ma is the best constraint considering all parameters. In the case of the Yerbal Formation, this age is further supported by K-Ar data of diagenetic illite (Table 4.1; Aubet et al., 2012). The Polanco Formation, in turn, predates deposition of the Barriga Negra Formation, as the latter lies discordantly over the former (Fambrini et al., 2005, and references therein). Hence, all available data supports models suggesting that the schist belt is older and discordantly overlain by post-collisional Ediacaran foreland deposits (Basei et al., 2000; Fambrini et al., 2005; Almeida et al., 2010).

On the other hand, age constraints of granites intruding the metasedimentary cover indicate that most units are older than Cambrian. This conclusion is also consistent with ages based on the fossil content of some of these units (Gaucher et al., 2003, 2008b; Pecoits et al., 2008).

All samples from Las Tetas Complex (BUY 76-11, UY 22-13 and UY 24-13) are characterized by the absence of Proterozoic detrital zircons in concordance with preliminary data reported by Hartmann et al. (2001). The youngest age in detrital zircon of this unit continues to be 2717 ± 24 Ma (Hartmann et al., 2001), whereas similar ages are reported in this study. The minimum age of this complex, in turn, is constrained by new Ar/Ar data, which indicate an early Ediacaran age for the metamorphism (Chapter 7).

4.5.2. Provenance of the western Dom Feliciano Belt

All new data together with previous results of detrital zircons from the western Dom Feliciano Belt (Mallmann et al., 2007; Basei et al., 2008; Gaucher et al., 2008a; Blanco et al., 2009; Rapalini et al., 2015) are summarized in Figure 4.5. Three main peaks at 2.8-2.7, 2.5-2.4 and 2.2-2.0 Ga are recognizable, whereas subordinated peaks at 3.15-3.00, 1.8-1.7 and 0.65-0.60 Ga and minor Mesoproterozoic contribution are present as well.

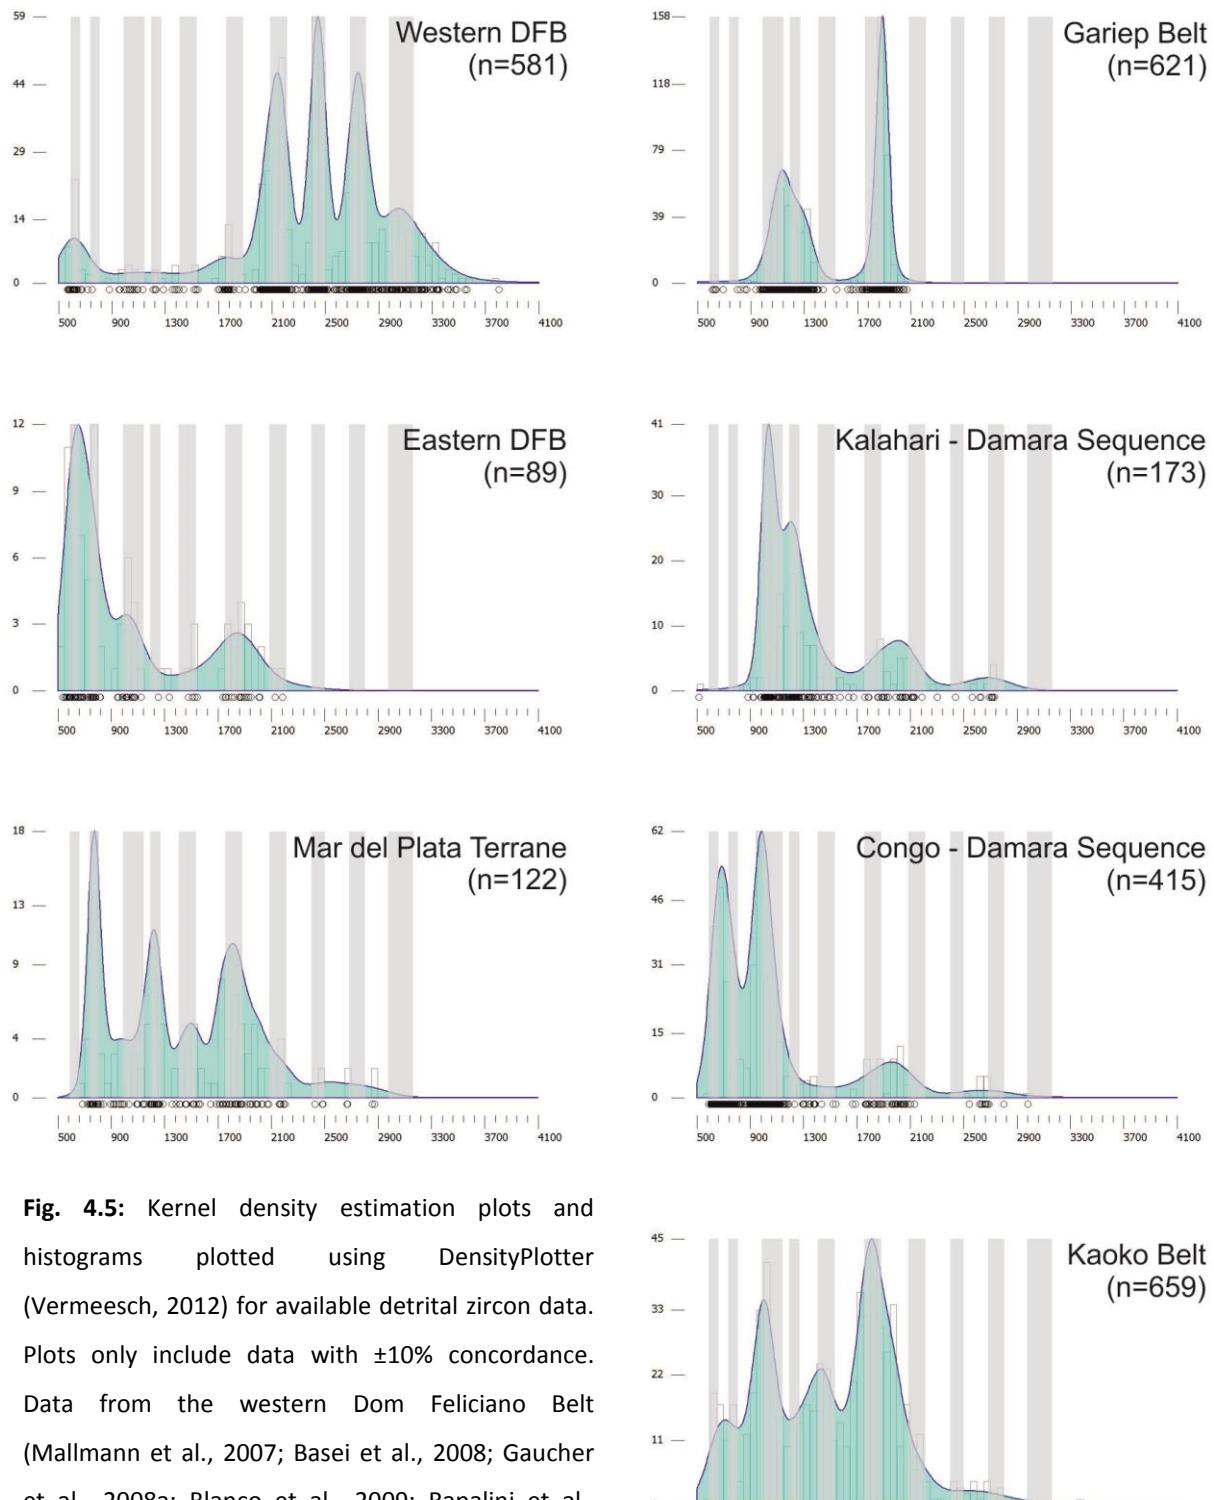

Fig. 4.5: Kernel density estimation plots and histograms plotted using DensityPlotter (Vermeesch, 2012) for available detrital zircon data. Plots only include data with $\pm 10\%$ concordance. Data from the western Dom Feliciano Belt (Mallmann et al., 2007; Basei et al., 2008; Gaucher et al., 2008a; Blanco et al., 2009; Rapalini et al., 2015; this work) are compared with data from the eastern Dom Feliciano Belt (Basei et al., 2005; Gaucher et al., 2014b, 2014c) and the Mar del Plata Terrane (Rapela et al., 2011) on the South American margin, and also with data from the African Damara (Foster et al., 2015), Kaoko (Konopásek et al., 2014) and Gariep belts (Basei et al., 2005; Hofmann et al., 2014).

Archean and Paleoproterozoic peaks match ages recorded in the basement of the Nico Pérez Terrane, which underlies the metasedimentary sequences. Archean rocks are present in the Pavas Block (Hartmann et al., 2001; Gaucher et al., 2011a) and 2.2-2.0 Ga ages are recorded in the Valentines-Rivera Granulitic Complex (Santos et al., 2003; Oyhantçabal et al., 2012). Additionally, the Campanero Unit and the Illescas granite account for the 1.8-1.7 Ga detrital ages (Campal and Schipilov, 1995; Mallman et al., 2007). On the other hand, Mesoproterozoic grains may indicate that the Parque Ute Group in the Nico Pérez Terrane (Oyhantçabal et al., 2005; Gaucher et al., 2011a) and/or the Cerro Olivo Complex (Basei et al., 2011b) acted as a minor source during Neoproterozoic sedimentation. Neoproterozoic grains, in turn, may derive from widespread Neoproterozoic magmatism recorded in the area (e.g., Hartmann et al., 2002; Oyhantçabal et al., 2007, 2009, 2012).

Previous contributions attributed the rocks of the Río de la Plata Craton and the Sierras Pampeanas as source for the Archean, Paleo- and Mesoproterozoic zircons of the Arroyo del Soldado Group (Gaucher et al., 2008a; Blanco et al., 2009), though strongly argued by Zimmermann (2011). In contrast, detrital zircons from the Playa Hermosa Formation show a main peak at 2.2-2.0 Ga and a secondary peak at ca. 600 Ma, and lack in Archean, Statherian and Mesoproterozoic ages (Rapalini et al., 2015). The main peak may thus represent ages of the basement of the Río de la Plata Craton (e.g., Cingolani, 2011; Oyhantçabal et al., 2011), which is further supported by SW paleocurrent directions (Pazos et al., 2011). Consequently, the Playa Hermosa Formation may represent the only metasedimentary unit of the western Dom Feliciano Belt that truly reflects provenance from the Río de la Plata Craton, being thus the basement of the Nico Pérez Terrane the dominant source for all other metasedimentary sequences.

As indicated by U-Pb geochronology, Hf data shows a significant contribution of old crust, which was mostly generated during the Paleo- and Eoarchean. Nevertheless, Neo- and Mesoarchean addition is also noticeable. This may reflect the role of the gneisses of the La China Complex as source for the metasediments of the western Dom Feliciano Belt (Hartmann et al., 2001; Gaucher et al., 2011a). Archean and Paleoproterozoic zircon Hf model ages suggest that this was also a major

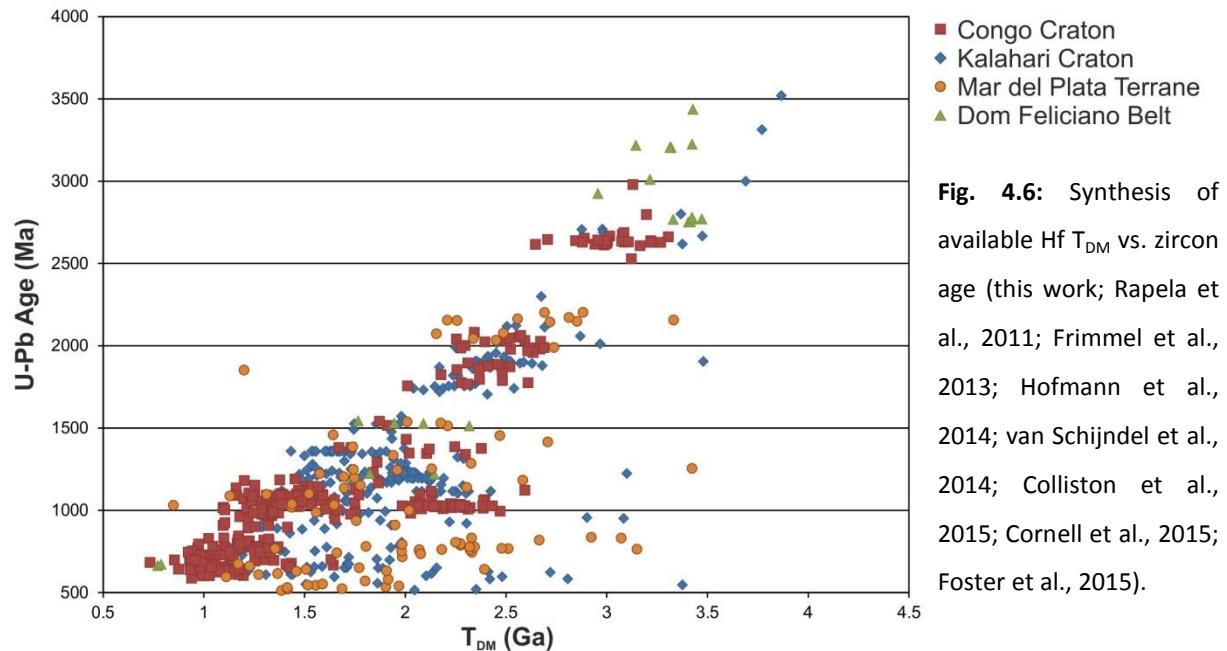

crustal growth period for the source area. These results are in good agreement with available Sm-Nd data from the western Dom Feliciano Belt metasediments (Mallmann et al., 2007; Blanco et al., 2009; Oyhantçabal et al., submitted) and Hf and Sm-Nd data from the Nico Pérez Terrane basement (Mallmann et al., 2007; Oyhantçabal et al., 2011a; Oriolo et al., 2016a; Chapter 3). In contrast, Hf and Sm-Nd data indicate a dominance of Paleoproterozoic juvenile crust for the Río de la Plata Craton (Peel and Preciozzi, 2006; Cingolani, 2011; Oyhantçabal et al., 2011; Oriolo et al., 2016a; Chapter 3). On the other hand, the two Cryogenian grains show juvenile Hf isotope compositions. Both the Cerro Olivo Complex and the São Gabriel Block present evidences of Cryogenian magmatism (Saalmann et al., 2005; Basei et al., 2011a; Lenz et al., 2011) and may account as possible sources for the obtained model ages. However, the Cerro Olivo Complex presents Paleo- and Mesoproterozoic xenocrysts, negative ε_{Nd} values and Sm-Nd Paleo- and Mesoproterozoic model ages, indicating that the Cryogenian magmatism reworked much older crust (Basei et al., 2011a; Lenz et al., 2011; Saalmann et al., 2011). The São Gabriel Block, in contrast, is made up of juvenile material (Saalmann et al., 2005; Fortes de Lena et al., 2014) and can be thus interpreted as the source for these grains. This can be further supported by similar detrital zircon patterns observed in some units of the Porongos Group in southernmost Brazil (Pertille et al., 2015a, 2015b).

4.5.3. Regional implications

Archean and Paleoproterozoic zircon Hf model ages suggest that these were the major crustal growth periods for the source areas. Compared with available U-Pb and Hf zircon data (Fig. 4.6), data from the western Dom Feliciano Belt suggest an African signature, either related to the Congo or the Kalahari Craton.

However, the allochthony of the Nico Pérez Terrane and its similitude regarding Archean and Proterozoic events suggests that it may represent a fragment of the Congo Craton separated during the Cryogenian rifting of Rodinia (Rapela et al., 2011; Oyhantçabal et al., 2011a; Oriolo et al., 2016a; Chapter 3). The dominance of Archean and Paleoproterozoic ages in both the Nico Pérez Terrane and

the overlying metasedimentary sequence may support an origin from the Angola Block of the Congo Craton. This could be supported by the juvenile Hf signature of Cryogenian grains, which is restricted to the western Dom Feliciano Belt and the Congo Craton (Fig. 4.6).

Several differences arise from the comparison between the western and eastern Dom Feliciano Belt in Uruguay (Fig. 4.5). In the eastern Dom Feliciano Belt, main peaks at 1.9-1.7, 1.1-1.0, 0.80-0.75 and 0.65-0.55 Ga are present (Basei et al., 2005; Gaucher et al., 2014b, 2014c). Paleo- and Mesoproterozoic ages coincide with ages recorded in the Gariep Belt (Fig. 4.5; Basei et al., 2005; Hofmann et al., 2014), which indicate provenance from the western Kalahari basement, particularly from the Namaqua-Natal Belt, the Vioolsdrif Granite Group and the Orange River Group (Blanco et al., 2011; Hofmann et al., 2014). Likewise, the 0.65-0.55 and 0.80-0.75 Ga peaks match ages of the Neoproterozoic magmatic rocks and the Cerro Olivo Complex, respectively (Hartmann et al., 2002; Oyhantçabal et al., 2007, 2009a, 2012; Basei et al., 2011b; Lenz et al., 2011). These similarities support the role of the Kalahari Craton basement as source for the sediments of the eastern Dom Feliciano Belt and the Gariep Belt (Basei et al., 2005; Hoffmann et al., 2014), which lacks in the western Dom Feliciano Belt (Fig. 4.5). Comparable peaks are also recorded in the Punta Mogotes Formation of the Mar del Plata Terrane and Damara sequences (Fig. 4.5; Rapela et al., 2011; Foster et al., 2015), providing further evidences of an African fingerprint.

It is important to outline that detrital zircon data in the eastern Dom Feliciano Belt of Uruguay are only available for units younger than ca. 590 Ma (Table 4.1). Interestingly, unpublished detrital zircon data from a quartzite of the basement of the eastern Dom Feliciano Belt show a distinct pattern (Nedrebø, 2014), which is similar to the one recorded in the western Dom Feliciano Belt (Fig. 4.5). Consequently, detrital zircon data support models indicating that the accretion of the Río de la Plata and Congo cratons predates the accretion of the Kalahari Craton (Prave, 1996; Rapela et al, 2011; Oriolo et al, 2016b; Chapter 6). Furthermore, detrital zircon data from the Kaoko Belt could reinforce this hypothesis, as the onset of Namaqua-age zircons is only recorded in the upper part of the Neoproterozoic cover (Konopásek et al., 2014). Additionally, similarities between detrital zircon ages from the western Dom Feliciano Belt and data from Nedrebø (2014) may suggest that both areas comprised a single block, in contrast to previous hypothesis (Bossi and Gaucher, 2004; Gaucher et al., 2010; Basei et al., 2011a).

4.6. Conclusions

Detrital zircon ages show late Ediacaran maximum deposition age for the Barriga Negra and Playa Hermosa formations, whereas a Neoproterozoic deposition age older than ca. 600 Ma can be constrained for units of the schist belt. The Neoproterozoic schist belt seems thus to predate the deposition of post-collisional sequences described as part of the foreland basin.

Comparison of U-Pb detrital zircon age distributions and model ages from potential source regions indicates that the Nico Pérez Terrane and not the Río de la Plata Craton was the main source of detritus. The similitude of Archean and Proterozoic events recorded in the Nico Pérez Terrane basement and the overlain metasedimentary cover of the western Dom Feliciano Belt support an African derivation of the former, most probably from the Congo Craton. In contrast, the source area for metasedimentary sequences in the eastern Dom Feliciano Belt was the Kalahari Craton. As this source is only recorded in units younger than ca. 590 Ma, detrital data also suggest that the Congo-

Río de la Plata amalgamation predates the accretion of the Kalahari Craton during Gondwana assembly.

-CHAPTER 5-**Structure of the Sarandí del Yí Shear Zone****5.1. Introduction**

Shear zones are common features in the crust that occur on a wide range of scales, P-T conditions and tectonic settings. As they may represent terrane boundaries (e.g., Jégouzo, 1980; van der Pluijm et al., 1994; West, 1998; Höckenreiner et al., 2003; Goodenough et al., 2010; Wong et al., 2011), crustal-scale shear zones are structures with a significant role in the evolution of orogens that can provide irreplaceable information about the timing and mechanisms of accretion and amalgamation of crustal blocks.

Since the early works of Ramsay and Graham (1970), Sibson (1977), Ramsay (1980) and White et al. (1980), contributions about shear zones and associated rocks have diversified. The nucleation and evolution of shear zones related to lithospheric strain localization and, particularly, how these processes operate at different depths have been of particular interest (Grocott, 1977; Sibson, 1983; Hanmer, 1988; Jessel and Lister, 1991; Siegesmund et al., 2008; Platt and Behr, 2011a, 2011b; Montési, 2013).

The Sarandí del Yí Shear Zone is a crustal-scale mylonitic belt located in southern Uruguay (Fig. 5.1). It was first defined as a structural lineament by Preciozzi et al. (1979) and as a dextral structure that separates different tectonostratigraphic terranes by Bossi and Campal (1992). Oyhantçabal et al. (1993) considered it as a pre-Brasiliano dextral shear zone that was subsequently reactivated during the late Neoproterozoic exhibiting a sinistral shear sense. Later, Oyhantçabal et al. (2011a) proposed it as the eastern margin of the Río de la Plata Craton.

The dextral shearing is inferred from the bending of the 1.79 Ga old Florida doleritic dyke swarm (Fig. 5.1; Teixeira et al., 1999, 2013) and of the Paleoproterozoic fabrics of the Piedra Alta Terrane (Oyhantçabal et al., 1993). The subsequent sinistral movement is considered to be Neoproterozoic in age due to the emplacement of the syntectonic Solís de Mataojo Granitic Complex (Oyhantçabal et al., 2001, 2007). Due to the lack of structural and geochronological studies of this

shear zone, its evolution is still controversial (Oyhantçabal et al., 1993, 2011a; Gaucher et al., 2011a), even though it represents a key element for the understanding of the early amalgamation of Western Gondwana.

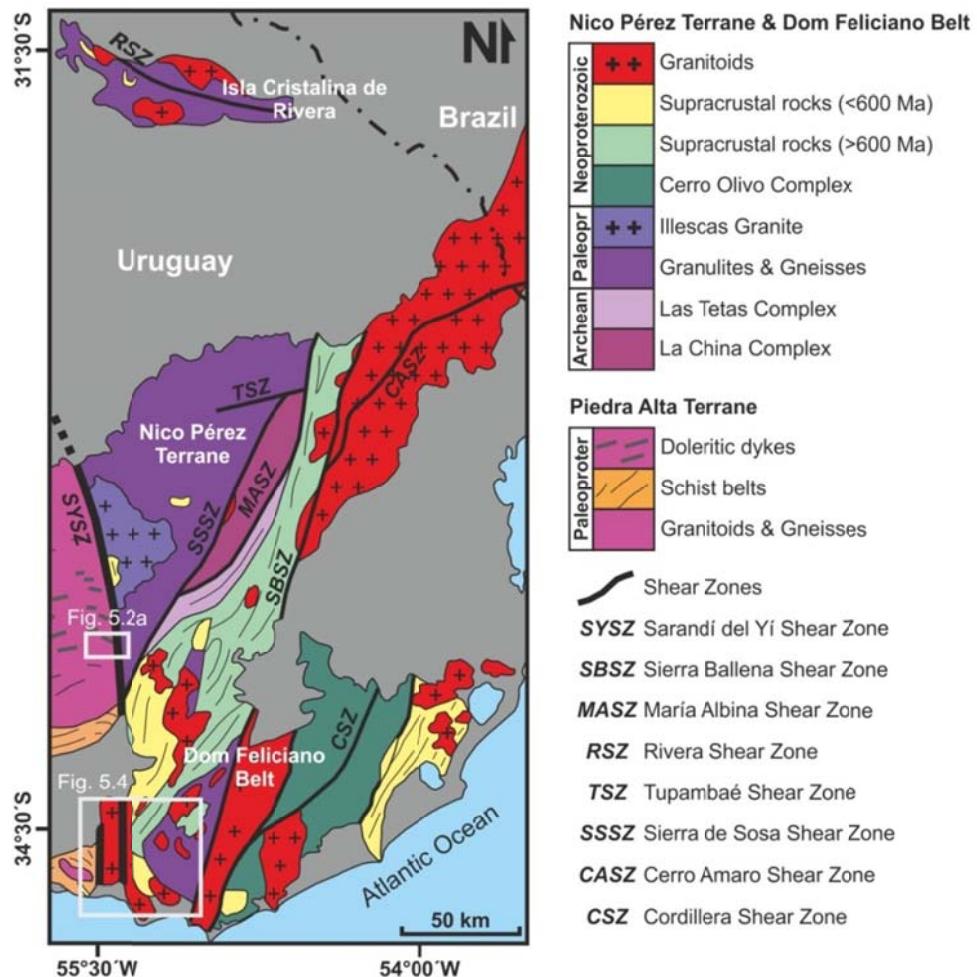

Fig. 5.1.: Geological map of the Precambrian of Uruguay modified after Oyhantçabal et al. (2011a) and references therein. Investigated areas of Figures 5.2a and 5.4 are shown.

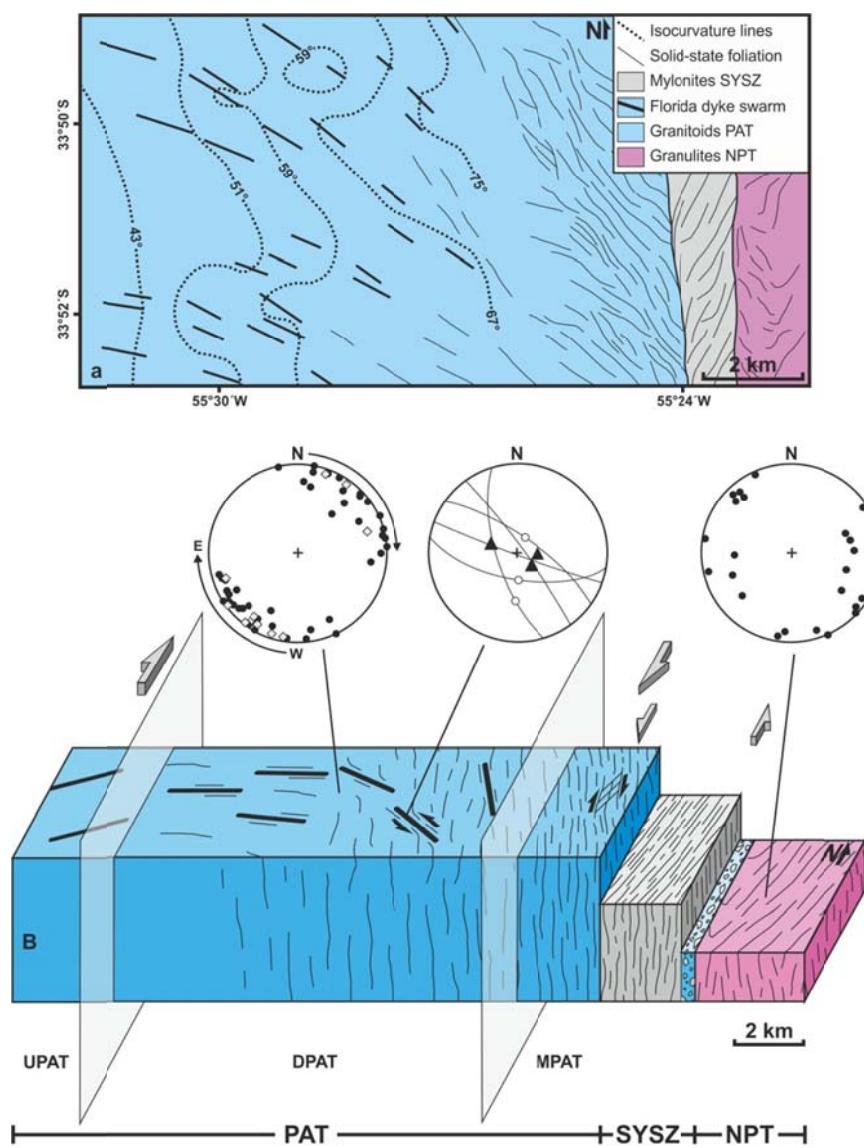

5.2. Macro- and mesostructures

5.2.1. Structural domains

On the basis of regional mapping, three main structural domains I, II and III can be recognized in the study area. Domain I corresponds to the Piedra Alta Terrane, domain II comprises the shear zone and associated intrusions and, finally, domain III includes the Dom Feliciano Belt and Nico Pérez Terrane (Fig. 5.1, 5.2). As both domains I and III represent the neighbouring blocks of the Sarandí del Yí Shear Zone, they provide constraints on the relationship between syn- and pre-shearing fabrics.

5.2.2. Domain I: Piedra Alta Terrane

The granitic-gneissic areas, metasediments of the schist belts and shear zones show ages between 2.0 and 1.9 Ga and are dominated by E-ENE subvertical foliations (Oyhantçabal et al., 2006, 2011a). On the other hand, the 1.79 Ga Florida doleritic dyke swarm is made up of subvertical dykes that trend ca. 060° (Halls et al., 2001; Oyhantçabal et al., 2011a; Morales Demarco et al., 2011; Teixeira et al., 2013).

undeformed Piedra Alta Terrane, DPAT: deformed Piedra Alta Terrane and MPAT: mylonites of the Piedra Alta Terrane). Subsequent sinistral shearing and late cataclastic reactivation in the Sarandí del Yí Shear Zone are also shown. Lower hemisphere equal area projections of the orientation of the doleritic dykes (grey diamonds, n=11) and the solid-state foliation in their wall-rock (black dots, n=50) from west to east; foliations (lines, n=5), lineations (white circles, n=3) and fold axes (black triangles, n=3) within the strained doleritic dykes; and high-T foliation in the granulitic gneisses (black dots, n=23) are included.

Fig. 5.2: a) Schematic geological map showing the structure of the easternmost Piedra Alta Terrane. Values shown in the isocurvature lines indicate angular differences between the strike of undeformed (060°) and deformed dykes. b) Schematic structural profile summarizing the main structural features in the Piedra Alta Terrane (PAT, domain I), the Sarandí del Yí Shear Zone (SYSZ, domain II) and the Nico Pérez Terrane (NPT, domain III). Strain increase in the Piedra Alta Terrane related to dextral shearing of the Sarandí del Yí Shear Zone is schematized considering three structural subdomains (UPAT:

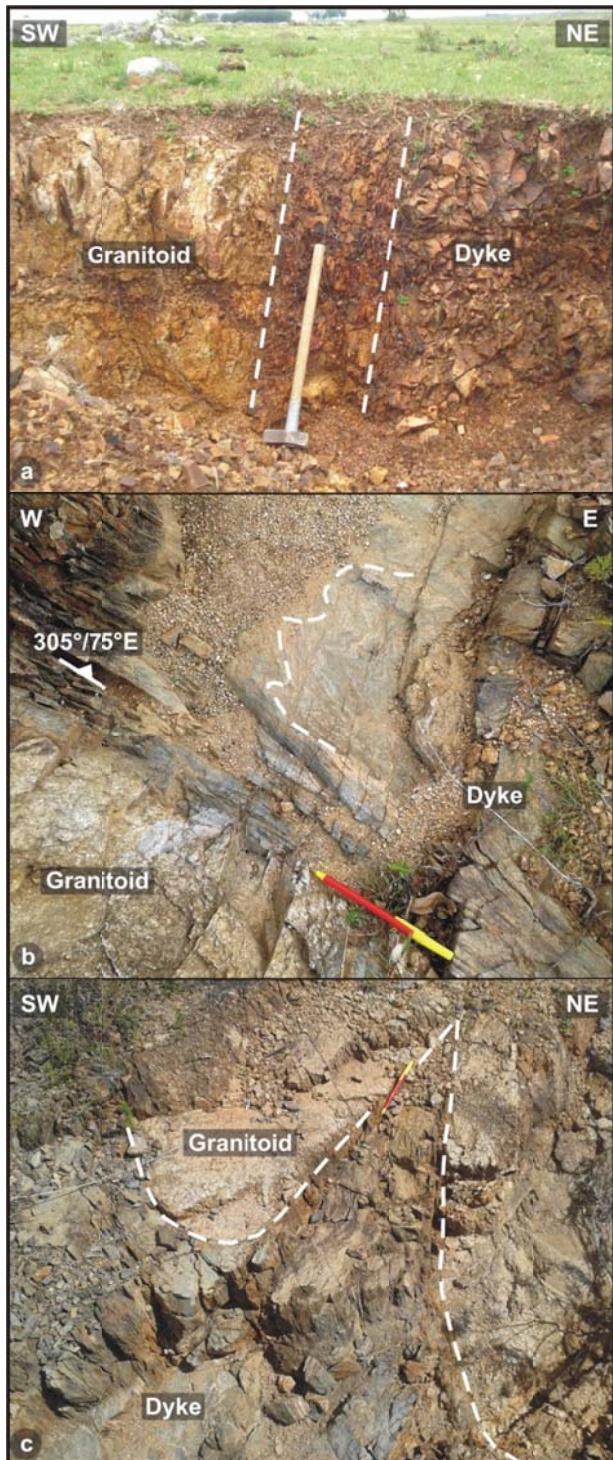

Fig. 5.3: Field photographs of structures in the eastern Piedra Alta Terrane. a) Slightly bent dyke with spaced cleavage subparallel to the contact with the granitic wall-rock. b) Strained and folded dyke. The geometry of the fold is schematically shown. c) Cuspate-lobate fold.

However, detailed mapping of the dykes shows their progressive clockwise rotation about a vertical axis towards the Sarandí del Yí Shear Zone in a ca. 10-km-wide zone (Fig. 5.2). Slightly bent dykes exhibit a spaced cleavage in contact with granitoids and gneisses (Fig. 5.3a), which show both magmatic and local solid-state foliations that strike WNW. Further to the east, the dykes are not only bent but also display a NW-WNW penetrative foliation that is frequently folded or sheared (Fig. 5.3b, 5.3c). Minor drag folds as well as S-C' shear bands in the foliated dykes indicate sinistral shearing. Granitoids show a solid-state foliation that is parallel to the fabric in the dyke along their mutual

contacts but strikes NNW further away. Scarce stretching lineations in both dykes and their wall-rock are steeply dipping (Fig. 5.2b).

The easternmost area of the Piedra Alta Terrane is made up of granitic mylonites and protomylonites striking NNW. They are coarser-grained than the mylonites of the Sarandí del Yí Shear Zone and present S-C' shear bands that indicate dextral shearing (Fig. 5.2b).

5.2.3. Domain II: Sarandí del Yí Shear Zone

5.2.3.1. Mylonites

The Sarandí del Yí Shear Zone is a ca. 2-km-wide mylonitic belt that is exposed over at least 200 km in N-S direction (Fig. 5.1). Despite being covered by Phanerozoic rocks, it can be traced further to the north as a marked gravimetric anomaly (Oyhantçabal et al., 2011a). Its regional trend changes from N-S in the south to NNW-SSE in its northern part (Fig. 5.1).

Proto- to ultramylonites constitute the shear zone and present a dominant subvertical NNE-striking foliation with a mean orientation of $184^{\circ}/81^{\circ}\text{W}$ and a mean stretching lineation of $182^{\circ}/06^{\circ}$ (Figs. 5.4, 5.5). A transition from proto- to ultramylonites is observed from west to east. S-C' shear bands and σ -type feldspar mantled porphyroclasts are frequent and indicate a sinistral sense of shearing (Fig. 5.6a, 5.6b).

Tight to isoclinal symmetrical folds of the mylonites are typically found in the eastern part of the shear zone (Figs. 5.5, 5.6c). Fold axes with a mean orientation of $024^{\circ}/01^{\circ}$ are subparallel to the lineation, and sometimes a subvertical fold axial plane cleavage is developed (Fig. 5.5). Open folds are extremely rare and, when present, occur in the west. Minor drag folds are also observed (Fig. 5.6d). Parasitic folds are frequently present (Fig. 5.6e).

The eastern margin of the shear zone is cataastically reworked (Fig. 5.5). Brittle deformation and pseudotachylite veins in the mylonites as well as phyllonites and cataclasites with mylonitic fragments are observed (Fig. 5.6f).

5.2.3.2. Solís de Mataojo Granitic Complex

The Solís de Mataojo Granitic Complex is a N-trending elongate body that intrudes the Sarandí del Yí Shear Zone in its southern portion (Fig. 5.4). The ages of 580 ± 15 Ma (Rb-Sr whole rock, Umpierre and Halpern, 1971) and 584 ± 13 Ma (single-phase Pb-Pb stepwise leaching titanite, Oyhantçabal et al., 2007) are interpreted as the crystallization age.

The wall-rock of this intrusion is made up of mylonites of the Sarandí del Yí Shear Zone, which correspond to the Aguas Blancas and the Arroyo Solís mylonites to the east and to the west, respectively (Fig. 5.5; Oyhantçabal et al., 1993, 2001). On the basis of structural similarities between the Solís de Mataojo Granitic Complex and the mylonites, Oyhantçabal et al. (2001) and Oyhantçabal (2005) inferred that the emplacement of this pluton in the shear zone occurred during sinistral shearing.

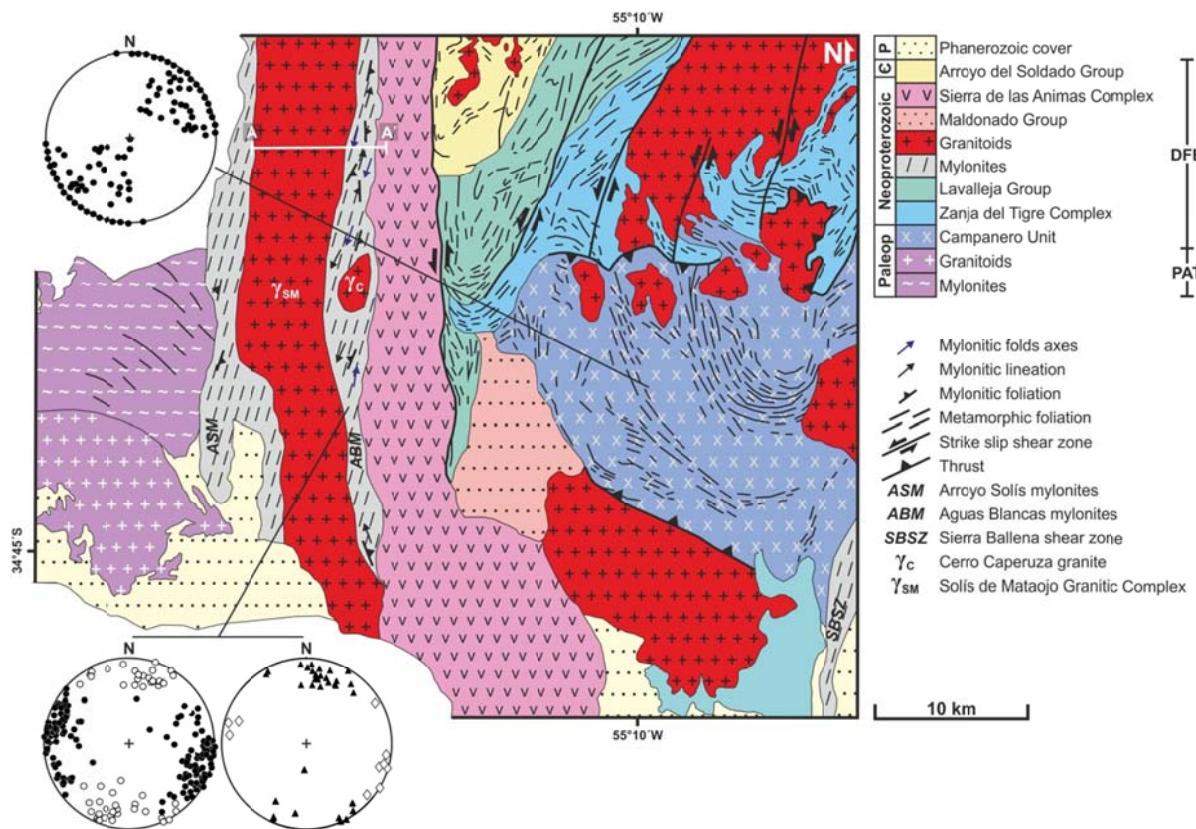

Fig. 5.4: Geological map of the southernmost Sarandí del Yí Shear Zone and adjacent blocks (modified after Oyhantçabal et al., 2001, 2005; Spoturno et al., 2004, 2012). The shear zone includes the Aguas Blancas and Arroyo Solís mylonites. Lower hemisphere equal area projections of foliations (black dots, n=155), lineations (white dots, n=55), fold axial planes (white diamonds, n=11) and fold axes (black triangles, n=36) of the mylonites of the Sarandí del Yí Shear Zone, as well as high-T foliation of the Campanero Unit (data from Oyhantçabal, 2005, n=148), are shown. The location of the structural profile in Fig. 5.5 is also indicated. DFB: Dom Feliciano Belt, PAT: Piedra Alta Terrane.

5.2.3.3. Cerro Caperuza granite

This NNE-SSW elongate intrusion is located in the southern Sarandí del Yí Shear Zone (Fig. 5.4). It is a medium-grained equigranular to porphyritic granite related to the magmatism of the

Sierra de las Ánimas Complex (Oyhantçabal et al., 1993). However, no geochronological or geochemical data are available for this intrusion. Except for quartz veins and fracturing, the Cerro Caperuza granite shows no significant macro-mesoscopic evidence of deformation indicating a late-to post-kinematic emplacement regarding ductile deformation of the Sarandí del Yí Shear Zone.

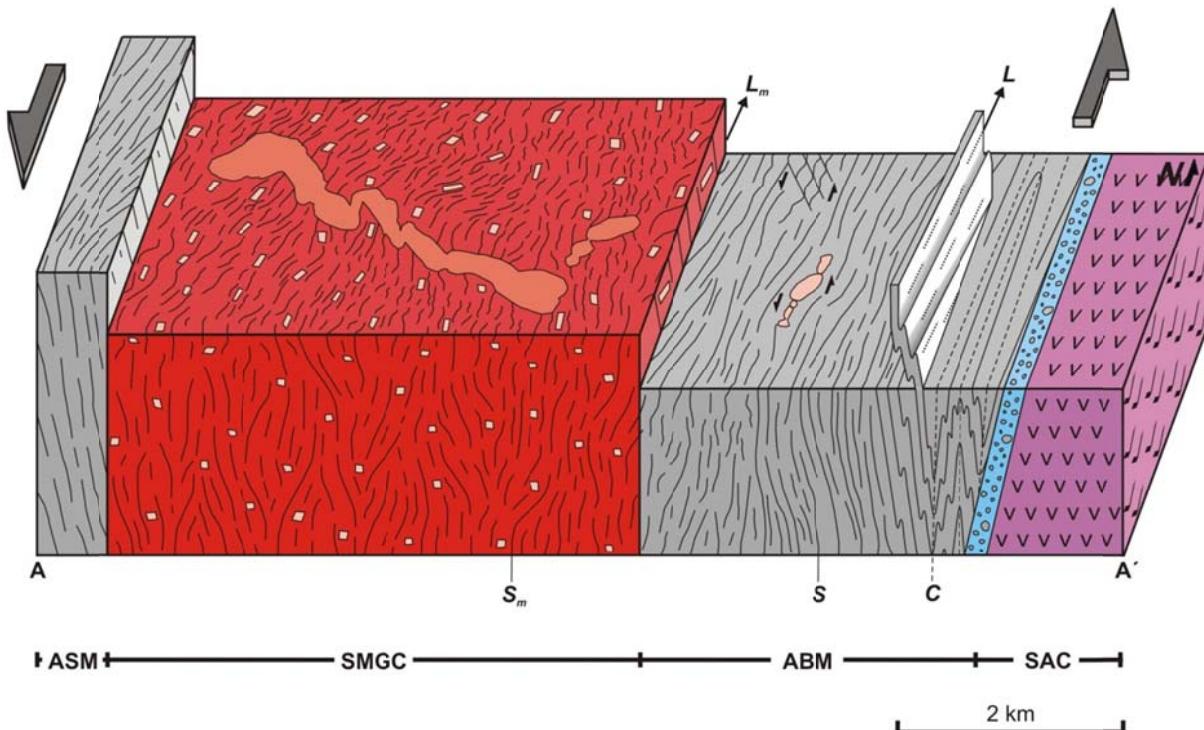

Fig. 5.5: Structural profile of the Sarandí del Yí Shear Zone (SYSZ, see location in Fig. 5.4). The contact between the Arroyo Solís mylonites (ASM) and the Solís de Mataojo Granitic Complex (SMGC) is schematic because it is not observable in the field, whereas the contact between the latter and the Aguas Blancas mylonites (ABM) is transitional. The cataclasites in the easternmost Sarandí del Yí Shear Zone (light blue, schematic orientation) represent the contact with the Sierra de las Ánimas Complex (SAC). Main structural elements of the SMGC (K-feldspar megacrystal fabric, deformed late pegmatitic veins, S_m : magmatic foliation, L_m : magmatic lineation; after Oyhantçabal et al., 2001) and the SYSZ (S: mylonitic foliation, L: stretching lineation, C: axial plane cleavage in chevron folds) are summarized.

5.2.4. Domain III: Nico Pérez Terrane and Dom Feliciano Belt

5.2.4.1. Nico Pérez Terrane

A high-T gneissic foliation can be locally found in the granulites, though without systematic orientation, whereas the Neoproterozoic granitoids show dominant equigranular textures. Therefore, there are no clear deformation patterns in the basement of the Nico Pérez Terrane that

could be related to the Sarandí del Yí Shear Zone. However, gneisses with NNW- to NW-striking foliation and local NNW-trending protomylonitic belts in the westernmost Illascas granite can be found close to the shear zone (Fig. 5.2). The Valentines-Rivera Granulitic Complex also shows cataclastic overprinting towards the Sarandí del Yí Shear Zone.

Fig. 5.6: Field photographs of structures developed in the Sarandí del Yí Shear Zone. a) Sinistral σ -type K-feldspar mantled porphyroclasts in granitic mylonites with mafic enclaves (arrow) that are cross-cut by a post-mylonitic pegmatitic vein. b) Sinistral σ -type feldspar mantled porphyroclasts with recrystallized tails. c) Tight to isoclinal fold with fold axis parallel to the stretching lineation. d) Sinistral drag fold. e) Parasitic folds developed in a tight mylonitic fold. f) Cataclasite of the easternmost Sarandí del Yí Shear Zone with mylonitic fragments. The arrow points to a fine-grained ultramylonitic fragment.

5.2.4.2. Dom Feliciano Belt

The Campanero Unit presents a folded steep high-T foliation, whereas the metasediments are strongly deformed and folded with NNE- or SSW-plunging axes (Fig. 5.4; Oyhantçabal, 2005; Oyhantçabal et al., 2009a; Spoturno et al., 2012). Major NNE-striking sinistral lineaments transect both units.

5.3. Microstructures

5.3.1. Domain I: Piedra Alta Terrane

The wall-rock of the dykes in the easternmost Piedra Alta Terrane comprises mostly granites and granodiorites with equigranular to porphyritic texture. Those granitoids with evidences of solid-state deformation show quartz crystals with interlobate grain boundaries (Fig. 5.7a) and chessboard extinction (Fig. 5.7b). Local recrystallization along the edge of the grains is also observed in feldspars.

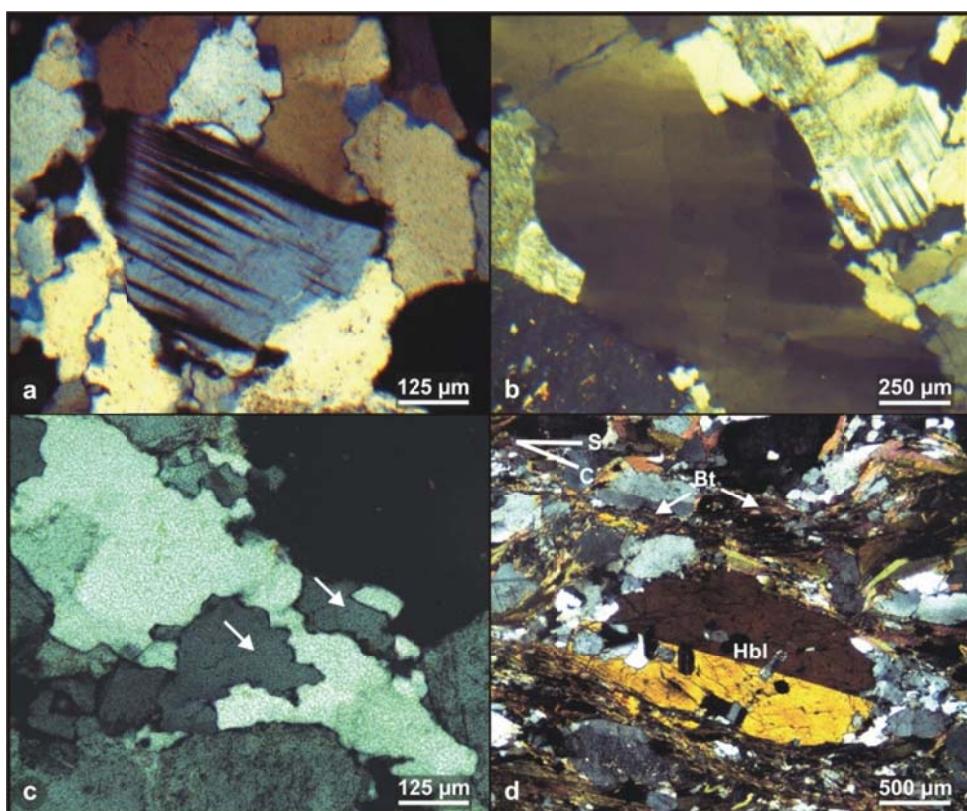

Fig. 5.7: Photomicrographs of microstructures from rocks of the eastern Piedra Alta Terrane (cross-polarized light). a) Mechanical twins in plagioclase and quartz crystals with sutured grain boundaries. b) Chessboard extinction in quartz. c) Interlobate grain boundaries and left-over grains (arrows) in quartz. d) Dextral S-C' shear bands in mylonites with shape-preferred orientation of biotite and hornblende.

The dykes display a significant variation of microstructures from west to east. In the slightly rotated dykes, pyroxenes are partly replaced by hornblende, in some cases as reaction rims. Further to the east, the primary mineral association is strongly replaced by hornblende, plagioclase, chlorite, epidote, clinozoisite, muscovite-sericite, biotite, quartz and opaque minerals.

The NNW-striking mylonites and protomylonites in the easternmost area of the Piedra Alta Terrane are made up of quartz, K-feldspar, plagioclase, biotite and scarce hornblende. Quartz shows sutured grain boundaries with minor chessboard extinction (Fig. 5.7c). Feldspars exhibit local recrystallization along the edge of the grains. Biotite is preferentially oriented in two planes that define the S and C' of dextral shear bands, whereas hornblende presents only minor fracturing (Fig. 5.7d).

5.3.2. Domain II: Sarandí del Yí Shear Zone

5.3.2.1. Mylonites

The protoliths of the Sarandí del Yí Shear Zone are dominantly granitoids, with minor participation of volcanic-subvolcanic and sedimentary rocks. Likewise, sheared quartz and quartz-feldspar veins and veinlets as well as amphibolitic xenoliths are recognizable.

Deformation is heterogeneously distributed with increasing intensity towards the east, which is accompanied by grain size decrease. Kinematic indicators include S-C' shear bands, σ-type feldspar mantled porphyroclasts with asymmetric myrmekites, mica fish and oblique foliation of elongated quartz grains, which support a subhorizontal sinistral sense of shear (Fig. 5.8a, 5.8b).

Quartz grains are mostly sutured (Fig. 5.8c). In some cases, elongate grains of relatively uniform size are developed due to progressive subgrain rotation, particularly in microfolds (Fig. 5.8d). Recrystallization in feldspars is localized at the edges of the grains or within microshear zones. Hornblende exhibits only fracturing (Fig. 5.8e). White mica and minor fine-grained biotite are typically oriented parallel to the S or C' planes.

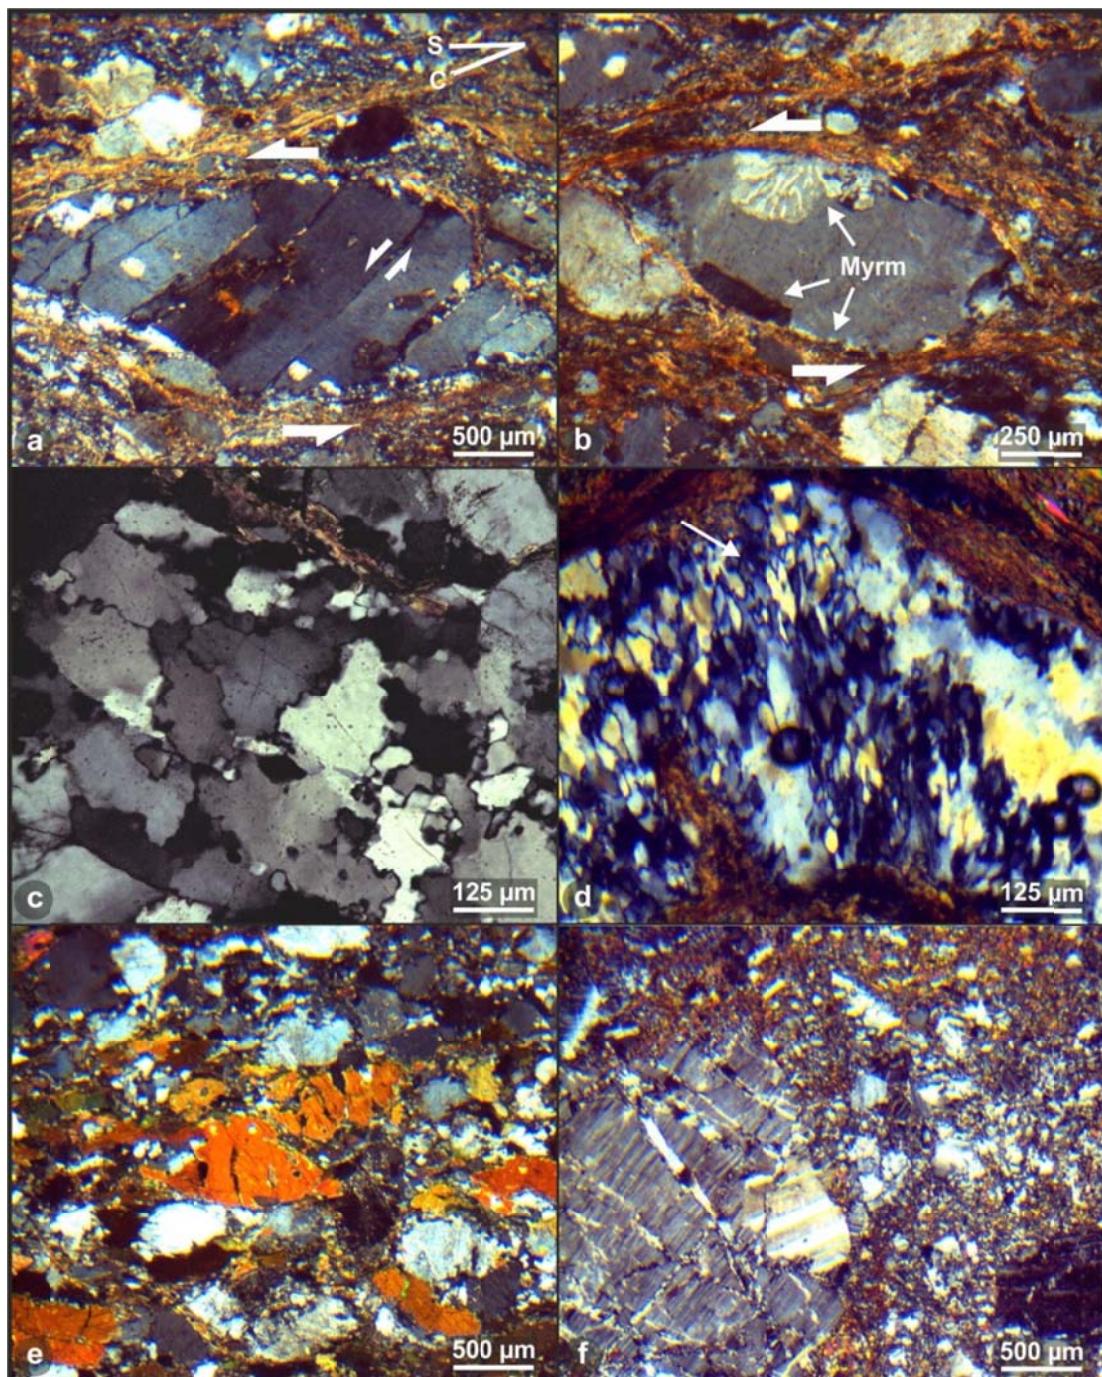

Fig. 5.8: Photomicrographs of microstructures from rocks of the Sarandí del Yí Shear Zone (cross-polarized light). a) Sinistral S-C' shear band and σ -type K-feldspar mantled porphyroblast with anti-bookshelf structure. Synthetic microshear zones with localized recrystallization of feldspar are also indicated. b) Sinistral quarter structure of K-feldspar mantled porphyroblast with asymmetric myrmekites and recrystallized tails. c) Sutured quartz crystals with interfingering grain boundaries. d) Elongate grains parallel to Y of relatively uniform size developed due to subgrain rotation in the hinge of a microfold (YZ section). e) Fractured hornblende crystals. f) Cataclastic texture in sample from the easternmost part of the shear zone. Note the large fragment of a plagioclase crystal showing a cataclastic texture.

The cataclasites located in the easternmost part of the shear zone consist of angular polycrystalline fragments immersed in a very fine-grained matrix of quartz + plagioclase + K-feldspar + epidote + opaque minerals ± clinzoisite ± zoisite ± chlorite ± sericite ± carbonates (Fig. 5.8f). The fragments consist of quartz, plagioclase and K-feldspar with minor participation of micas. They show microstructures similar to those found in the mylonites but significantly overprinted by cataclasis. Locally, phyllonites are also recognizable.

5.3.2.2. Solís de Mataojo Granitic Complex

Microstructures indicate a transition from magmatic to low-T solid-state deformation processes, though a major part of the deformation took place under magmatic and high-T solid-state conditions (Oyhantçabal et al., 2001).

5.3.2.3. Cerro Caperuza granite

The Cerro Caperuza granite is made up of quartz, microcline, plagioclase and biotite with zircon as the main accessory mineral phase. Quartz crystals exhibit undulose extinction and subgrain formation with peripheral bulging and recrystallization. Microcline shows flame perthites, whereas bending and deformation twins are identifiable in plagioclase grains.

5.3.3. Domain III: Nico Pérez Terrane and Dom Feliciano Belt

5.3.3.1. Nico Pérez Terrane

Granulites exhibit granoblastic textures in feldspars and pyroxenes. In the western Nico Pérez Terrane, feldspar shows evidence of localized recrystallization along the edges. Quartz develops sutured boundaries and occasionally triple junctions. Chessboard extinction is frequent, and subgrain formation is sometimes present.

The Illescas granite displays porphyritic to equigranular textures. Quartz exhibits chessboard extinction, whereas plagioclase shows occasionally bent twinning. In the NNW-trending

protomylonitic belts that affect this granitoid in the west, quartz shows recrystallized bulges along grain boundaries with local evidences of subgrain rotation as well as deformation bands and fracturing. Feldspars exhibit only significant fracturing.

5.4. Strain analysis

5.4.1. Passive markers

The Florida doleritic dyke swarm has a regional strike of *ca.* 060° and thus is considered as a passive marker for strain associated with the dextral shearing. The analysis was carried out with the Mohr circle method of Lisle (2014), which is supported by previous models (Ramsay, 1980). Based on the orientation of a deformed and undeformed passive marker and the mylonitic foliation, the method allows obtaining a 2D graphical solution for the shear zone strain. Figure 5.9a shows a schematic representation of the geometrical relationships of the shear zone boundary (x), the orientation of the deformed and undeformed dykes (m' and m , respectively) and the orientation of the mylonitic foliation (S_1).

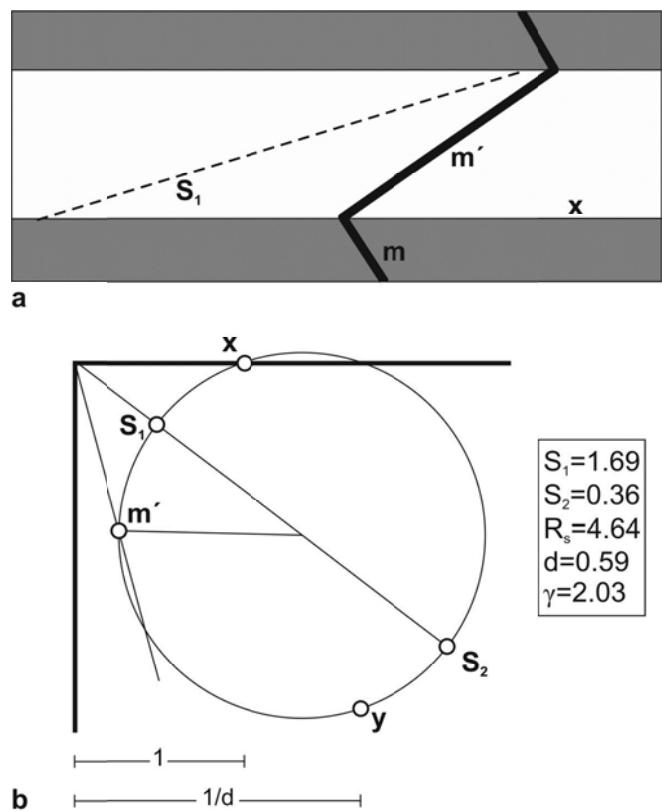

Fig. 5.9: Schematic representation of the dataset (a) and Mohr circle construction (b) used for the strain estimation based on the method of Lisle (2014). The structural elements (x: shear zone boundary; m' and m : orientation of the deformed and undeformed dykes, respectively; S_1 : orientation of the mylonitic foliation) as well as the obtained parameters are shown (S_1 and S_2 : main stretching axes, R_s : strain ratio, d : proportional volume change, γ : shear strain).

The easternmost outcrops, where both dykes and mylonitic foliation could be measured in the field, were used for the analysis ($m^m' = 75^\circ$, $x^S_1 = 17^\circ$, $x^m' = 35^\circ$). Therefore, values presented herein represent minimum estimates because deformation increases further to the east, where the mylonitic belt is present but no dykes were recognized (Fig. 5.2).

The obtained geometrical solution and the calculated values are presented in Fig. 5.9b. On the basis of these results, a significant deviation from simple shear is observed, with a 41 % volume decrease and a shear strain of 2.03. However, volume loss should be even higher considering the strain within the dykes themselves, whereas shear strain is heterogeneously distributed and even higher towards the shear zone.

5.4.2. *S-C'* shear bands

A quantitative strain analysis of the Sarandí del Yí mylonites was carried out on the basis of the method of Kurz and Northrup (2008), which allows to estimate vorticity values in thin sections on the basis of the angle between the mylonitic foliation (S) and the maximum inclined shear band orientation (C'). Within high-strain rocks, the most steeply inclined shear band orientation provides the best estimate of the bulk kinematic vorticity W_k . Consequently, S-C' shear band measurements allow characterizing the coaxiality/non-coaxiality of general shear.

W_k values range between 0.00 and 0.24, considering the maximum inclined shear band orientation for each sample (Fig. 5.10). Since these values indicate a proportion of simple shear lower than 15%, pure-shear dominated deformation related to sinistral shearing of the shear zone is inferred.

5.5. Quartz CPO patterns

Samples of the mylonites were collected to analyse the CPO of quartz. All samples were obtained from the Sarandí del Yí Shear Zone, except AA-12, which corresponds to the mylonites of the easternmost Piedra Alta Terrane. Sample locations are presented in Appendix 1.

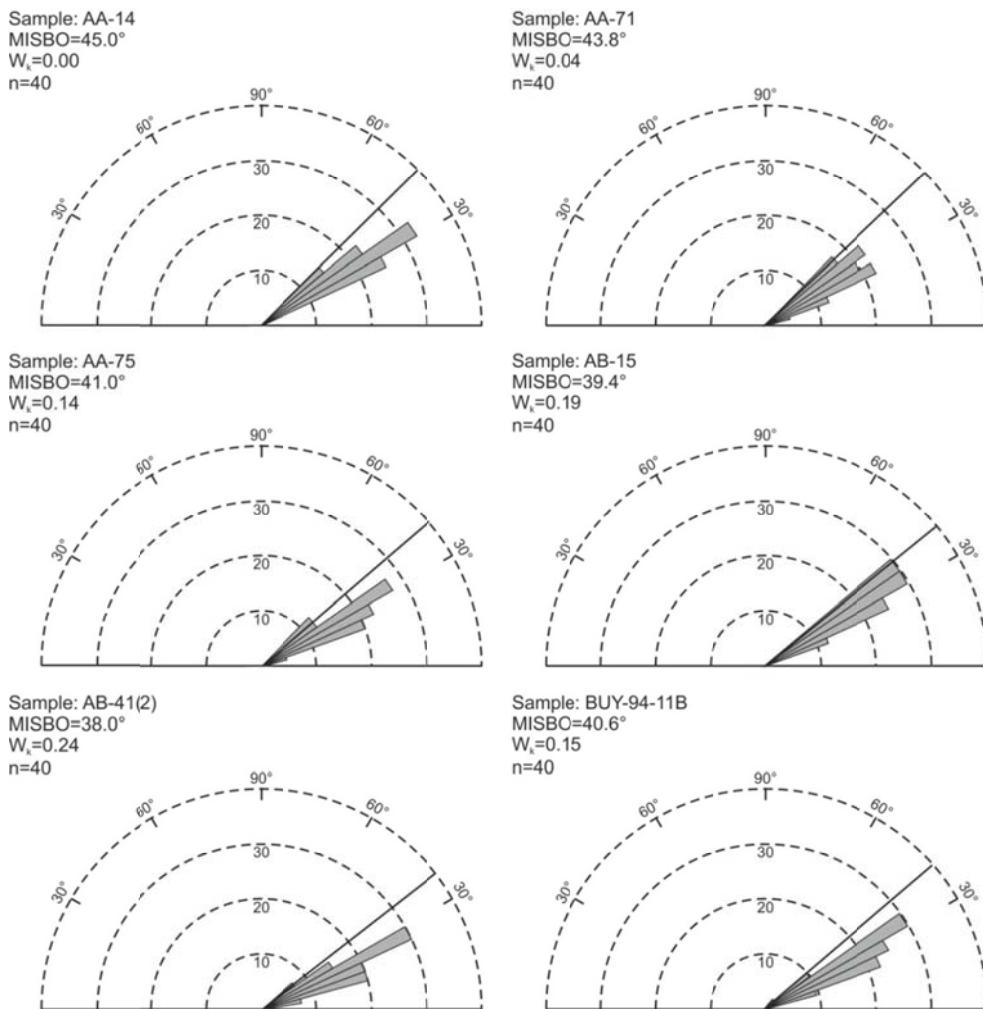

Fig. 5.10: Rose diagrams of synthetic S-C' shear bands orientations according to the method of Kurz and Northrup (2008). Frequency is indicated in percentage. The full line shows the orientation of the maximum inclined shear band orientation (MISBO). W_k : bulk kinematic vorticity, n : number of measurements.

Quartz [c]-axis pole figures show crossed girdles with well-defined maxima subparallel to the Y direction, which are accompanied by girdle distributions of {a}- and {m}-planes perpendicular to Y (Fig. 5.11). These data would account for prism $\langle a \rangle$ as the main slip system during the mylonitization. Relative symmetric textures indicate pure-shear dominated deformation, according to criteria from Schmid and Casey (1986). However, the weak asymmetry of the [c]-axis pole figure of the sample AA-12 indicates a dextral shear sense. Despite the low reliability of quartz [c]-axis pole figures as shear sense indicators (Killian et al., 2011), these data match kinematic indicators obtained in these mylonites.

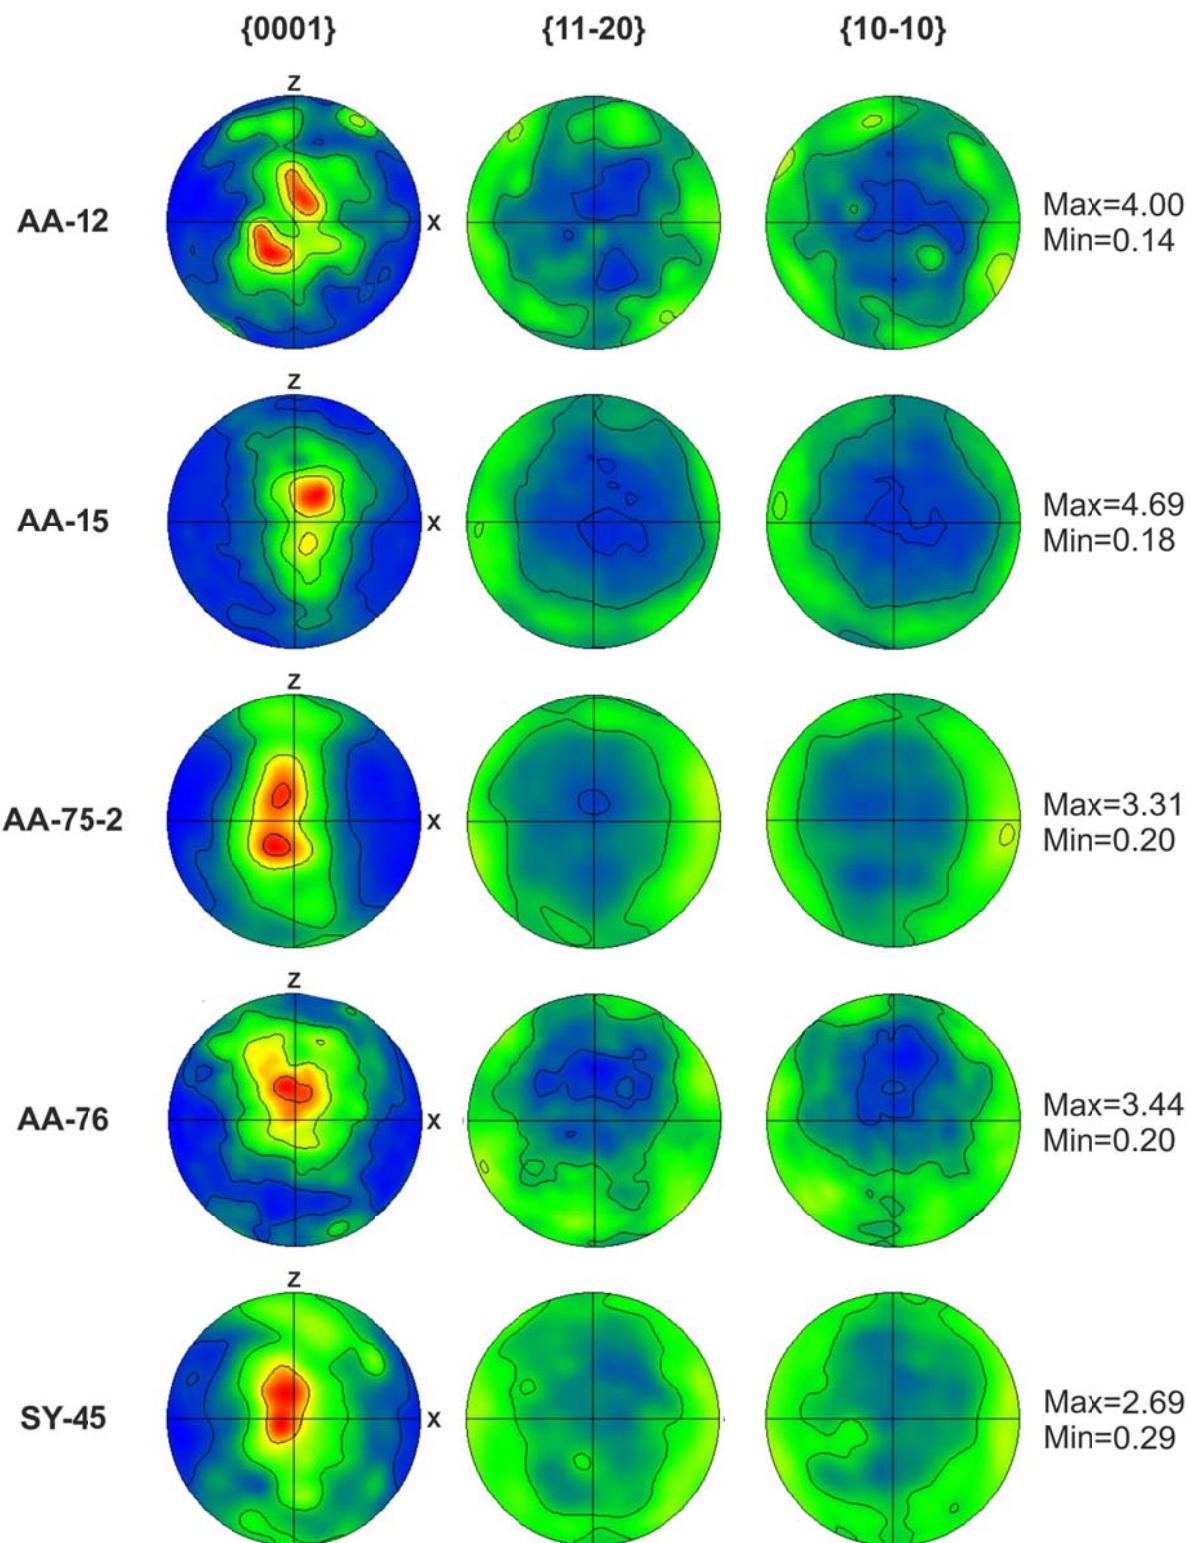

Fig. 5.11: Quartz CPO pole figures from samples of the mylonites. All samples correspond to the Sarandí del Yí Shear Zone, except for AA-12 that represents the mylonites of the easternmost Piedra Alta Terrane. Pole of the foliation (Z) and the lineation (X) are marked. Contour levels are at 0.5, 1, 2 and 3 multiples of uniform distribution (m.u.d.). Colour scaling is from blue (minimum) to red (maximum). Sample locations are indicated in Appendix 1.

5.6. Discussion

5.6.1. Deformation of the eastern Piedra Alta Terrane

On the basis of detailed mapping in the Piedra Alta Terrane, a progressive strain increase towards the east can be identified in its eastern part. This fact is documented by the increase in both the magnitude of the rotation of the dykes and the strain within them and by the presence of mylonites further to the east (Fig. 5.2). The obliquity between the mylonitic foliation and the margins of the belt, S-C' shear bands and the clockwise rotation of the dykes point to dextral shearing. Volume loss (>40%) was associated with the dextral shearing and could result either from metamorphic reactions and/or from vertical extension supported by the scarce subvertical lineations (Fig. 5.2b).

Reaction of pyroxene and plagioclase to hornblende, plagioclase, chlorite, epidote, clinozoisite, muscovite-sericite, biotite, quartz and opaque minerals in the strained dykes indicates maximum amphibolite facies metamorphism during the shearing event. Quartz microstructures observed in the wall-rock account for grain boundary migration recrystallization, probably at temperatures above 600°C due to the presence of chessboard pattern extinction (Kruhl, 1996; Stipp et al., 2002). Recrystallization and formation of subgrains along the edges of feldspars indicate deformation conditions above ca. 550°C (Völl, 1976; Pryer, 1993). Furthermore, quartz microstructures in the mylonites indicating grain boundary migration recrystallization associated with prism $\langle a \rangle$ slip detected by CPO patterns point to deformation conditions between 500 and 650°C (Mainprice et al., 1986; Stipp et al., 2002). Therefore, the dextral shearing in the eastern margin of the Piedra Alta Terrane is interpreted to occur under middle to upper amphibolite facies conditions (ca. 600-650°C).

5.6.2. Deformation of the Sarandí del Yí Shear Zone

Both macro- and microindicators are indicative of sinistral shear for the Sarandí del Yí Shear Zone. Likewise, the dominance of protomylonites to the west and ultramylonites to the east as well

as the concentration of tight to isoclinal folds in the easternmost shear zone indicates a strain increase towards the east.

No switching in the orientation of the lineation with progressive deformation is observed, suggesting flattening with both vertical and lateral extension (Sengupta and Ghosh, 2004). Pure-shear dominated deformation with flattening is also indicated by the orientation of folds axes and planes (Jones et al., 2004) and supported by the W_k values obtained by the strain analysis of the S-C' shear bands as well as the quartz CPO fabrics (Schmid and Casey, 1986). This is further constrained by strain data from Oyhantçabal et al. (2001), which suggest pure-shear dominated deformation under magmatic conditions during the emplacement of the synkinematic Solís de Mataojo Granitic Complex. Therefore, pure-shear dominated deformation with a subordinated sinistral strike-slip component is interpreted for the Sarandí del Yí Shear Zone.

The abundance of core and mantle structures in feldspars with new grains sometimes also within internal microshear zones accounts for dislocation climb and recrystallization of feldspars at temperatures of 450-550°C (Passchier and Trouw, 2005, and references therein). Quartz microstructures denote dominant diffusion processes and recrystallization due to grain boundary migration, also indicated by quartz CPO data. However, local evidence of subgrain rotation recrystallization, particularly in folds, may support a late activity of this mechanism; hence, deformation conditions probably occurred at grain boundary migration recrystallization conditions near the transition with the subgrain rotation regime (450-550°C; Stipp et al., 2002). On the other hand, formation of synkinematic white mica is interpreted to have taken place due to the breakdown of feldspar, which points to temperatures below 500°C (Wiberley, 1999, and references therein). Deformation conditions during sinistral shearing can thus be constrained to lower amphibolite to upper greenschist facies conditions (*ca.* 550-450°C). Lastly, a significant cataclastic reworking is observed in the Sarandí del Yí Shear Zone. The mineral association indicates greenschist to subgreenschist conditions during this event.

5.6.3. Structural evolution of the Sarandí del Yí Shear Zone

Heterogeneous shear zones are characterized by lateral variations of strain parameters, generally with strain increase towards the core of the shear zone. However, long-lived shear zones may show not only spatial but also temporal variations of strain. Shear zones can thus be classified based on thickness variation with time (Means, 1984, 1995; Hull, 1988; Horsman and Tikoff, 2007; Vitale and Mazzoli, 2008). Increasing and decreasing thickness may be interpreted in terms of strain hardening and softening, respectively, that in turn can result from the combination of different deformation conditions and processes.

Since deformation of the eastern margin of the Piedra Alta Terrane seems to be related to the evolution of the Sarandí del Yí Shear Zone, a polyphase evolution can be interpreted (Fig. 5.12). Cross-cutting relationships indicate retrograde conditions (e.g., mylonitic protoliths in the cataclasites) associated with progressive strain localization towards the east. In this context, a first phase of dextral shearing took place under middle to upper amphibolite facies conditions (Fig. 5.12a). A subsequent sinistral event under lower amphibolite to upper greenschist facies conditions reworked the eastern margin of the shear zone giving rise to the development of the Sarandí del Yí mylonitic belt (Fig. 5.12b). During this stage, more localized strain in the easternmost part of the shear zone gave rise to the development of late folded mylonitic foliation. This high strain zone was then overprinted by cataclasis (Fig. 5.12c).

This evolutionary model is thus comparable with the conceptual model of Sibson (1977, 1983) and natural examples such as the Nordre Strømfjord Shear Zone (Bak et al., 1975), the Great Slave Lake Shear Zone (Hanmer, 1988) and the Imbricate Zone and the Stortrømmen Shear Zone (Smith et al., 2007), among others. Consequently, the Sarandí del Yí Shear Zone represents an example of shear zone with thickness decreasing in time that evolved from upper amphibolite to subgreenschist facies conditions and records a kinematic switch from dextral to sinistral shear at ca. 600-550°C.

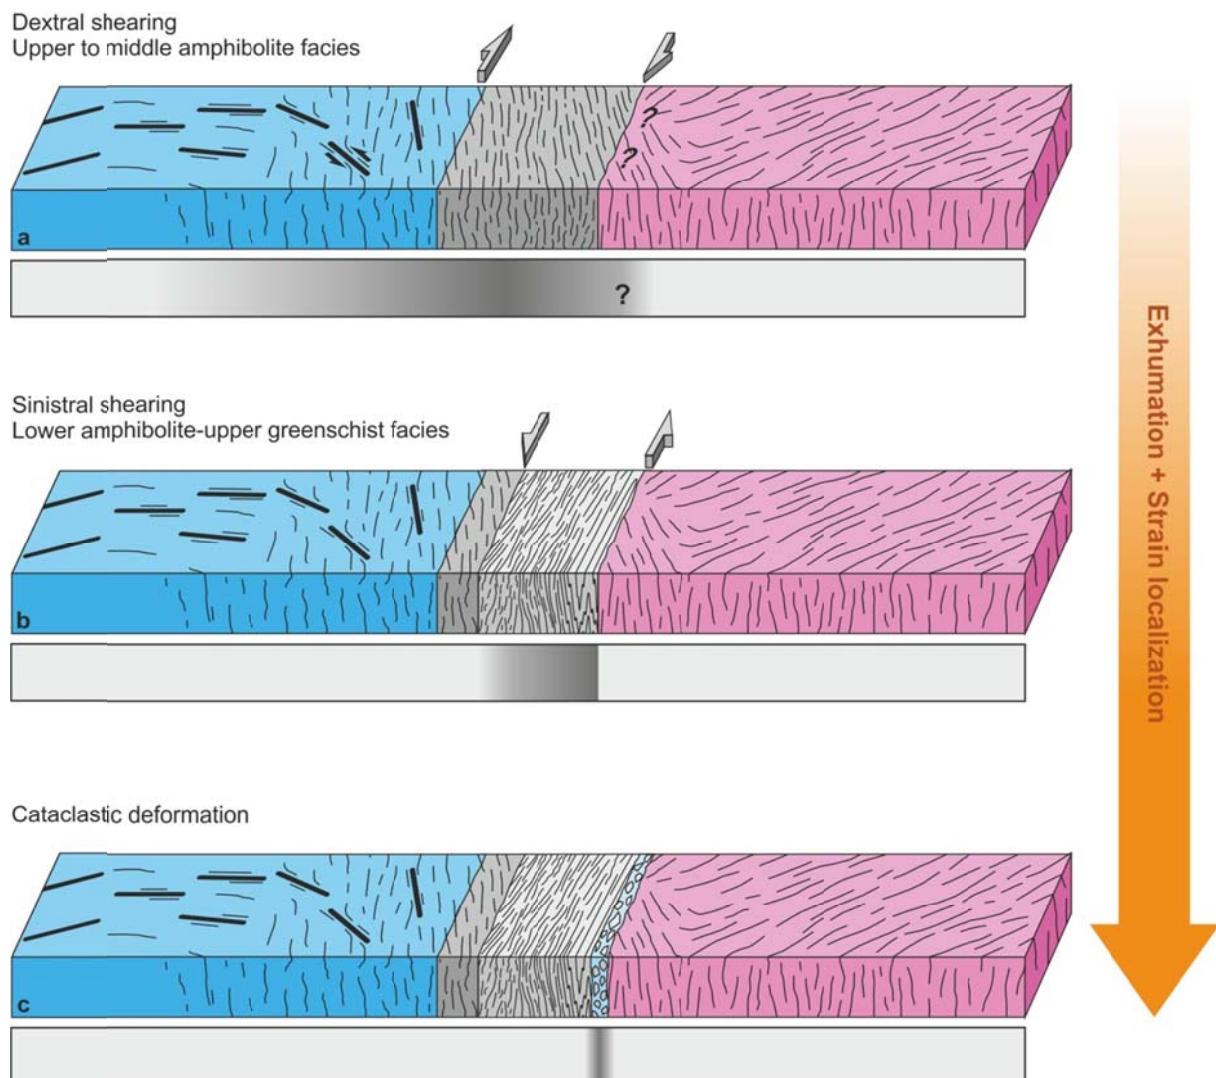

Fig. 5.12: Structural evolution of the Sarandí del Yí Shear Zone related to progressive strain localization under retrograde conditions. Schematic strain distribution is indicated with the grey scale (darker colours indicate higher strain).

The preservation of deformation of the Sarandí del Yí Shear Zone under different conditions is related to progressive strain localization linked to strain softening processes. In this case, the nucleation of the shear zone may be controlled by the presence of a former terrane boundary that started to evolve as a shear zone after continental collision (Oyhantçabal et al., 2011a). Towards the eastern part of the Piedra Alta Terrane, a mylonitic foliation and grain size reduction are observed and can be considered as responsible for the strain softening (Platt and Behr, 2011a; Rennie et al., 2013; Sullivan et al., 2013). Subsequently, the zone with the highest strain was reactivated during exhumation, obliterating the previous fabric that was only preserved in lower strain domains. Such

domains may have experienced only partial annealing but no significant deformation during retrograde conditions, as schematized by Herwegh et al. (2008).

5.7. Conclusions

Integration of macro- to microstructural data indicates that the Sarandí del Yí Shear Zone represents a crustal-scale shear zone that underwent complex long-term deformation. During juxtaposition of the Piedra Alta (Río de la Plata Craton) and Nico Pérez terranes, deformation in the Sarandí del Yí Shear Zone started under upper to middle amphibolite facies conditions with dextral shearing in the easternmost Piedra Alta Terrane. Subsequent lower amphibolite-upper greenschist facies metamorphism was related to pure-shear dominated sinistral shearing, which was accompanied by contemporaneous plutonism reflected by the Solís de Mataojo Granitic Complex. Post-mylonitization magmatism is indicated by the Cerro Caperuza granite. Afterwards, a late cataclastic event took place and reworked the easternmost border of the shear zone.

The evolution of the shear zone reflects progressive strain localization under retrograde metamorphic conditions during crustal exhumation. Furthermore, strain localization also resulted in decrease in the shear zone thickness.

-CHAPTER 6-**Geochronology of the Sarandí del Yí Shear Zone****6.1. Introduction**

Exhumed long-lived shear zones represent fundamental structures that allow studying the coupling between crustal exhumation and strain localization processes as well as the timing at which they take place in the lithosphere. However, assessing the age of the deformation is not a simple task, due to the overprinting caused by the youngest events that may reset the isotopic systems that are used as thermochronometers. It is even more complex to integrate geochronological with macro- and microstructural data as well as kinematics in order to create a robust model of the tectonometamorphic evolution of shear zones, which can further constrain the evolution at the orogen-scale.

Several methods can be applied to study the temperature-time (T-t) paths of metamorphic rocks, which are based on closure temperatures of isotopic geochronometers (Table 6.1; Dodson, 1973; Villa, 1998). The most widespread methods to constrain the age of the deformation in shear zones consist in either dating synkinematic intrusions or minerals that were formed during mylonitization, or constraining the T-t paths of adjacent blocks (van der Pluijm et al., 1994). All these methods, though potentially powerful, have some limitations. Dating synkinematic intrusions represents an indirect and interpretative method (van der Pluijm et al., 1994), whereas dating minerals in the mylonites themselves may be limited by the problem of whether these ages represent neocrystallization or cooling ages (Dunlap, 1997; Mulch and Cosca, 2004). On the other hand, establishing T-t paths of neighbouring blocks may be helpful but nevertheless indirect and, in many cases, difficult to obtain due to the lack of equivalent datable minerals associations on both sides of the shear zones.

As previously indicated (Chapter 5), no geochronological data are available for the mylonites of the Sarandí del Yí Shear Zone. Though the sinistral shearing is considered to be Neoproterozoic in age due to the emplacement of the synkinematic Solís de Mataojo Granitic Complex (580 ± 15 Ma,

Rb-Sr whole rock, Umpierre and Halpern, 1971; 584 ± 13 Ma, single phase Pb-Pb stepwise leaching titanite, Oyhantçabal et al., 2007), the timing of the dextral shearing is not well constrained. This first event took place prior to the Neoproterozoic sinistral shearing and also postdates the emplacement of the 1.79 Ga old Florida doleritic dyke swarm (Teixeira et al., 1999, 2013; Halls et al., 2001), as these dykes are dextrally sheared towards the shear zone (Chapter 5; Oyhantçabal et al., 1993; Oriolo et al., 2015). Therefore, the onset of the deformation during accretion of the Nico Pérez Terrane to the eastern margin of the Río de la Plata Craton could be placed at any time between the late Paleoproterozoic (< 1.79 Ga) and the Ediacaran.

6.2. Sample description

Samples AA-13, BUY-81-11, BUY-84-11, BUY-92-11, BUY-93-11 and BUY-94-11 were collected from mylonites of the Sarandí del Yí Shear Zone itself (Fig. 6.1, Appendix 2). On the other hand, AA-12 corresponds to a granitic mylonite located in the easternmost Piedra Alta Terrane, which was deformed during dextral shearing along the shear zone. A sample (UY-22-14) from the Cerro Caperuza granite was obtained as well (Fig. 5.4), as it intrudes the shear zone and shows no significant ductile deformation, thus providing a constraint on the end of the mylonitization. Sample locations and applied methods are presented in Appendix 2.

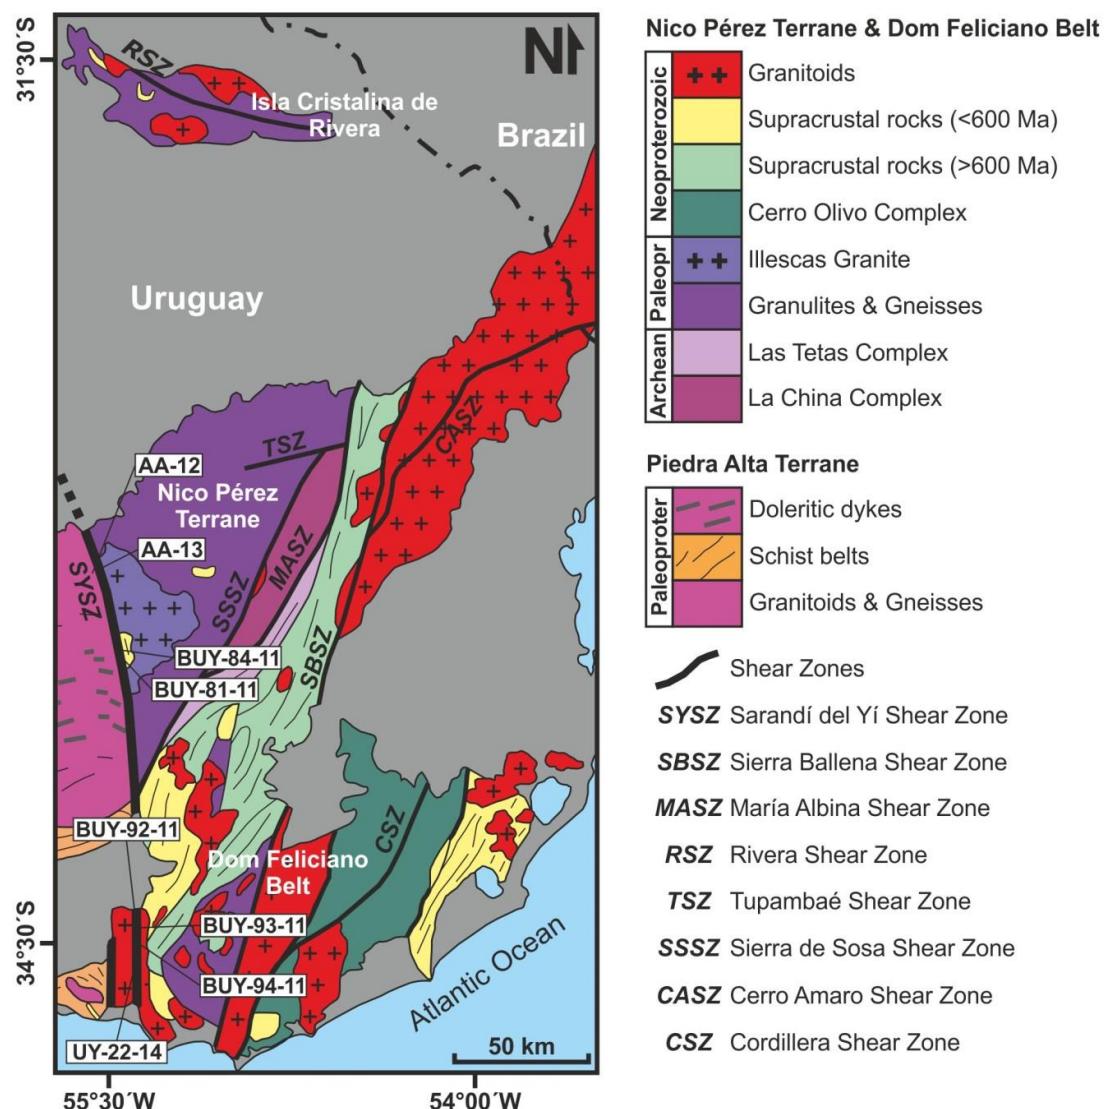

Fig. 6.1: Geological map of the Nico Pérez Terrane and adjacent blocks (modified after Oyhantçabal et al., 2011a, and references therein). Sample locations are shown.

The sample AA-12 corresponds to a mylonite made up of quartz, K-feldspar, plagioclase, hornblende and biotite. Quartz shows interlobate grain boundaries, left-over grains and minor chessboard extinction, which accounts for grain boundary migration recrystallization at temperatures above ca. 600°C (Kruhl, 1996; Stipp et al., 2002). Feldspars exhibit local recrystallization along the edge of the grains, indicating recrystallization temperatures above 550°C (Völl, 1976; Pryer, 1993). Biotite and hornblende are preferentially oriented in two planes that define the S and C' of dextral shear bands, which are also observable at mesoscale. Hornblende crystals are typically euhedral and present only minor fracturing.

The sample AA-13 from a granitic mylonite is made up of quartz, K-feldspar and plagioclase. S-C' shear bands and feldspar σ -type mantled porphyroblast microstructures indicate sinistral shearing. Sutured grain boundaries point to grain boundary migration recrystallization in quartz, although minor evidences of subgrain rotation recrystallization can be recognized as well, indicating recrystallization temperatures of 450-550°C (Stipp et al., 2002). Feldspars develop core and mantle structures with occasionally anti-bookshelf structures, indicating temperatures of 450-550°C (Passchier and Trouw, 2005, and references therein). Scarce sericite and epidote are also present along shear band planes.

The mylonite of the sample BUY-81-11 is constituted by quartz, K-feldspar, plagioclase and hornblende. Sutured grain boundaries point to grain boundary migration recrystallization at ca. 500-550°C for quartz (Stipp et al., 2002). Core and mantle structures in feldspars reveal sinistral shearing both at meso- and microscale and point to recrystallization temperatures of 450-550°C (Passchier and Trouw, 2005, and references therein). Hornblende crystals present significant fracturing and are sometimes boudinaged parallel to the stretching lineation direction.

The sample BUY-84-11 is an ultramylonite constituted by quartz, feldspar and sericite. Quartz crystals form aggregates with foam textures indicating recovery. Core and mantle structures in feldspars show sinistral shearing and point to recrystallization temperatures of 450-550°C (Passchier and Trouw, 2005, and references therein). Pressure solution is revealed by the presence of opaque-minerals-rich solution seams.

UY-22-14 corresponds to the Cerro Caperuza granite, which presents equigranular texture and is constituted by quartz, K-feldspar, plagioclase and scarce biotite.

The deformed porphyritic felsic intrusion of the sample BUY-93-11 is made up of quartz and feldspar. Sutured grain boundaries point to grain boundary migration recrystallization at ca. 500-550°C for quartz (Stipp et al., 2002). Core and mantle structures in feldspars reveal sinistral shearing and recrystallization temperatures of 450-550°C (Passchier and Trouw, 2005, and references therein).

Both BUY-92-11 and BUY-94-11 correspond to mylonites, which are constituted by quartz, K-feldspar, plagioclase and muscovite. Sinistral shearing is indicated by S-C' shear bands, σ -type feldspar mantled porphyroclasts with asymmetric myrmekites, mica fish and oblique foliation of elongated quartz grains. S-C' shear bands and σ -type feldspar mantled porphyroclasts are also observable at mesoscale. Sutured grain boundaries point to grain boundary migration recrystallization in quartz and recrystallization temperatures of 500-550°C (Stipp et al., 2002). Feldspars develop core and mantle structures, which are sometimes accompanied by microshear zones that show internal recrystallization, indicating temperatures of 450-550°C (Passchier and Trouw, 2005, and references therein). Muscovite typically develops mica fish microstructures and is oriented parallel to the S or C' planes of the shear bands in the mylonites, suggesting that they are synkinematic minerals. This interpretation is further supported by the lack of muscovite in the protolith of the mylonites, i.e., the Solís de Mataojo Granitic Complex. Locally, solution seams parallel to shear band planes can be recognized as well. They are made up of fine-grained aggregates of biotite and opaque minerals.

6.3. Results

6.3.1. U-Pb geochronology and Hf isotopes

Zircons from the sample AA-12 are typically prismatic to equant and show oscillatory zoning, sometimes with homogeneous bright cores (Fig. 6.2a). A concordant age of 596.0 ± 3.3 Ma was obtained considering 15 out of 24 spots (Fig. 6.3a, data points with low correlation coefficients rejected), which is interpreted as the crystallization age of the magmatic protolith. Titanites, in turn, show a slightly older concordant age of 602.7 ± 4.3 Ma (18 out of 19 points), which seems to reflect the crystallization age of the protolith as well (Fig. 6.4a).

In the case of AA-13, zircons present oscillatory zoning as well as homogeneous dark or bright cores (Fig. 6.2b). A 2048.3 ± 11.0 Ma concordia age is interpreted as the age of the crystallization of the magmatic protolith based on 23 out of 26 data points (Fig. 6.3b, discordant data

rejected). In addition, Hf model ages (T_{DM}) between 2.20 and 2.47 Ga as well as $\epsilon_{Hf}(t1)$ between +2.26 and +7.23 were obtained for the zircons (Fig. 6.3c, Appendix 4). On the other hand, a concordant titanite age of 588.0 ± 7.1 Ma (7 out of 19 spots, discordant data or with high common ^{206}Pb content rejected) seems to represent the timing of the metamorphism associated with sinistral shearing (Fig. 6.4b), although microstructures indicates deformation temperatures slightly lower than the titanite closure temperature. Inheritance is recorded as well, as two titanite grains yield $^{207}Pb/^{206}Pb$ ages of ca. 2.05 Ga (Appendix 3).

Zircons from BUY-81-11 are prismatic and, in some cases, fragmented. Cores are dominantly homogeneous (Fig. 6.2c) and present a weighted mean $^{207}Pb/^{206}Pb$ age of 2025 ± 37 Ma (Fig. 6.3d, 6 spots, discordant data rejected). On the other hand, oscillatory zoning is found in the rims, which show a concordant age of 623.0 ± 5.1 Ma based on 6 out of 15 data points (Fig. 6.3e, data with high U or common ^{206}Pb content rejected).

Zircons from BUY-84-11 are prismatic and occasionally round, and exhibit homogeneous dark cores surrounded by overgrowths with oscillatory zoning (Fig. 6.2d). A concordia age of 2068.9 ± 4.2 Ma considering 6 out of 8 spots is interpreted as the crystallization age of the magmatic protolith, which is recorded in both cores and overgrowths (Fig. 6.3f, discordant data rejected).

In the Cerro Caperuza granite (sample UY-22-14), zircons are prismatic with oscillatory zoning and present a concordant age of 570.9 ± 11.0 Ma considering 5 out of 26 data points (Fig. 6.2e, 6.3g, highly discordant data or with high U or common ^{206}Pb content rejected). Some spots show slightly older concordant ages that may indicate reworking of magmatic zircons with ages between ca. 620-580 Ma (Fig. 6.3g).

Prismatic to slightly rounded zircons with cores that are either homogeneous or zoned were recognized for BUY-93-11. Homogeneous bright cores present a weighted mean $^{207}Pb/^{206}Pb$ age of 2115 ± 38 Ma (Fig. 6.3h, 7 out of 26 spots). 3 points measured in overgrowths with oscillatory zoning exhibit a concordant age of 589.1 ± 1.5 Ma (Fig. 6.2f, 6.3i, highly discordant data or with high U or common ^{206}Pb content rejected).

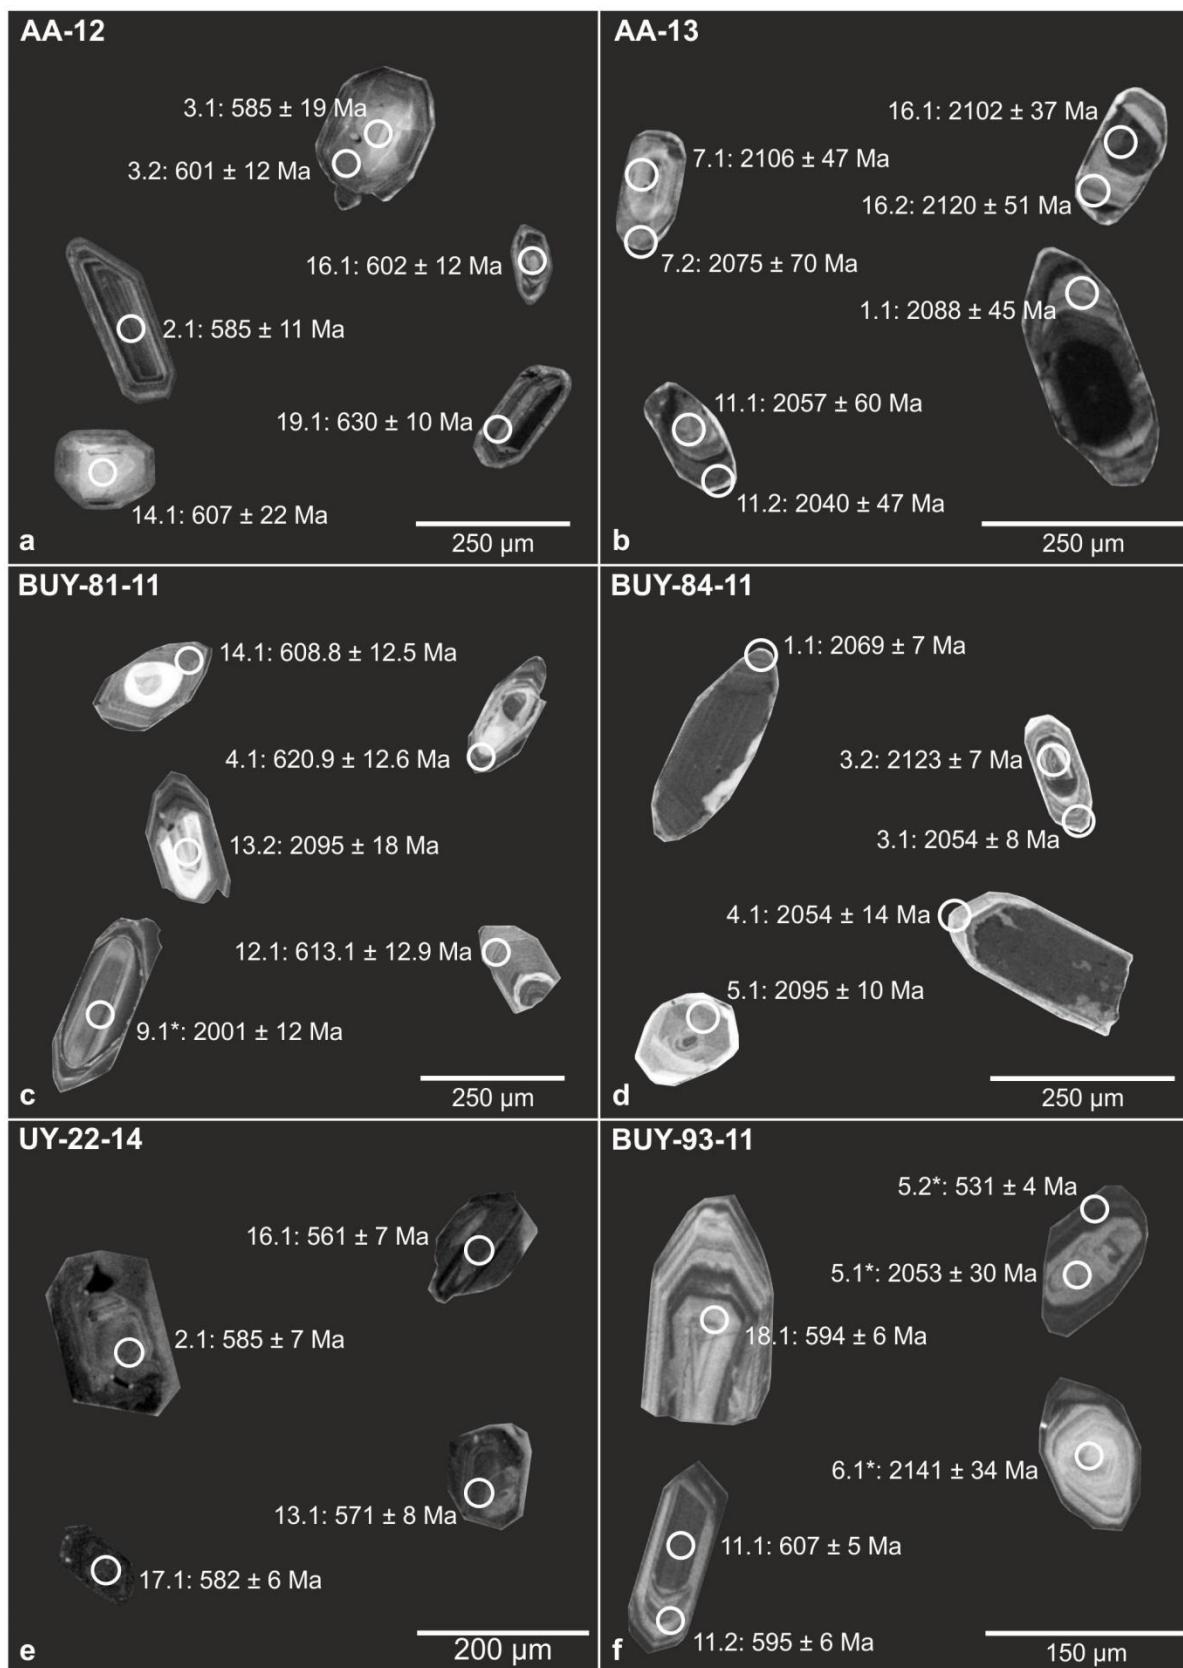

Fig. 6.2: Cathodoluminescence (CL) images of representative zircons. Individual U-Pb ages are shown. Asterisks indicates discordant ages.

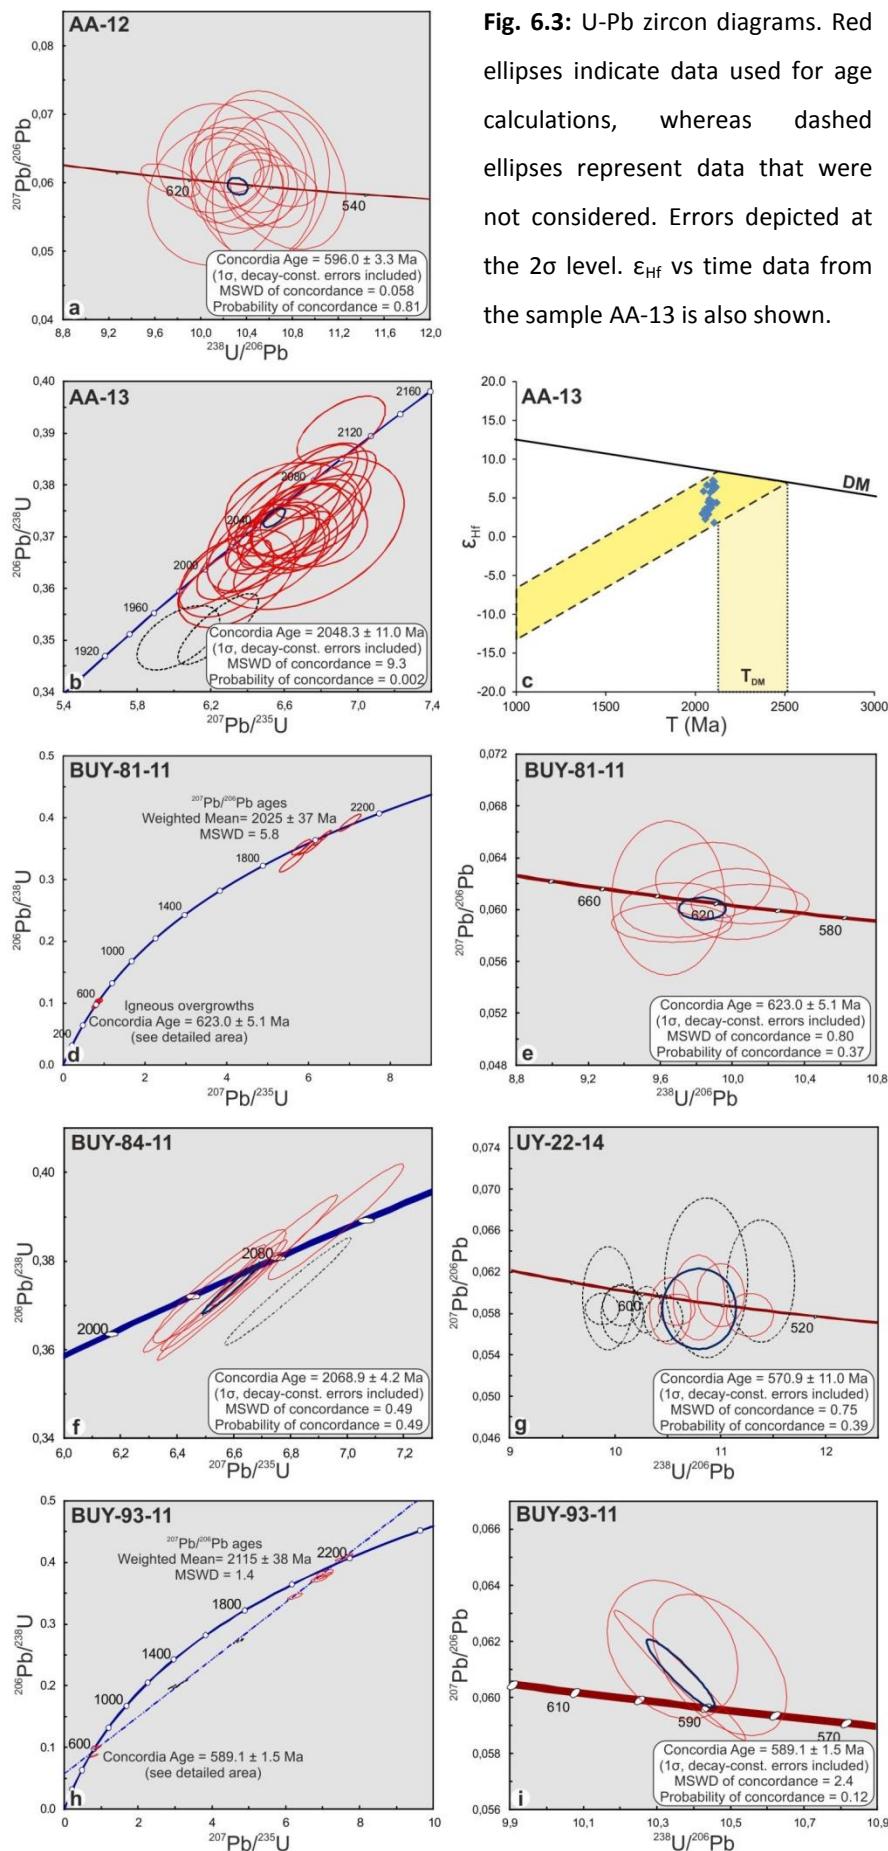

Fig. 6.3: U-Pb zircon diagrams. Red ellipses indicate data used for age calculations, whereas dashed ellipses represent data that were not considered. Errors depicted at the 2σ level. ϵ_{Hf} vs time data from the sample AA-13 is also shown.

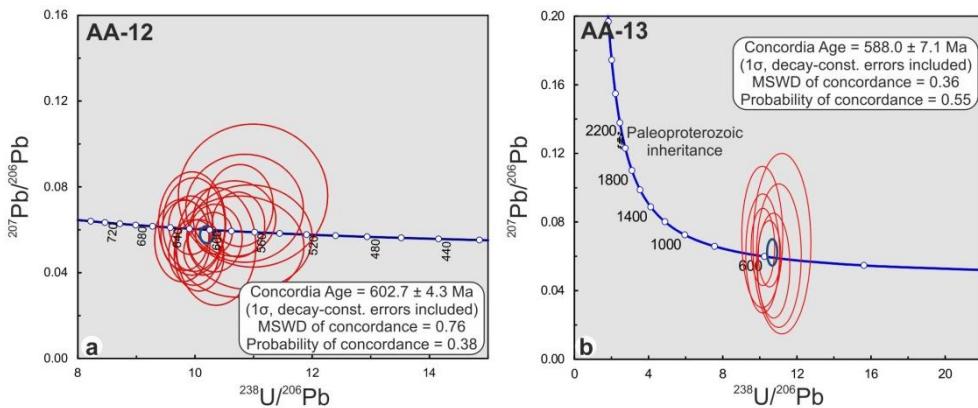

Fig. 6.4: U-Pb titanite diagrams. Red ellipses indicate data used for age calculations, whereas dashed ellipses represent data that were not considered. Errors depicted at the 2σ level.

6.3.2. $^{40}\text{Ar}/^{39}\text{Ar}$

A hornblende plateau age of 600.1 ± 3.4 Ma was obtained for the sample AA-12, whereas the sample BUY-81-11 presents a hornblende plateau age of 590.2 ± 2.6 Ma (Fig. 6.5a, 6.5b). On the other hand, the white mica concentrates yield plateau ages of 594.41 ± 0.98 Ma and 587.6 ± 1.5 Ma for the samples BUY-92-11 and BUY-94-11, respectively (Fig. 6.5c, 6.5d).

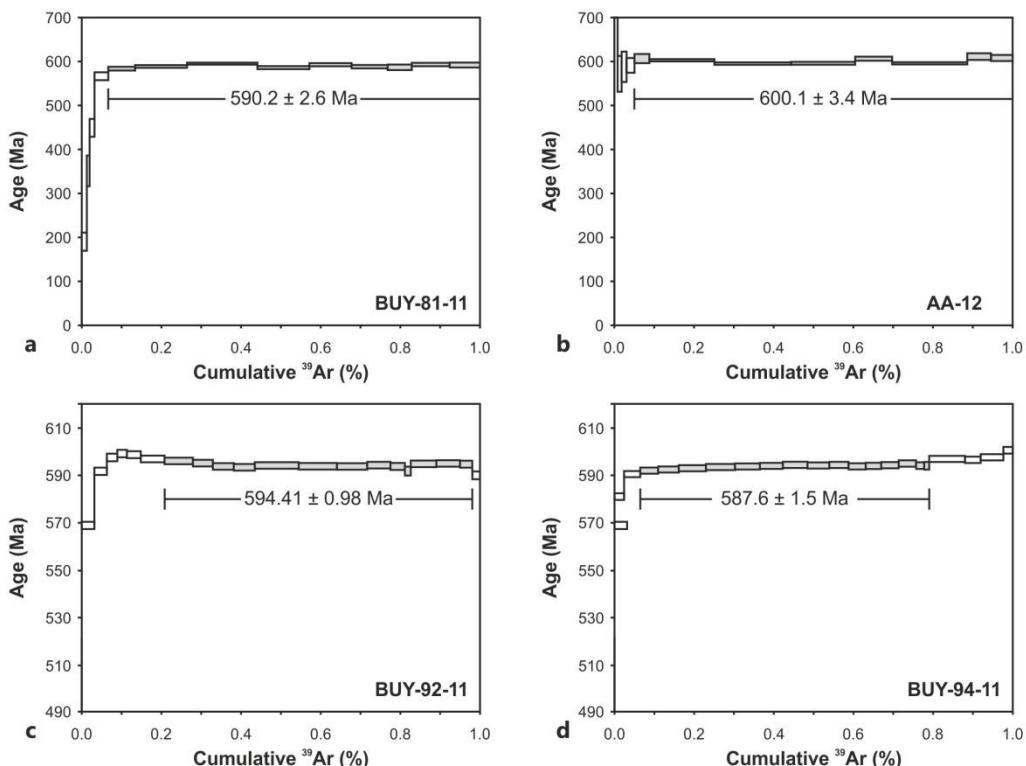

Fig. 6.5: Ar/Ar age spectrum from hornblende and muscovite samples. Plateau steps are colored in grey whereas rejected steps are indicated in white.

6.3.3. Rb-Sr

Two Rb-Sr isochrone ages were defined by muscovite and WR concentrates from the same muscovite samples that were analysed using the $^{40}\text{Ar}/^{39}\text{Ar}$ method. The sample BUY-92-11 shows an age of 566.1 ± 2.9 Ma, whereas the sample BUY-94-11 presents an age of 566.6 ± 2.9 Ma (Appendix 5).

6.4. Discussion

6.4.1. Protolith petrogenesis

U-Pb zircon data reveal two protoliths generated during the Paleo- and the Neoproterozoic. However, no significant textural differences are observed between both zircon groups. Zircons are prismatic and occasionally round with oscillatory zoning and $\text{Th}/\text{U} > 0.1$ (Fig. 6.2, Appendix 3), which is indicative of a magmatic origin (Hoskin and Schaltegger, 2003, and references therein). As deformation conditions along the Sarandí del Yí Shear Zone did not surpass amphibolite facies conditions (Chapter 5), U-Pb zircon ages are interpreted to represent the age of the magmatic protolith rather than a direct age constraint on the deformation along the shear zone.

Two concordant ages of 2048.3 ± 11.0 Ma (sample AA-13) and 2068.9 ± 4.2 Ma (sample BUY-84-11) as well as two $^{207}\text{Pb}/^{206}\text{Pb}$ weighted mean ages of 2025 ± 37 Ma (sample BUY-81-11) and 2115 ± 38 Ma (sample BUY-93-11) provide evidence of a late Rhyacian-early Orosirian magmatic event and are equivalent to ages of granitoids and gneisses of the basement of the Piedra Alta Terrane (Fig. 6.3; Hartmann et al., 2000a; Santos et al., 2003; Peel and Preciozzi, 2006). Hf isotopes from the zircons of the sample AA-13 yield a T_{DM} age range from 2.20 to 2.47 Ga as well as $\epsilon_{\text{Hf}}(t_1)$ between +2.26 and +7.23 (Fig. 6.3c), which indicates contribution of Paleoproterozoic juvenile continental crust. Hf isotopes from the Cerro Colorado granite (eastern Piedra Alta Terrane) are identical (Fig. 3.6) and similar Sm-Nd model ages were obtained in different intrusions of the Piedra Alta Terrane as well (Peel and Preciozzi, 2006), thus supporting a crustal affinity of the mylonitic protolith with the Piedra Alta Terrane.

On the other hand, Neoproterozoic concordant ages of 596.0 ± 3.3 Ma (sample AA-12), 623.0 ± 5.1 Ma (sample BUY-81-11) and 589.1 ± 1.5 Ma (sample BUY-93-11) were obtained in three samples (Fig. 6.3). The zircons of AA-12 yield only Neoproterozoic ages, but BUY-81-11 and BUY-93-11 also show inheritance of Paleoproterozoic zircons (Fig. 6.3, Appendix 3). In addition, Neoproterozoic ages in BUY-81-11 zircons were only detected in overgrowths, whereas BUY-93-11 contains Neoproterozoic neoformed zircons as well (Fig. 6.2). Consequently, obtained Neoproterozoic ages may have resulted from both re-equilibration of inherited Paleoproterozoic crystals and neocrystallization in the presence of a melt (Bea et al., 2007; Geisler et al., 2007).

6.4.2. Tectonometamorphic evolution of the Sarandí del Yí Shear Zone

Despite previous works suggested a Mesoproterozoic age for the onset of the deformation (Bossi and Cingolani, 2009; Gaucher et al., 2011a), new results provide solid evidence of Neoproterozoic nucleation for the Sarandí del Yí Shear Zone (Fig. 6.6a). The only previous constraint for the dextral shearing was the bending of the 1.79 Ga old Florida doleritic dyke swarm, which provides a maximum age for this event. Results obtained for the sample AA-12 indicate dextral shearing up to 596 Ma. Similar zircon, titanite and hornblende ages together with hornblende microstructures point to emplacement and fast cooling of this intrusion below ca. 500°C during dextral shearing. Likewise, the oldest concordant age of 623.0 ± 5.1 Ma (sample BUY-81-11) represents a maximum age for magmatism related to deformation along the shear zone. This value is thus interpreted as syn- to early post-collisional magmatism related to the amalgamation of the Nico Pérez Terrane and the Río de la Plata Craton along the Sarandí del Yí Shear Zone. As this sample shows evidence of sinistral shearing at temperatures of 450-550°C, which are similar to the closure temperature for amphibole, the significantly younger $^{40}\text{Ar}/^{39}\text{Ar}$ plateau age of 590.2 ± 2.6 Ma from strongly deformed hornblende crystals may indicate reworking of these rocks and resetting of the K-Ar system at ca. 590 Ma. This is also supported by structural evidence indicating progressive strain localization towards the east (Chapter 5).

The onset of deformation along the Sarandí del Yí Shear Zone at 630-625 Ma constrains the age of the amalgamation of the Nico Pérez Terrane and the Río de la Plata Craton. These results support models from Oyhantçabal et al. (2011a) and Rapela et al. (2011) considering juxtaposition of both crustal blocks during the Neoproterozoic, previously constrained by the 584 ± 13 Ma age of the Solís de Mataojo Granitic Complex (Rapela et al., 2011). Contrasting cooling age patterns on both sides of the shear zone reinforce this interpretation (Fig. 6.6c; Oyhantçabal et al., 2011a).

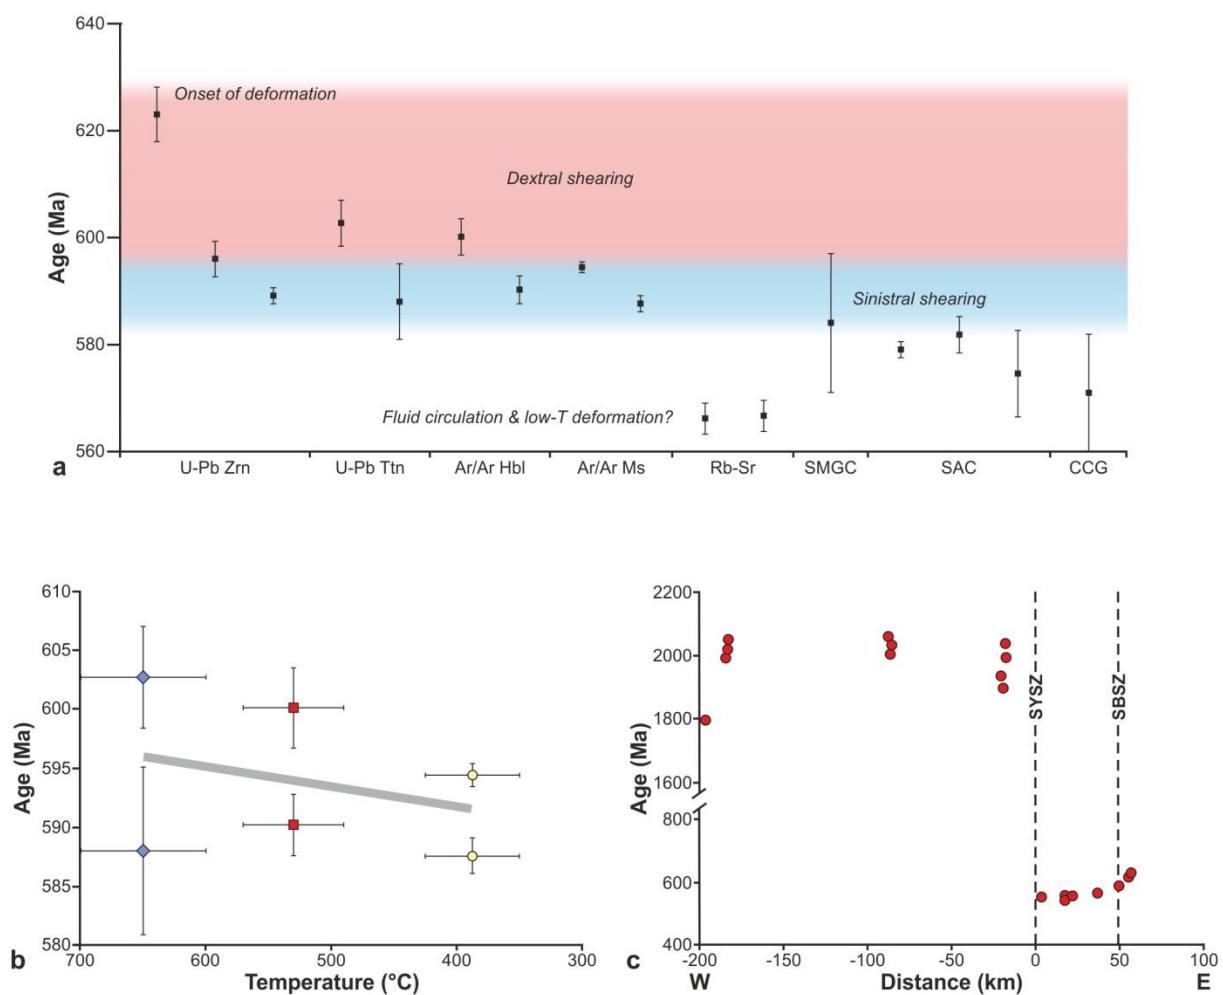

Fig. 6.6: a) Summary of geochronological data from the Sarandí del Yí Shear Zone. Ages of associated intrusions are also shown (SMGC: Solís de Mataojo Granitic Complex, Oyhantçabal et al., 2007; SAC: Sierra de las Ánimas Complex, Oyhantçabal et al., 2007; Rapalini et al., 2015; CCG: Cerro Caperuza granite, this work). The age of the dextral (red) and the sinistral shearing (blue) are indicated as well. b) t vs T plots based on titanite (blue diamonds), hornblende (red squares) and muscovite (yellow circles) data with average cooling path. Closure temperatures after references from Table 6.1. c) West-east K-Ar muscovite profile across the Piedra Alta Terrane, the Nico Pérez Terrane and the Dom Feliciano Belt (modified after Oyhantçabal et al., 2011). The position of the Sarandí del Yí Shear Zone (SYSZ) and the Sierra Ballena Shear Zone (SBSZ) are presented.

The subsequent sinistral movement was previously constrained by the age of the synkinematic Solís de Mataojo Granitic Complex (Fig. 5.4; Oyhantçabal et al., 2001, 2007). The U-Pb zircon concordant age of 589.1 ± 1.5 Ma and the titanite concordant age of 588.0 ± 7.1 Ma together with the $^{40}\text{Ar}/^{39}\text{Ar}$ hornblende plateau age of 590.2 ± 2.6 Ma of sinistrally-sheared mylonites and $^{40}\text{Ar}/^{39}\text{Ar}$ plateau ages of 594.41 ± 0.98 Ma and 587.6 ± 1.5 Ma of synkinematic muscovites constrain the sinistral shearing at ca. 594-584 Ma. As temperature conditions for the sinistral shearing are constrained at 450-550°C, which are above the closure temperature of the K-Ar system for muscovites, muscovite ages probably reflect cooling after synkinematic crystallization (Mulch and Cosca, 2004; Rolland et al., 2008).

Rb-Sr data are significantly younger than the respective $^{40}\text{Ar}/^{39}\text{Ar}$ muscovite ages. As the latter match other geochronological data as well as geological evidences (e.g., intrusion of the Cerro Caperuza granite postdating the ductile deformation along the shear zone), Rb-Sr data may not reflect true cooling stories (Jenkin, 1997). As indicated by Eberlei et al. (2015), deformation strongly affects the Rb-Sr geochronometer at <500°C. Likewise, Bozkurt et al. (2011) demonstrated that fluid-assisted deformation under cataclastic conditions may reopen this isotopic system. Local cataclastic reworking, pressure-solution and associated fluid circulation are recorded in these samples, which could account for reequilibration of the Rb-Sr system during low-temperature fluid-assisted deformation. However, $^{40}\text{Ar}/^{39}\text{Ar}$ muscovite ages seem to remain unaffected by these processes, which may suggest that Sr presents an unlikely more effective diffusivity than Ar under similar conditions. Alternatively, a more plausible explanation could be that the Rb-Sr system has remained closed for the muscovites, but was affected for the whole rock system, giving rise to whole rock-muscovite isochron ages that are younger than expected.

On the basis of titanite, hornblende and muscovite geochronological data, a cooling rate of ca. 60°C Ma^{-1} between ca. 597-592 Ma can be estimated for the Sarandí del Yí Shear Zone (Fig. 6.6b). This cooling rate may have resulted from fast exhumation during sinistral shearing. Vertical extrusion related to pure shear dominated deformation along the Sarandí del Yí Shear Zone could account for

this process (Chapter 5). Comparable cooling rates related to shearing and rapid exhumation were also reported from the Carthage-Colton Mylonite Zone of the Adirondack Mountains (Bonamici et al., 2014).

Nevertheless, the estimated cooling rates have to be considered carefully due to the complexity of the processes involved in the shearing. Particularly, the existence of several intrusions during deformation appears to be one of the most significant processes affecting isotopic systems, as the existence of magmatism reset the chronometers and true cooling paths cannot be calculated (Fig. 6.6a). In addition, strain localization during exhumation of the shear zone also induces local reworking of the mylonitic belt and consequent reset of the thermochronometers (Mulch et al., 2006). Comparison of titanite and hornblende data from the dextrally and sinistrally sheared domains show younger ages in the latter, supporting progressive strain localization towards the east inferred from structural data (Chapter 5). Consequently, recrystallization-related processes such as strain and fluids as well as magmatism play a major role in the closure of isotopic systems in mylonites, being temperature not the only significant variable, as outlined by Villa (1998).

The age of 570.9 ± 11 Ma for the Cerro Caperuza granite together with the age of the alkaline plutonic-volcanic Sierra de las Ánimas Complex (Fig. 5.4; 579 ± 1.5 Ma, Ar/Ar hornblende, Oyhantçabal et al., 2007; 581.8 ± 3.4 Ma, 574.5 ± 8.1 Ma, U-Pb SHRIMP zircon, Rapalini et al., 2015) provide a solid constraint for the end of the ductile deformation in the shear zone (Fig. 6.6a). Likewise, the Rb-Sr ages of the mylonites can be interpreted as the result of the reequilibration of the Rb-Sr isotopic system due to fluid circulation, probably associated with low temperature deformation that is recognizable in both mylonites and the Cerro Caperuza granite (Chapter 5). It can be thus inferred that cataclastic deformation in the easternmost shear zone started after 570 Ma. Moreover, the Arroyo de la Pedrera Formation is folded and affected by low-T shear zones and faults near the cataclasites of the Sarandí del Yí Shear Zone in the western Nico Pérez Terrane (Fig. 4.1; Montaña and Sprechmann, 1993; Oriolo et al., 2015). As this unit did not achieve metamorphic conditions higher than lower greenschist facies (Gaucher, 2000; Blanco et al., 2009; Sánchez Bettucci et al.,

2010) and may present a late Ediacaran-lower Cambrian age (Montaña and Sprechmann, 1993; Blanco et al., 2009; Gaucher et al., 2004, 2011b), deformation of these sequences may be related to late Ediacaran-Cambrian cataclastic deformation along the shear zone. Furthermore, Rapalini and Sánchez Bettucci (2008) interpreted a post-folding remagnetization event in the Arroyo de la Pedrera Formation as evidence for an early Cambrian event. Consequently, brittle deformation in the Sarandí del Yí Shear Zone can be characterized as a long-term process that took place between the late Ediacaran and the Cambrian.

The existence of collisional events between ca. 625-600 Ma in South America can be further traced to the north along the Transbrasiliiano Lineament (Ganade de Araujo et al., 2014a, 2014b). This crustal-scale structure has been correlated with the easternmost Pampean Belt in the Sierras Pampeanas, mostly based on geophysical data (e.g., Rapela et al., 2007; Peri et al., 2015). Nevertheless, the collisional phase of the Pampean Belt was placed at the lower Cambrian (Rapela et al., 1998, 2007; Siegesmund et al., 2010), which is considerably younger than the collision recorded along the Transbrasiliiano Lineament (Ganade de Araujo et al., 2014a, 2014b). The Sarandí del Yí Shear Zone, in contrast, shows both timing of deformation and kinematics, which are comparable with those recorded along the Transbrasiliiano Lineament. Consequently, the amalgamation of the Gondwanic domains in the South American Platform (Brito Neves and Fuck, 2014) was completed at ca. 600 Ma and resulted from the accretion of African blocks to the eastern margin of the South American older nuclei, i.e., the Amazonas and Río de la Plata cratons, along crustal-scale shear zones.

6.5. Conclusions

Multithermochronometric and structural data from the mylonites combined with geochronological information from shear zone-related magmatism as well as cooling ages of the adjacent blocks were integrated to constrain the tectonometamorphic evolution of the Sarandí del Yí shear Zone. The onset of the deformation is related to the collision of the Río de la Plata and Nico Pérez Terrane at 630-625 Ma, giving rise to dextral shearing up to 596 Ma along the Sarandí del Yí

Shear Zone under upper to middle amphibolite conditions in a post-collisional setting. Subsequent sinistral shearing took place between 594-584 Ma under lower amphibolite to upper greenschist facies conditions, which was followed by emplacement of the Sierra de las Ánimas Complex and the Cerro Caperuza granite. Further deformation under brittle conditions was recorded after ca. 570 Ma.

Additionally, the obtained data reveal the complexity in assessing the age of deformation of long-lived shear zones. Strain partitioning and localization with time, magma emplacement and fluid circulation were identified as the main processes affecting the isotopic systems. Therefore, multiple geochronometers from the mylonitic belts and their adjacent blocks as well as detailed structural analysis have to be integrated in order to establish solid tectonothermal models of crustal-scale shear zones.

-CHAPTER 7-**Structure and geochronology of the Dom Feliciano Belt****7.1. Introduction**

Harland (1971) defined transpression as a combination of compression and transcurrent motion that results from oblique plate convergence at crustal scale. This term was then extended by Sanderson and Marchini (1984), who considered transpression as deformation developed between two undeformed blocks resulting from both simple and pure shear, independently of the scale. Subsequent contributions presented deviations from these first models and demonstrated the 3D complexity of transpressional orogens (Fossen et al., 1994; Dewey et al., 1998; Fossen and Tikoff, 1998; Jones et al., 1997, 2004; Fernández and Díaz-Azpiroz, 2009; Fernández et al., 2013; Massey and Moehler, 2013), especially when related to strain partitioning (Lister and Williams, 1983; Tikoff and Teyssier, 1994; Jones and Tanner, 1995; Teyssier et al., 1995). Although strain partitioning refers to heterogeneous spatial distribution of deformation, changes with time are also frequent (Lister and Williams, 1983). Among others, shear zone nucleation due to strain localization is one of the most common consequences of temporal strain variations (e.g., Hobbs et al., 1990; Jessell and Lister, 1991; Platt and Behr, 2011).

Although the regional structure of the Pan-African mobile belts was thoroughly investigated (Hälbich and Alchin, 1995; Goscombe et al., 2003, 2005; Konopásek et al., 2005; Goscombe and Gray, 2008; Ulrich et al., 2011; Lehmann et al., 2016), contributions regarding structural aspects of the Dom Feliciano Belt focused mostly on the Major Gercino-Sierra Ballena shear zone system (Fernandes et al., 1992; Fernandes and Koester, 1999; Oyhantçabal et al., 2009b, 2011b; Passarelli et al., 2010, 2011). Likewise, constraints on the timing of deformation and metamorphism are scarce (Oyhantçabal et al., 2009a, 2009b, 2011b), thus being the tectonothermal evolution of the belt still elusive.

7.2. Structural architecture of the Dom Feliciano Belt

7.2.1. Introduction

The Dom Feliciano Belt in Uruguay can be divided into two domains, which are separated by the Sierra Ballena Shear Zone. The western domain is dominated by metavolcano-sedimentary units, whereas the eastern domain is mostly made up of granitoids (Fig. 7.1). In order to assess the macro- and mesostructural aspects of both domains, two key areas were studied in detail (Fig. 7.2, 7.3).

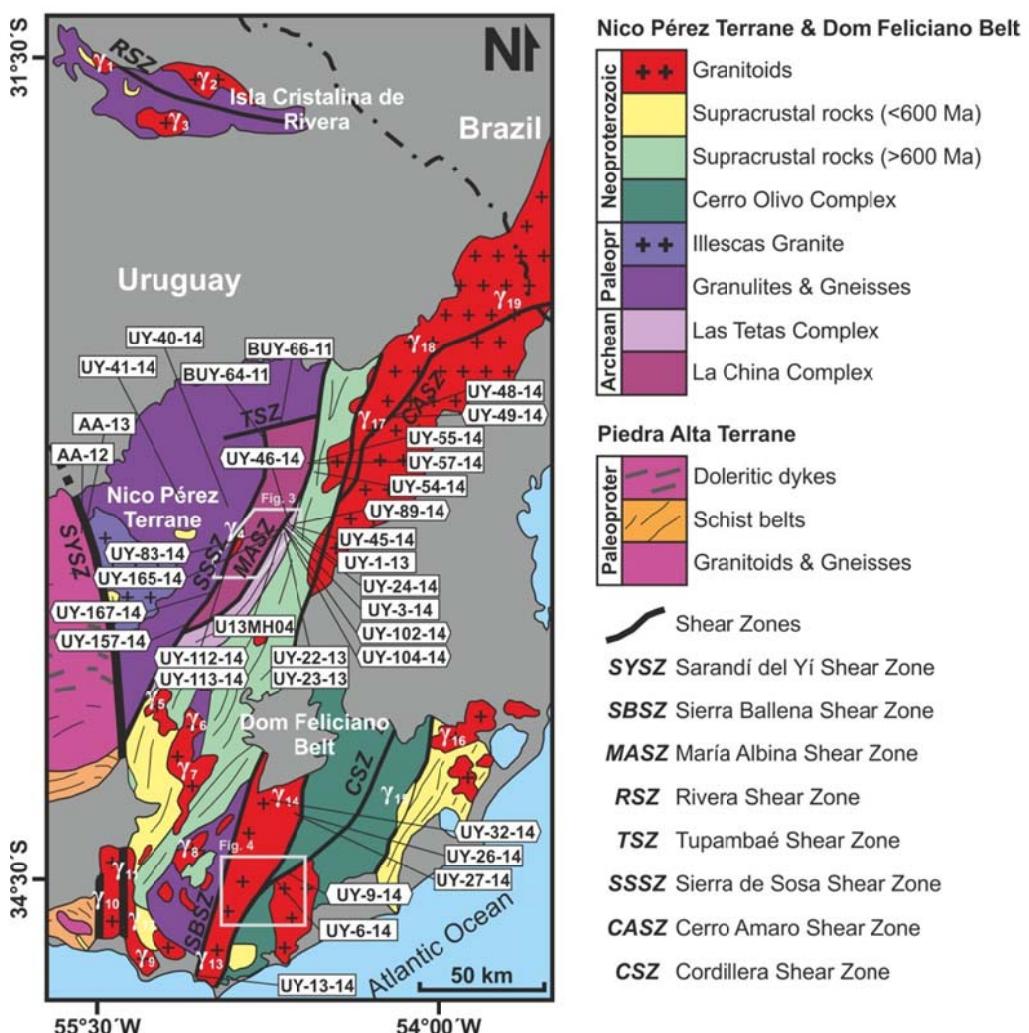

Fig. 7.1: Geological map of the Precambrian of Uruguay (modified after Oyhantçabal et al., 2011a and references therein). Detailed areas of Fig. 7.2 and 7.3 are shown. Geochronological and quartz CPO samples are indicated with rectangles and prisms, respectively. Magmatic units are indicated as well (γ_1 : Sobresaliente granite, γ_2 : Amarillo granite, γ_3 : Las Flores granite, γ_4 : Zapicán granodiorite, γ_5 : Lavaderos granite, γ_6 : Arroyo Mangacha granite, γ_7 : Puntas del Santa Lucía monzogranite, γ_8 : Puntas del Mataojo granodiorite, γ_9 : Pan de Azucar intrusion, γ_{10} : Solís de Mataojo Granitic Complex, γ_{11} : Sierras de las Ánimas Complex, γ_{12} : Las Ventanas Formation, γ_{13} : Maldonado granite, γ_{14} : Valdivia granite, γ_{15} : Cerro Aguirre dacite, γ_{16} : Santa Teresa granite, γ_{17} : Cerro Amaro granite, γ_{18} : Arroyo Malo granite, γ_{19} : Sarandí del Yaguarón granite).

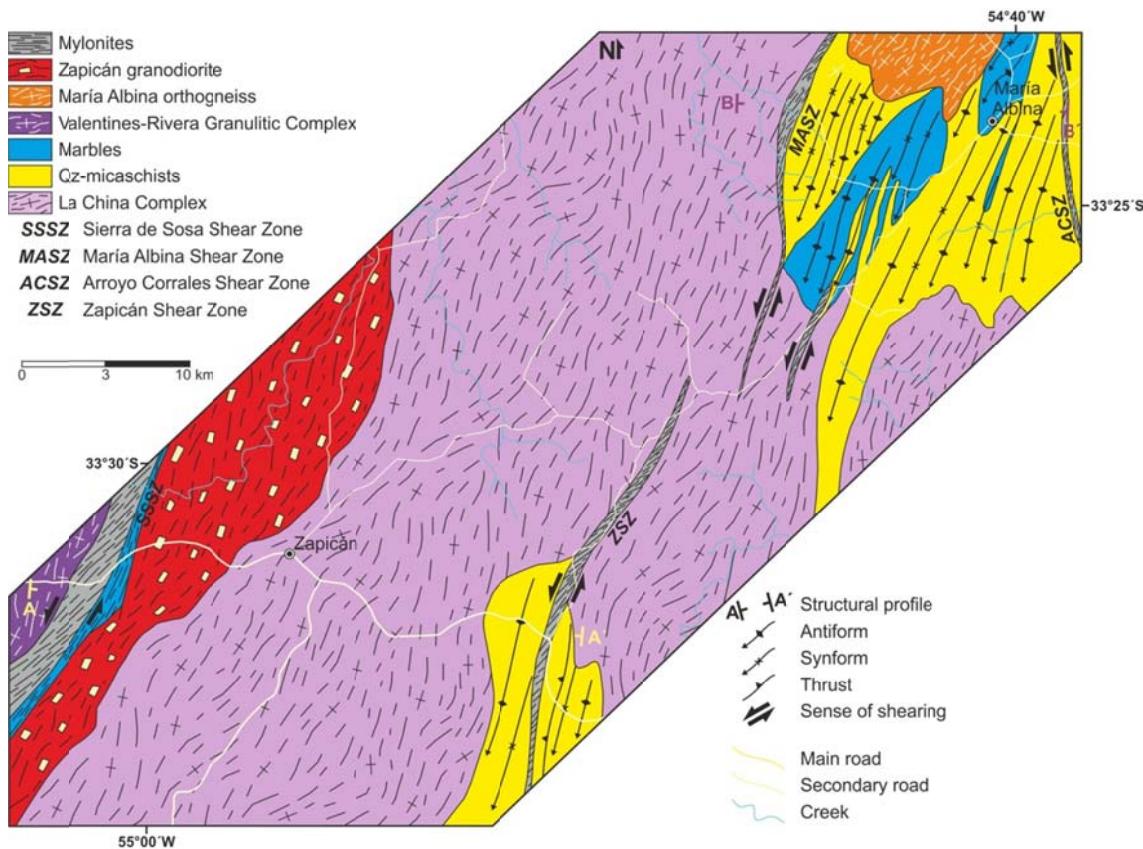

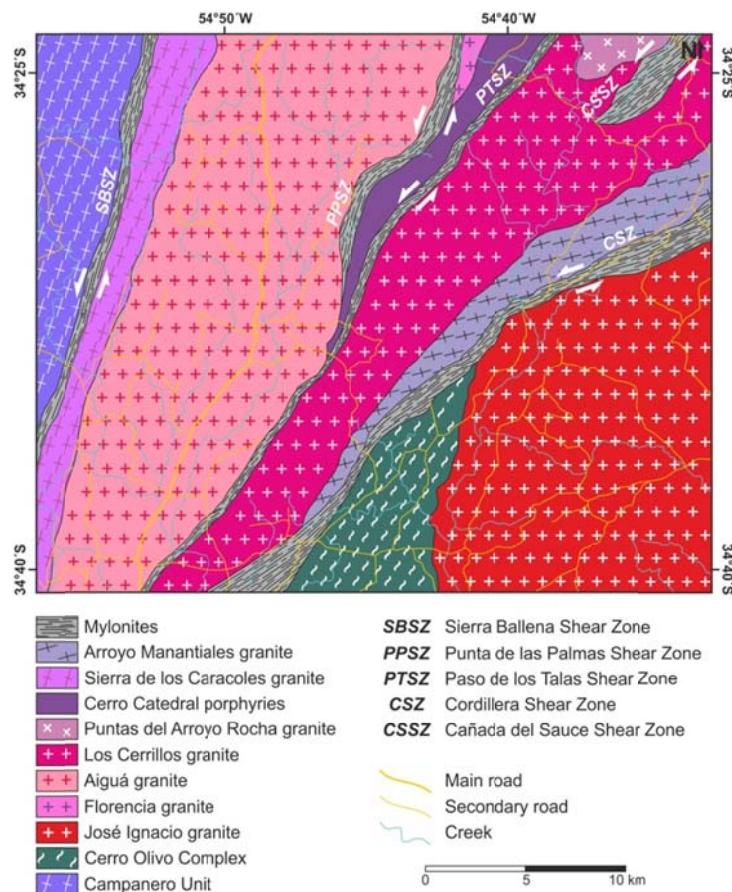

Fig. 7.2: Detailed geological map of the western Dom Feliciano Belt (modified after Preciozzi, 1987; Hartmann et al., 2001). Locations of structural profiles of figures 7.4 (A-A') and 7.5 (B-B') are shown as well.

Fig. 7.3: Detailed geological map of the eastern Dom Feliciano Belt (modified after Spoturno et al., 2012).

7.2.2. Western domain

The northwestern area of the western domain is constituted by the Paleoproterozoic Valentines-Rivera Granulitic Complex, which represents the basement of the Nico Pérez Terrane and is affected by Neoproterozoic magmatism and shear zones (Fig. 7.1; Oyhantçabal et al., 2011a, 2012). Minor NNW-striking protomylonitic belts were recognized in the western Nico Pérez Terrane and are related to the Sarandí del Yí Shear Zone (Oriolo et al., 2015). Likewise, oblique shear zones are also recognizable. The dextral Tupambaé Shear Zone affects the Valentines-Rivera Granulitic Complex in the northern Nico Pérez Terrane, whereas the sinistral Rivera Shear Zone cross-cuts the same unit in the Isla Cristalina de Rivera (Fig. 7.1).

The Valentines-Rivera Granulitic Complex is bounded to the southeast by the Sierra de Sosa Shear Zone, which separates it from the La China Complex. The former comprises felsic and subordinated intermediate to mafic granulites and orthogneisses, whereas the latter is mostly made up of amphibolite facies felsic orthogneisses with mafic to ultramafic intercalations (Hartmann et al., 2001; Oyhantçabal et al., 2011a, 2012; Spoturno et al., 2012). The Sierra de Sosa Shear Zone presents a mean mylonitic foliation of $219^{\circ}/70^{\circ}\text{W}$ and a mean stretching lineation of $225^{\circ}/15^{\circ}$ (Fig. 7.4). The gneisses of the Valentines-Rivera Granulitic Complex show a dominant subvertical NE-striking foliation towards the shear zone, which may indicate Neoproterozoic reworking due to shearing. Likewise, the marbles located to the east show a foliation with a mean orientation of $207^{\circ}/76^{\circ}\text{W}$, whereas the Zápicán granodiorite present a dominant NE-striking subvertical magmatic foliation defined by the shape preferred orientation of feldspars (Fig. 7.4). Structural data indicate that the deformation of the marbles and the emplacement of the Zápicán granodiorite took place during the evolution of the Dom Feliciano Belt, which is further supported by geochronological data of the intrusion (Chapter 3; Oriolo et al., 2016a). In contrast, felsic orthogneisses and associated mafic rocks of the Archean La China Complex present a higher complexity. High-T and migmatic foliations are frequent in the orthogneisses and show no clear relationship with the structure of the adjacent units (Fig. Fig. 7.4, 7.5, 7.6a), being thus probably related to the pre-Brasiliano evolution of these rocks.

Mafic rocks are frequently emplaced parallel to the foliation of the felsic orthogneisses but show in many cases equigranular textures (Fig. 7.6b). Further to the east, scarce outcrops of folded quartz-micaschists point to a dominant vergence to the SE and are cross-cut by the sinistral Zapicán Shear Zone, which exhibits a mean mylonitic foliation of $193^\circ/19^\circ\text{W}$ and a mean lineation of $211^\circ/09^\circ$ (Fig. 7.4). Thrusts are recognizable within the quartz-micaschists and also support vergence to the SE (Fig. 7.6c).

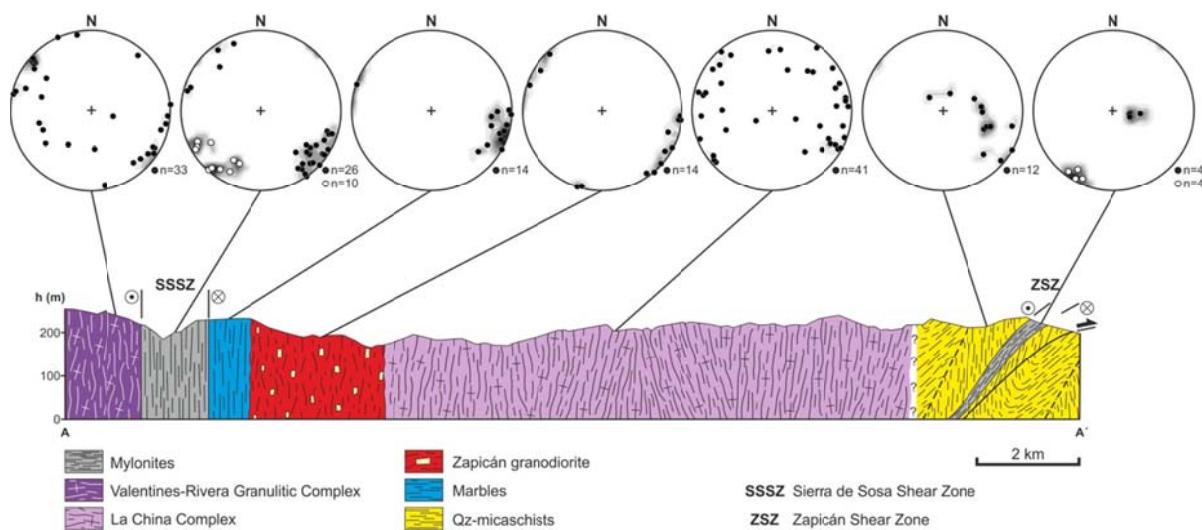

Fig. 7.4: Structural profile A-A'. Lower hemisphere equal area projection of foliations (black dots) and lineations (white dots). Diagrams were obtained using Stereonet 8 (Allmendinger et al., 2012).

On the other hand, the La China Complex is separated from the Las Tetas Complex by the María Albina Shear Zone (Fig. 7.5). However, orthogneisses are occasionally found to the east of the shear zone (e.g., María Albina orthogneiss), whereas the Las Tetas Complex is mostly made up in this area by folded quartz-micaschists and marbles, which present a mean stretching lineation of $194^\circ/18^\circ$ and $194^\circ/17^\circ$, respectively (Fig. 7.5, 7.7a). Folds display a typically inclined to overturned similar geometry and, despite being dominantly close, tight to isoclinal folds are frequent in the marbles. Cleavage is oblique to fold axes and fold axial planes and transects clockwise the folds. Fold axes are subparallel to stretching lineations excepting in some marbles, which exhibit slightly curvilinear hinge lines. NW-vergence is dominant, although SE-vergence can be recognized towards

the ESE (Fig. 7.5, 7.7b). Minor subvertical ENE-striking dextral shear zones cross-cut the metasediments (Fig. 7.7c).

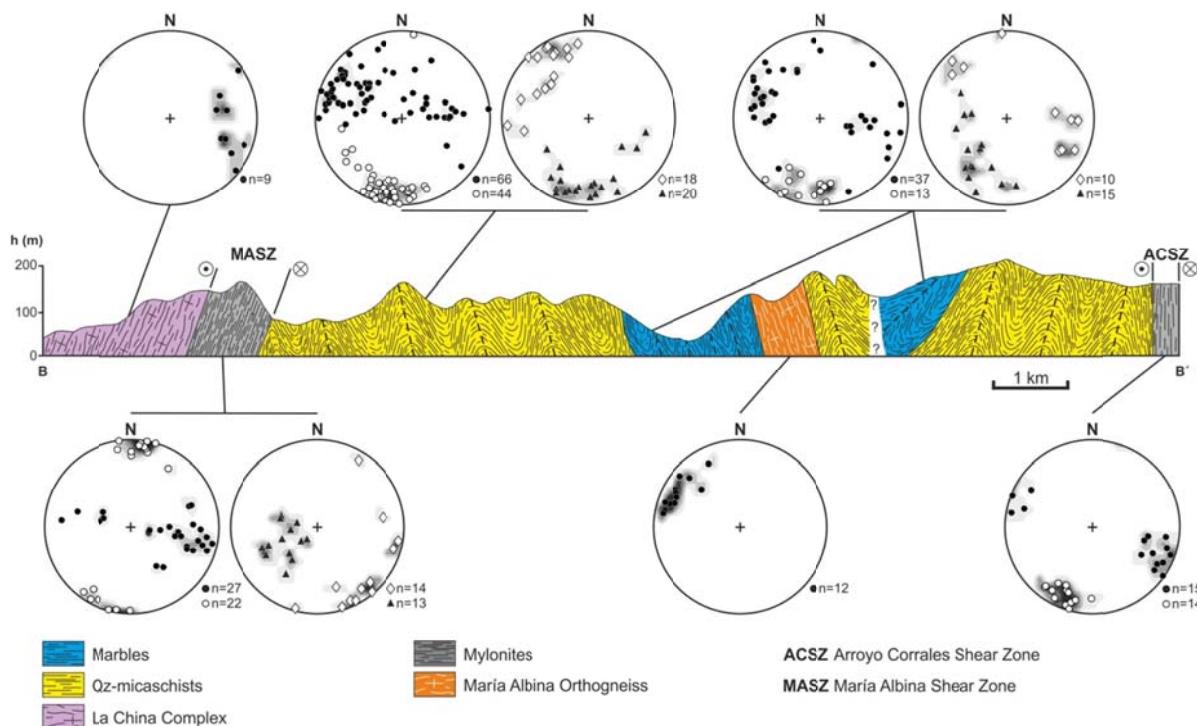

Fig. 7.5: Structural profile B-B'. Lower hemisphere equal area projection of foliations (black dots), lineations (white dots), fold axes (black triangles) and fold axial planes (white diamonds). Diagrams were obtained using Stereonet 8 (Allmendinger et al., 2012).

The María Albina Shear Zone shows a mean mylonitic foliation of $192^\circ/48^\circ\text{E}$ and a mean stretching lineation of $017^\circ/06^\circ$ (Fig. 7.5). Likewise, mylonitic folds present a mean axis of $244^\circ/56^\circ$ and a mean axial plane of $223^\circ/76^\circ\text{W}$ (Fig. 7.5, 7.7d). Sinistral shearing can be recognized on the basis of shear bands and feldspar mantle porphyroclasts. The western part of the mylonitic belt is cataastically overprinted.

To the east of the María Albina Shear Zone, a second sinistral mylonitic shear zone can be recognized, namely the Arroyo Corrales Shear Zone, which presents a mean mylonitic foliation of $199^\circ/80^\circ\text{E}$ and a mean stretching lineation of $203^\circ/14^\circ$ (Fig. 7.5). Likewise, discontinuous outcrops of mylonites with similar orientations of fabric elements can be identified further to the southwest, indicating that the María Albina, Arroyo Corrales and Zapicán shear zones comprise a complex system of anastomosing shear zones that cross-cut the metasediments.

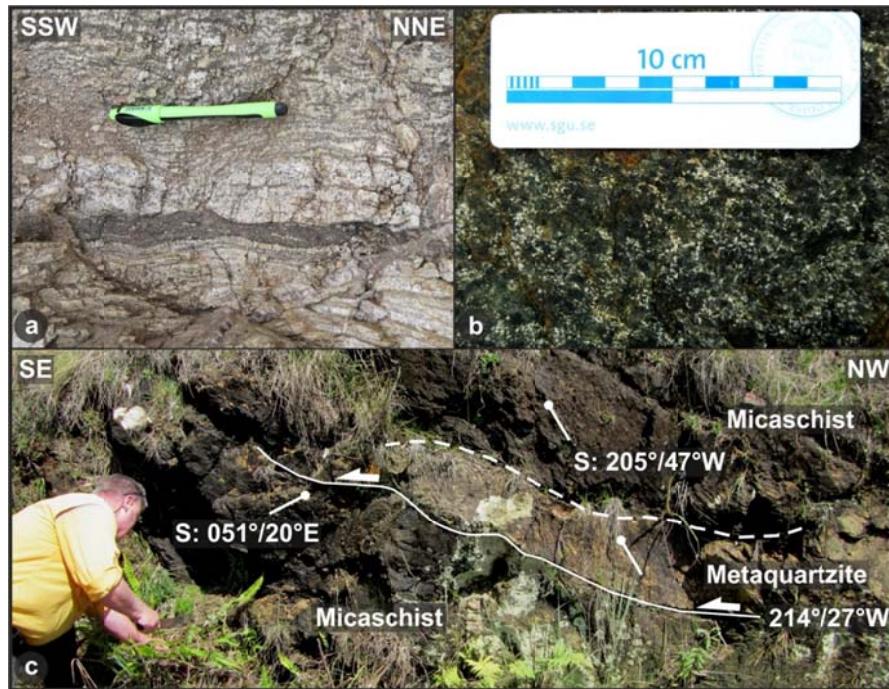

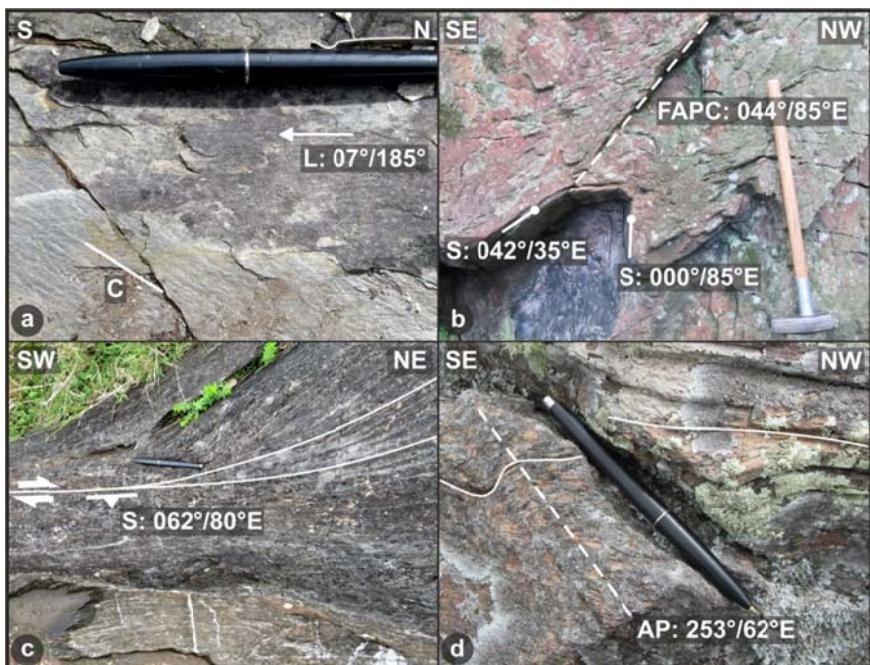

Fig. 7.6: Field photographs along the structural profile of Figure 7.4. a) Migmatic foliation in orthogneisses of the La China Complex. b) Equigranular texture in mafic rocks of the La China Complex. c) Minor SE-vergent thrust within metasediments.

Fig. 7.7: Field photographs along the structural profile of Figure 7.5. a) Lineation in micaschist of the Las Tetas Complex with transecting cleavage. b) Folded quartz-micaschists. Fold axial plane cleavage (FAPC) is indicated. c) ENE-striking dextral shear zone cross-cutting marbles of the Las Tetas Complex. d) Folded mylonitic foliation of the María Albina Shear Zone. Axial plane is indicated (AP).

7.2.3. Eastern domain

The area located to the east of the Sierra Ballena Shear Zone is fundamentally made up of Neoproterozoic granitoids and subordinated subvolcanic rocks (Fig. 7.1, 7.3; Spoturno et al., 2012). These granitoids present either equigranular textures or magmatic to high-T solid-state foliations.

Solid-state foliations are subvertical and strike NE (Fig. 7.8a), and are particularly frequent close to shear zones.

Several sinistral shear zones are also distinguishable. The Cordillera Shear Zone is the most outstanding one and reworks the northern margin of the José Ignacio granite, separating this intrusion from the Los Cerrillos granite, and exhibits a mean mylonitic foliation of $220^\circ/71^\circ\text{E}$ and a mean stretching lineation of $217^\circ/19^\circ$ (Fig. 7.8b). However, a relictic lineation that predates the latter is occasionally present and plunges moderately to the WNW. Scarce fold axes plunge moderate to steeply towards the WSW (Fig. 7.8b). Similar structural features can be recognized in the Puntas de las Palmas, Paso de los Talas and Cañada del Sauce shear zones, which constitute NE- to NNE-trending shear zones that separate different magmatic bodies as well (Fig. 7.3; Spoturno et al., 2012). Subvolcanic synkinematic dykes (Cerro Catedral porphyries) are emplaced between the Puntas de las Palmas and Paso de los Talas shear zones.

Further to the north, the Cerro Amaro Shear Zone cross-cuts the Aiguá Batholith (Fig. 7.1). It shows a mean mylonitic foliation of $215^\circ/70^\circ\text{W}$ and a mean stretching lineation of $037^\circ/04^\circ$.

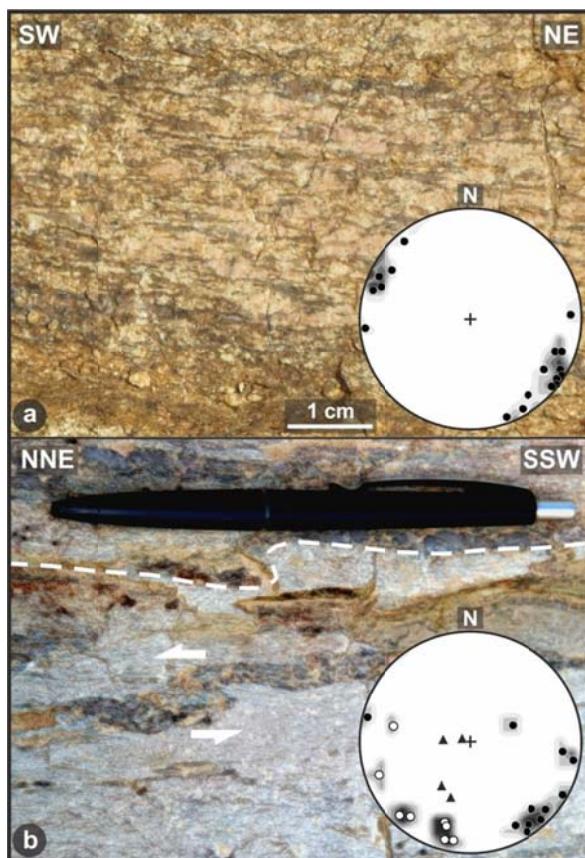

Fig. 7.8: Field photographs of the eastern Dom Feliciano Belt. a) Solid-state foliation in granitoids. Lower hemisphere equal area projection of foliations (black dots, n=18). b) Folded mylonitic foliation in the Cordillera Shear Zone. Lower hemisphere equal area projection of mylonitic foliations (black dots, n=11), lineations (white dots, n=8) and fold axes (black triangles, n=4).

7.3. Microstructures

7.3.1. Western domain

7.3.1.1. Tupambaé Shear Zone

The Tupambaé Shear Zone is made up of granitic mylonites. Oblique foliation in quartz and σ -type feldspar mantled porphyroclasts with tensional microfractures indicate a dextral sense of shear (Fig. 7.9a).

Scarce sutured coarse-grained crystals are present, although quartz typically constitutes polycrystalline aggregates of homogeneous fine-grained elongated crystals (Fig. 7.9a). These aggregates locally develop an oblique foliation. Feldspar porphyroclasts present microfracturing and cataclasis as well as recrystallization only localized in tails. Flame perthites are common in K-feldspar and bent twins are sometimes present in plagioclase.

A secondary paragenesis of fine-grained biotite + epidote + sericite + opaque minerals is observable within local cataclastic bands that rework the mylonites, particularly in areas with oblique foliation of quartz. These bands present Y and P shears, which support dextral shearing also under brittle conditions (Fig. 7.9a).

7.3.1.2. Sierra de Sosa Shear Zone

The Sierra de Sosa Shear Zone is made up of granitic and scarce quartz mylonites. S-C' shear bands as well as δ - and σ -type feldspar mantled porphyroclasts reveal a sinistral sense of shear (Fig. 7.9b).

Microstructures in the Sierra de Sosa Shear Zone are highly variable. Sutured quartz crystals are recognizable, but aggregates of fine- to medium-grained elongated crystals are more frequent. In some samples, large elongated relictic crystals with deformation lamellae, undulose extinction and subgrain formation are observable (Fig. 7.9c). In these cases, recrystallization is restricted to bulges along grain boundaries. Foam structures are present as well and point to subsequent static recrystallization. Feldspar porphyroclasts show recrystallized tails, boudinage and microfracturing,

giving rise in some cases to bookshelf or anti-bookshelf structures (Fig. 7.9b). Flame perthites and assymetric myrmekites are occasionally recognizable in K-feldspar, whereas secondary twinning and bent twins in plagioclase are frequent.

Likewise, localized deformation bands with significant grain size reduction of quartz and feldspars and associated fine-grained aggregates of sericite + biotite + opaque minerals \pm epidote \pm chlorite can be observed. These evidences account for pressure solution and cataclasis postdating ductile deformation.

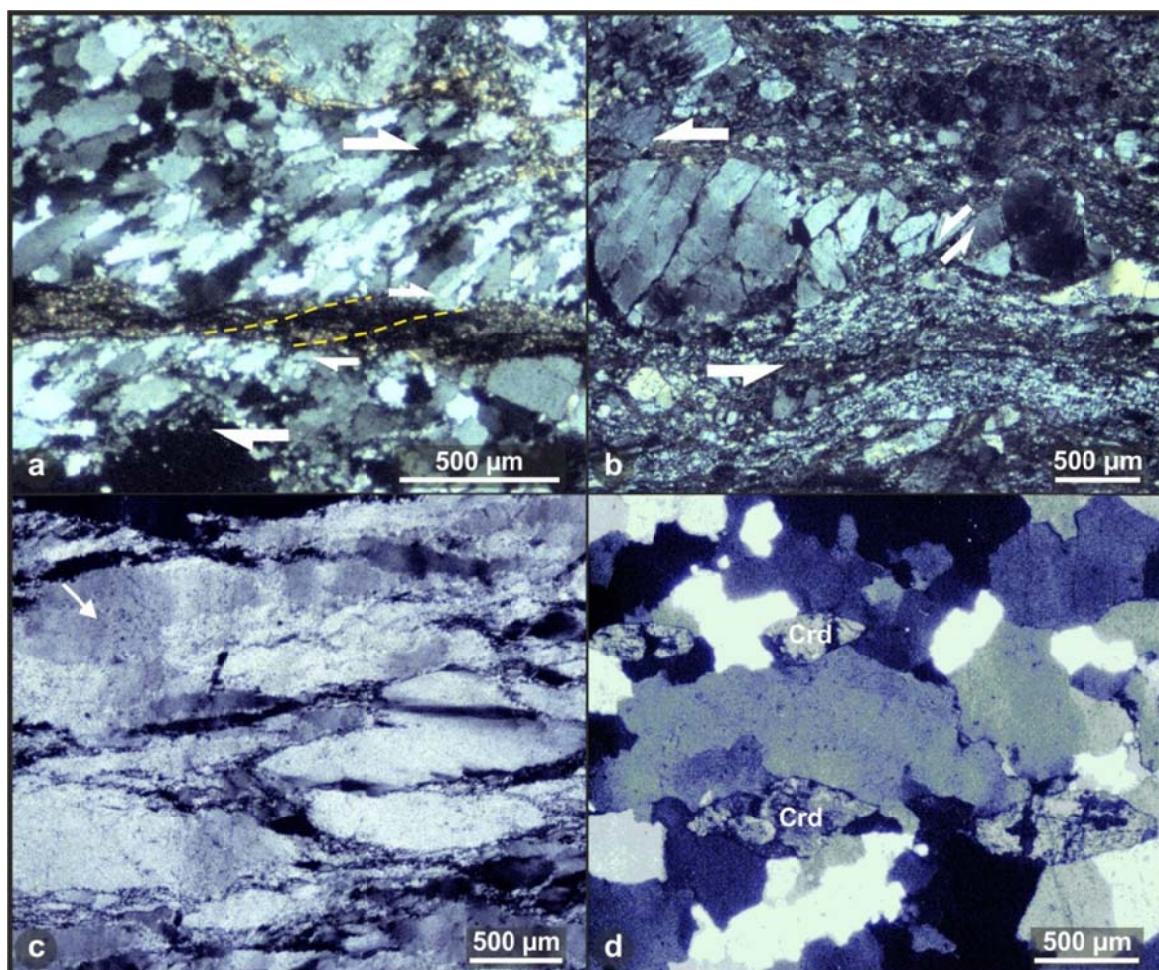

Fig. 7.9: Photomicrographs of microstructures from mylonites of the western Dom Feliciano Belt. a) Oblique foliation in quartz indicating dextral shearing in the Tupambaé Shear Zone. Dextral P shears (yellow lines) within low-grade localized bands constituted by fine-grained biotite + epidote + sericite + opaque minerals. b) Sinistral σ -type K-feldspar mantled porphyroblast in mylonites of the Sierra de Sosa Shear Zone. Synthetic microshear zones are also observed. c) Elongated relictic crystals with deformation lamellae and undulose extinction (arrow). Recrystallization is localized along grain boundaries indicating bulging recrystallization for the Sierra de Sosa Shear Zone. d) Microfracturing and boudinage of cordierite parallel to the stretching lineation direction in the María Albina Shear Zone.

7.3.1.3. María Albina and associated shear zones

The metasediments of the Las Tetas Complex dominantly comprise the protolith of the María Albina and associated mylonitic belts, although detrital zircon data seem to indicate that the Arroyo Corrales Shear Zone affects metasediments of the Lavalleja Group (Oyhantçabal et al., submitted). S-C' shear bands point to sinistral shearing.

Quartz typically develops sutured grain boundaries, although local subgrain rotation and peripheral bulging are also observable, particularly in the Arroyo Corrales Shear Zone. However, static recrystallization is frequent in quartz, as indicated by foam structures. Muscovite and fuchsite typically develop fish minerals. Cordierite is occasionally present and shows boudinage as well as microfractures perpendicular to the stretching lineation direction (Fig. 7.9d).

The western margin of María Albina Shear Zone is overprinted by cataclastic deformation that also affects the orthogneisses located to the west. Cataclasites constitute minor belts, which are oriented parallel to the mylonitic foliation and are made up of epidote + chlorite + sericite + opaque minerals + quartz.

On the other hand, the María Albina orthogneiss is located to the east of the María Albina Shear Zone (Fig. 7.2) and is constituted by quartz, K-feldspar, plagioclase and muscovite. Quartz presents foam textures, whereas feldspars show mostly microfracturing. Muscovite, in turn, is oriented parallel to the foliation.

7.3.2. Eastern domain

7.3.2.1. Cordillera Shear Zone

The protolith of the Cordillera Shear Zone are granitoids and, to a minor extent, metaquartzites and quartz-micaschists. S-C' shear bands, σ -type feldspar mantled porphyroclasts and mica fish indicate a dominant sinistral sense of shear, although dextral shear is locally recorded in ENE-striking restraining bends.

Quartz develops polycrystalline aggregates of homogeneous fine-grained elongated crystals. Nevertheless, flattened relictic coarser-grained crystals are frequently preserved, which exhibit subgrain development as well as undulose extinction (Fig. 7.10a). Feldspar porphyroclasts present microfracturing, which is frequently related to boudinage or bookshelf and anti-bookshelf structures. Recrystallization is scarce and restricted to tails. Deformation twins are frequent in plagioclase. Muscovite and biotite are locally present and develop fish structures.

Locally, evidences of pressure solution and cataclasis are observable and overprint the mylonitic features. In some cases, cataclasites are also associated with phyllonites and ultramylonites. The mineral association is typically made up of quartz + sericite + biotite \pm epidote \pm opaque minerals.

7.3.2.2. Punta de las Palmas Shear Zone

The Punta de las Palmas Shear Zone is made up of granitic mylonites. S-C' shear bands and σ -type feldspar mantled porphyroclasts indicate a sinistral sense of shear.

Although scarce relictic crystals are observable, quartz dominantly develops polycrystalline aggregates of homogeneous fine-grained elongated crystals. However, foam structures are frequent, indicating subsequent static recrystallization. Feldspar porphyroclasts internally present microfracturing and cataclasis, whereas recrystallization is only localized in tails. Bent twins are present in plagioclase (Fig. 7.10b). Boudinage parallel to the direction of the stretching lineation is recognizable in titanites as well as feldspars (Fig. 7.10c).

7.3.2.3. Cerro Amaro Shear Zone

The granitoids of the Aiguá Batholith constitute the protolith of the Cerro Amaro Shear Zone. A sinistral sense of shear can be inferred from S-C' shear bands and σ -type feldspar mantled porphyroclasts (Fig. 7.10d).

Quartz develops sutured crystals, although recrystallized polycrystalline aggregates of homogeneous fine-grained crystals are locally recognisable as well. Feldspar presents microfracturing, which is sometimes related to bookshelf or anti-bookshelf structures. Recrystallization is restricted to tails (Fig. 7.10d). Deformation twins are frequent in plagioclase, whereas flame perthites are observable in K-feldspar. Muscovite develops mica fish structures with frequent kink bands, microfolding and boudinage.

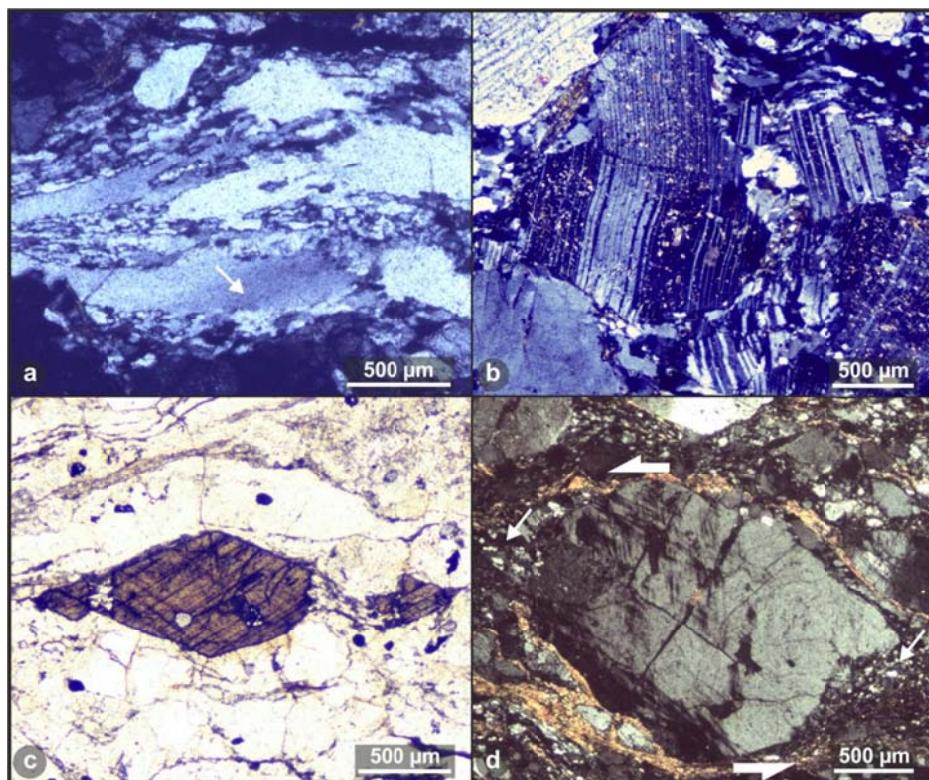

Fig. 7.10: Photomicrographs of microstructures from mylonites of the eastern Dom Feliciano Belt. a) Recrystallized elongated fine-grained and relict coarse-grained (arrow) quartz crystals in the Cordillera Shear Zone. b) Bent twins and microcataclasite in plagioclase of mylonites of the Puntas de las Palmas Shear Zone. c) Boudinage parallel to the stretching lineation direction in titanites of the Puntas de las Palmas Shear Zone. d) Sinistral σ -type K-feldspar mantled porphyroblast in the Cerro Amaro Shear Zone.

7.4. Quartz CPO patterns

Four samples were obtained from the Sierra de Sosa Shear Zone (Fig. 7.11). Sample UY-112-14 presents asymmetrical single girdles with quartz [c]-axes showing maxima slightly oblique to the Z direction and [a]-axes perpendicular to them. This accounts for dominant basal $\langle a \rangle$ slip, though a minor contribution of rhomb $\langle a \rangle$ slip is also observable. UY-113-14, in turns, shows symmetrical

crossed girdles of [c]-axes with two maxima in the YZ plane and [a]-axes developing a slightly defined maximum around X. Rhomb and basal $\langle a \rangle$ are interpreted to be the main slip systems. In contrast, sample UY-157-14 presents an almost symmetrical single girdle with a well-defined maximum parallel to the Y direction. Quartz [a]-axes are distributed perpendicular to Y and exhibit a maximum subparallel to X. In this case, prism $\langle a \rangle$ slip seems to be the dominant system, though minor rhomb $\langle a \rangle$ slip can be also inferred. A similar result was obtained for the sample UY-167-14, although the single girdle for this sample is clearly asymmetrical.

Likewise, samples were collected from the María Albina Shear Zone (Fig. 7.11). Sample UY-83-14 shows asymmetrical crossed girdles of quartz [c]-axes with maxima slightly oblique to the Z direction and [a]-axes perpendicular to them. Basal and minor rhomb $\langle a \rangle$ slip are thus interpreted as the main slip systems. Samples UY-102-14 presents dominant asymmetrical type I crossed girdles of quartz [c]-axes (Lister, 1977), whereas UY-61-14, UY-104-14 and UY-165-14 show asymmetrical single girdles. In all cases, well-defined maxima close to the Y direction are observed, which are accompanied by girdle distributions of the [a]-axes perpendicular to Y. Prism $\langle a \rangle$ slip is thus interpreted as the main slip system, although rhomb and basal $\langle a \rangle$ slip were also active, particularly in the case of UY-104-14.

Sample UY-46-14 from the María Albina orthogneiss shows clearly asymmetrical crossed girdles of quartz [c]-axes with maxima oblique to the Z direction and [a]-axes perpendicular to them. Hence, basal $\langle a \rangle$ slip is interpreted as the dominant slip system.

Samples UY-89-14-1 and UY-89-14-2 from the Arroyo Corrales Shear Zone present asymmetrical crossed girdles (Fig. 7.11). Quartz [c]-axes maxima are slightly oblique to the Z direction, whereas [a]-axes maxima are dominantly subparallel to X. Consequently, quartz CPO data point to basal and minor rhomb $\langle a \rangle$ slip.

In the case of shear zones of the eastern domain, three samples were obtained (Fig. 7.11). Sample UY-9-14-2 was collected from the Cordillera Shear Zone and exhibits type I crossed girdles of quartz [c]-axes (Lister, 1977) with well-defined maxima subparallel to the Z direction. Quartz [a]-axes

are distributed perpendicular to Z and exhibit a slightly defined maximum subparallel to X. Basal and minor rhomb $\langle a \rangle$ slip thus account as slip systems. Sample UY-49-14 from the Cerro Amaro Shear Zone shows a symmetrical single girdle with a well-defined maximum close to the Y direction. Quartz [a]-axes are distributed perpendicular to Y and exhibit a maximum subparallel to X. Prism $\langle a \rangle$ slip and minor rhomb $\langle a \rangle$ slip can be thus interpreted. In the case of sample UY-32-14 from the Puntas de las Palmas Shear Zone, a type II crossed girdle with [a]-axes distributed perpendicular to the [c]-axes maximum was obtained. The obtained pole figures seem to be slightly rotated along X, which might result from oblique cutting during sample preparation. Hence, prism $\langle a \rangle$ slip and subordinated rhomb and basal $\langle a \rangle$ slip seem to be the slip systems.

Samples from the María Albina and Arroyo Corrales shear zones show dominance of assymetrical textures, which indicate of sinistral simple-shear dominated strain according to criteria from Schmid and Casey (1986). Only sample UY-104-14 shows an opposite sense of shear, pointing to either local dextral shearing (e.g., bents) or flow partitioning (Killian et al., 2011). The María Albina orthogneiss (sample UY-46-14) shows a dextral shear sense as well. In the case of the Sierra de Sosa Shear Zone, samples UY-112-14 and UY-167-14 are also indicative of sinistral simple-shear dominated deformation, whereas samples UY-113-14 and UY-157-14 point to pure-shear dominated strain. This variation may also result from variations of strain along the shear zone (i.e., simple vs pure shear-dominated domains) or flow partitioning at the microscale (Killian et al., 2011). In contrast, shear zones from the eastern domain seem to show a larger contribution of pure-shear strain, as indicated by the dominance of more symmetrical quartz textures (Schmid and Casey, 1986).

7.5. Geochronology

7.5.1. Sample description

In order to constrain the timing of deformation and metamorphism of the Dom Feliciano Belt, several units were analysed using different geochronological systems. Sample locations are shown in Figure 7.1, whereas sample coordinates and applied methods are described in Appendix 2.

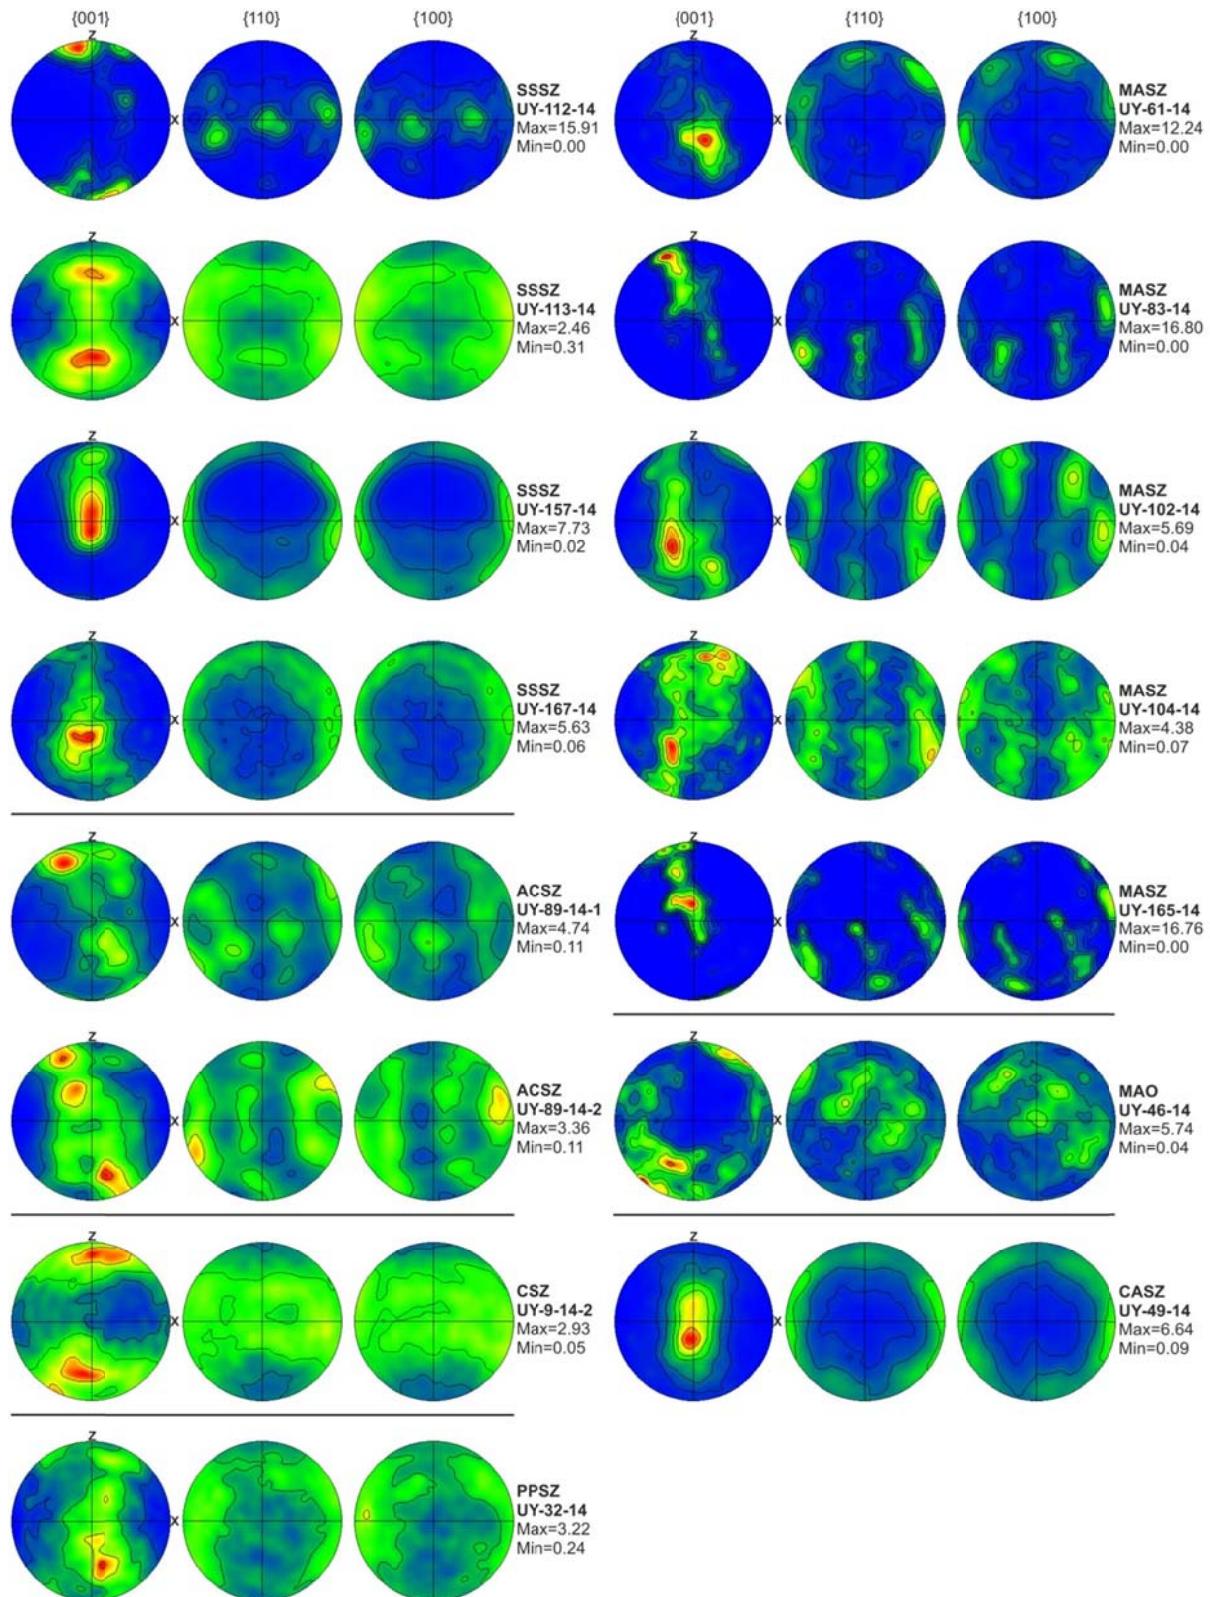

Fig. 7.11: Quartz CPO pole figures. Pole of the foliation (Z) and the lineation (X) are indicated. Contour levels are at 1 intervals up to 15 multiples of uniform distribution (m.u.d.). Colour scaling is from blue (minimum) to red (maximum). Sample locations are indicated in the Appendix 1. SSSZ: Sierra de Sosa Shear Zone, MASZ: María Albina Shear Zone, ACSZ: Arroyo Corrales Shear Zone, MAO: María Albina orthogneiss, CSZ: Cordillera Shear Zone, CASZ: Cerro Amaro Shear Zone, PPSZ: Puntas de las Palmas Shear Zone.

Sample BUY-64-11 comprises a granitic mylonite of the Sierra de Sosa Shear Zone. It is mostly made up of quartz and feldspars, which develop core and mantle structures. Quartz shows interfingering grain boundaries, whereas feldspars show recrystallized tails.

Sample BUY-66-11 corresponds to a granitic mylonite of the Tupambaé Shear Zone. Quartz and feldspars are most frequent minerals. Some quartz grains show interfingering boundaries, although finer-grained elongated crystals seem to dominate. Feldspars, in turn, develop core and mantle structures with recrystallized tails.

Sample UY-13-14 corresponds to a mylonite of the Sierra Ballena Shear Zone, which is made up by quartz, feldspar and minor honblende and sericite. Quartz develops homogeneous fine-grained elongated crystals, whereas feldspars show only microfracturing and cataclasis.

Two samples from the María Albina Shear Zone, namely UY-3-13 and UY-24-13, were collected as well. Both samples are made up of quartz, muscovite, fuchsite and cordierite. Quartz shows typically foam textures indicating recovery. Micas, in turn, develop fish microstructures, which are parallel to the mylonitic foliation.

On the other hand, several samples were collected from basement inliers of the western Dom Feliciano Belt. Samples UY-40-14 and UY-57-14 correspond to amphibolites, which are located to the west of the María Albina Shear Zone and thus probably correspond to the La China Complex. Sample UY-1-13 was collected from a phlogopite-bearing marble of the Las Tetas Complex, whereas UY-22-13, UY-23-13 and U13MH04 were obtained from quartz-micaschists of the same complex. UY-22-13 and U13MH04 are made up of quartz and muscovite, whereas UY-23-13 is constituted by quartz, fuchsite and scarce muscovite. UY-41-14 comprises a schist, which is made up of poikiloblastic cordierite, quartz, muscovite and biotite. It corresponds to an isolated outcrop of metasediments, which is located to the west of the Sierra de Sosa Shear Zone and may correspond to the Las Tetas Complex as well. UY-45-14, in turn, was collected from the María Albina orthogneiss, whereas UY-54-14 and UY-55-14 correspond to undifferentiated micaschists. Finally, one sample (UY-

64-14) was collected from a deformed pegmatite, which intrudes felsic orthogneisses of the La China Complex and is mylonitized together with them.

Likewise, two samples were collected from shear zones of the eastern Dom Feliciano Belt. UY-6-14 was collected from ultramylonites of the Cordillera Shear Zone, which are made up of quartz, feldspars and muscovite. Quartz is typically fine-grained and develops ribbons, whereas feldspars constitute porphyroclasts, which show sometimes boudinage. UY-48-14 corresponds to a granitic mylonite of the Cerro Amaro Shear Zone and is constituted by quartz, feldspars and muscovites. Interfingering grain boundaries are observed in quartz and recrystallization in feldspars is restricted to porphyroblast tails. Fish microstructures and kink bands are recognizable in muscovite, which is typically oriented parallel to the mylonitic foliation.

As reference, two samples were collected to constrain the regional cooling of the eastern Dom Feliciano Belt as well. UY-26-14 was obtained from the Puntas del Arroyo Rocha granite (Fig. 7.3), which is made up of quartz, feldspars and scarce hornblende and muscovite. UY-27-14, in turn, corresponds to a pegmatitic dyke that cross-cuts a mylonitic granitoid.

7.5.2. Results

7.5.2.1. U-Pb geochronology

Zircons of sample BUY-64-11 (Sierra de Sosa Shear Zone) are prismatic and up to 500 µm long. They typically exhibit oscillatory zoning, although some bright homogeneous cores are occasionally recognizable (Fig. 7.12). A concordia age of 598.1 ± 2.2 Ma was obtained considering 9 out of 26 spots (Fig. 7.13, discordant data or with high common Pb content rejected). Nevertheless, some spots present slightly older concordant ages that may indicate reworking of magmatic zircons with ages between ca. 650-600 Ma (Fig. 7.13, Appendix 3). Additionally, one spot yields a concordant age of ca. 2.7 Ga, indicating Archean inheritance (Appendix 3).

In the case of sample BUY-66-11 (Tupambaé Shear Zone), prismatic and subordinated ovoid zircons up to 300 µm long can be observed (Fig. 7.12). Oscillatory zoning is the most frequent texture

but bright homogeneous cores are sometimes present as well. Zircons yield a concordant age of 549.0 ± 2.9 Ma considering 8 out of 25 spots (Fig. 7.13, Appendix 3, highly discordant data or with high common Pb content rejected). Likewise, a few bright luminescent cores show concordant ages of 1.6–1.7 Ga, which indicates inheritance of Statherian zircons.

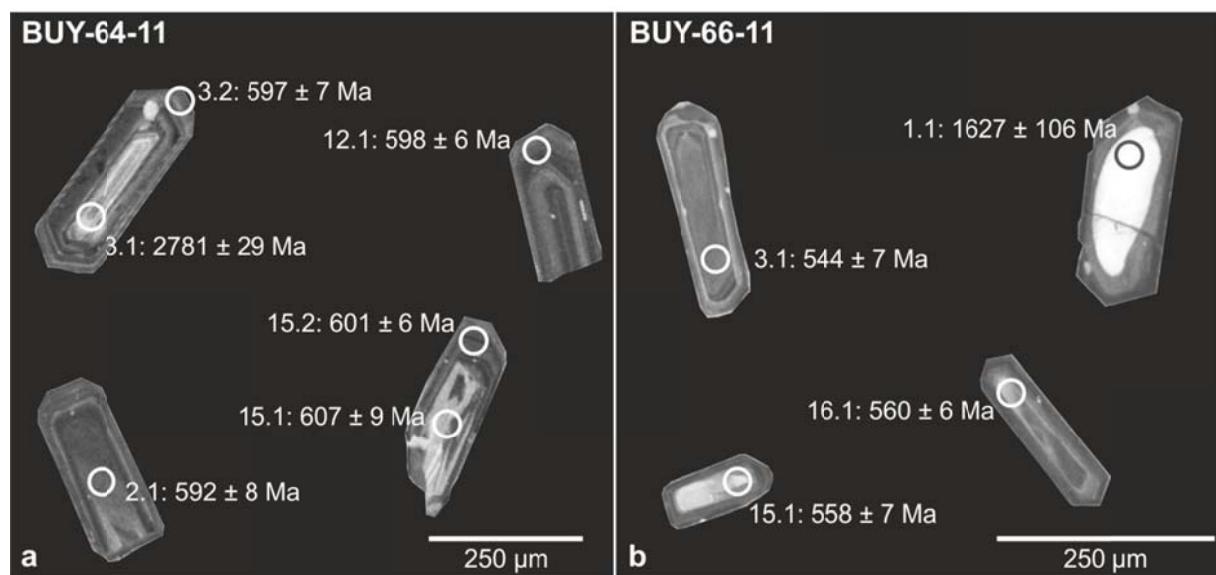

Fig. 7.12: Cathodoluminescence (CL) images of representative zircons. Individual U–Pb ages are shown.

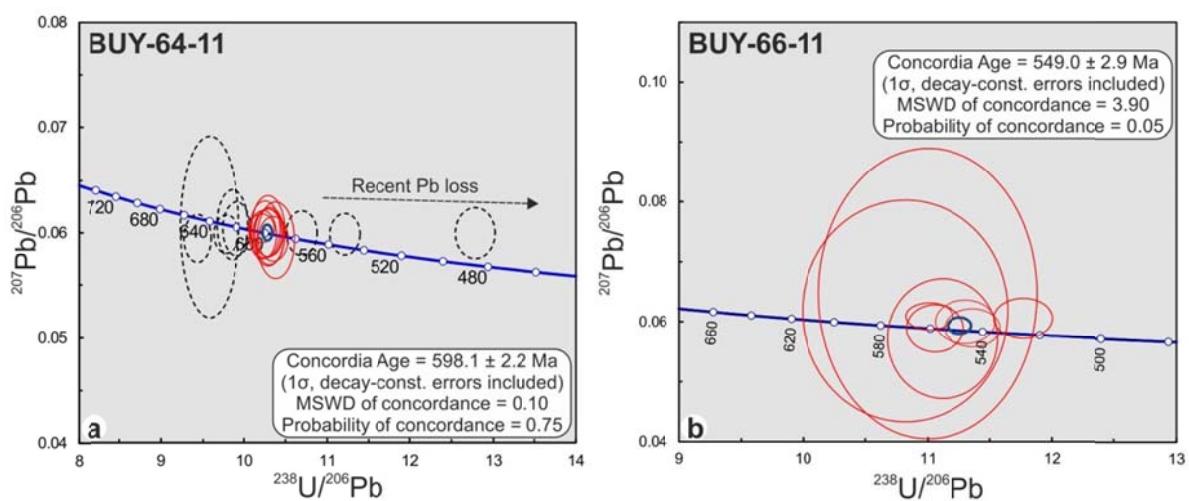

Fig. 7.13: U-Pb diagrams for zircons. Red ellipses indicate data used for age calculations, whereas dashed ellipses represent data that were not considered. Errors depicted at the 2σ level. Analytical data are presented in Appendix 3.

7.5.2.2. $^{40}\text{Ar}/^{39}\text{Ar}$ and K-Ar

Amphiboles from sample UY-13-14 (Sierra Ballena Shear Zone) show a significantly disturbed spectrum with a progressive stepping-up pattern (Fig. 7.14a). Inverse isochrones considering only the first or last steps would indicate a maximum age of ca. 420 Ma with excess Ar or a minimum age of ca. 2.0 Ga with subsequent Ar loss, respectively. A combination of these two-end member processes may be also feasible, therefore no further interpretations can be done for this sample. Disturbed spectrums were obtained as well for amphibolite samples of the basement of the western Dom Feliciano Belt (Fig. 7.14b, 7.14c). In the case of UY-40-14, an inverse isochrone shows an age of 604 ± 14 Ma and excess Ar considering steps 7 to 13 (Fig. 7.15). In a similar way, sample UY-57-14 yields an isochrone age (steps 8 to 15) of 639.5 ± 8.8 Ma (Fig. 7.15).

On the other hand, metasediments from the Las Tetas Complex yield $^{40}\text{Ar}/^{39}\text{Ar}$ and K-Ar ages between ca. 630 and 600 Ma (Fig. 7.14). Phlogopites from marbles yield a $^{40}\text{Ar}/^{39}\text{Ar}$ age of 621.4 ± 1.0 Ma (Fig. 7.14d), although it does not represent a true plateau age. In contrast, muscovite concentrates from quartz-micaschists yield $^{40}\text{Ar}/^{39}\text{Ar}$ plateau ages of 600.4 ± 1.1 and 600.9 ± 1.2 Ma (Fig. 7.14e, 7.14f). Two K-Ar ages of 623.9 ± 7.4 and 625.9 ± 7.4 Ma were obtained for fuchsite concentrates of sample UY-23-13. Muscovites of sample UY-41-14, in turn, yield a K-Ar age of 604.9 ± 6.3 Ma.

The María Albina orthogneiss yields a K-Ar muscovite age of 619.4 ± 8.5 Ma (sample UY-45-14), whereas muscovite concentrates from undifferentiated metasediments present K-Ar ages of 623.8 ± 6.6 and 610.4 ± 6.5 Ma (samples UY-54-14 and UY-55-14, respectively). Likewise, muscovites from sample UY-64-14 yield a K-Ar age of 618.1 ± 7.6 Ma.

In the case of the María Albina Shear Zone, two $^{40}\text{Ar}/^{39}\text{Ar}$ plateau ages were obtained for muscovite concentrates (Fig. 7.14g, 7.14h). Sample UY-3-13 yields an age of 596.8 ± 1.1 Ma, whereas an age of 597.2 ± 3.2 Ma was obtained for sample UY-24-13.

In the eastern Dom Feliciano Belt, the Puntas del Arroyo Rocha granite (sample UY-26-14) presents a K-Ar muscovite age of 589.7 ± 6.2 Ma, muscovite concentrates from sample UY-27-14 of a

pegmatitic dyke yields an age of 605.0 ± 7.2 Ma. On the other hand, K-Ar muscovites ages of 632.7 ± 6.1 and 615.2 ± 6.6 Ma were obtained for the Cordillera and Cerro Amaro shear zones, respectively (UY-6-14 and UY-48-14).

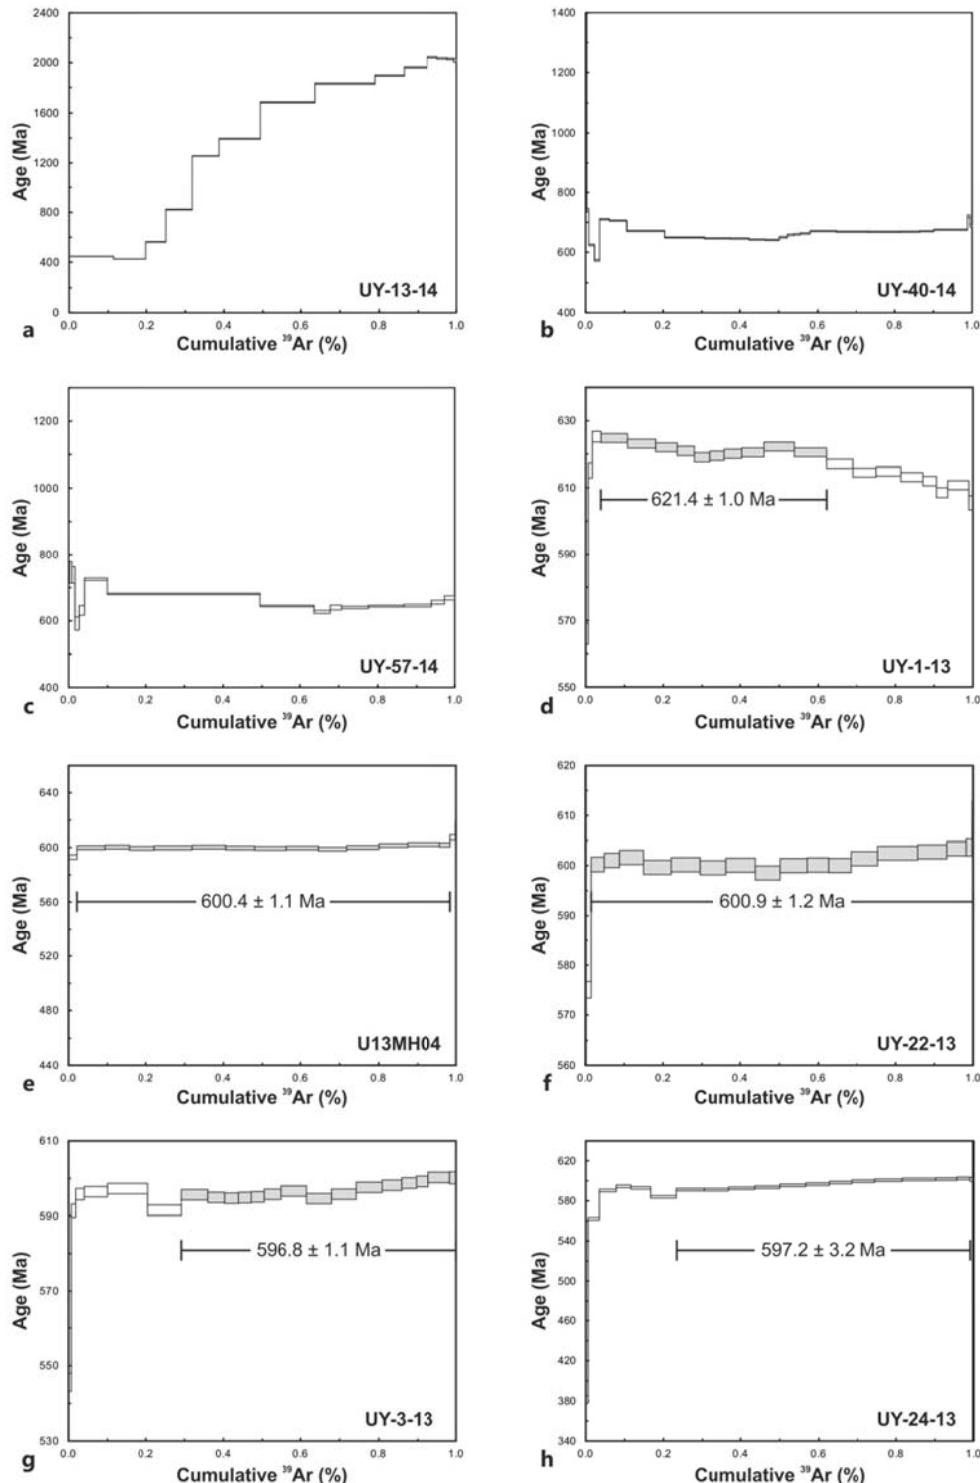

Fig. 7.14: Ar/Ar age spectrum from hornblende (UY-13-14, UY-40-14, UY-57-14), phlogopite (UY-1-13) and muscovite (UY-22-13, U13MH04, UY-3-13, UY-24-13) samples. Steps used for age calculations are colored in grey, whereas rejected steps are indicated in white.

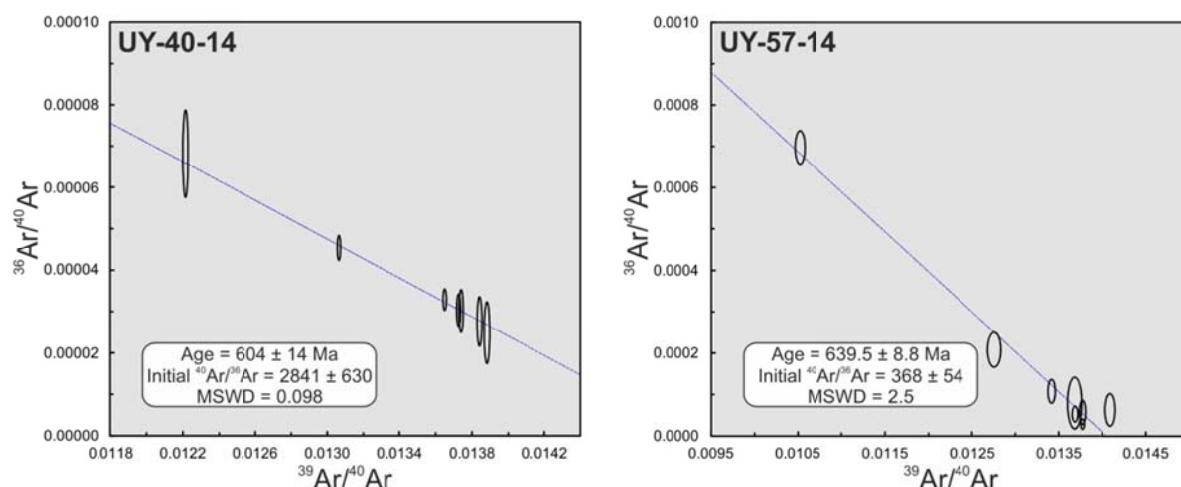

Fig. 7.15: Ar/Ar inverse isochrones for hornblende samples.

7.5.2.3. Rb-Sr

Two samples from the Las Tetas Complex were analysed using Rb-Sr mica and whole-rock (WR) isochrones. The sample UY-1-13 yields a phlogopite-WR isochrone age of 550.5 ± 2.7 Ma, whereas a muscovite-WR isochrone age of 590 ± 11 Ma was obtained for the sample U13MH04 (Appendix 5).

7.6. Discussion

7.6.1. Shear zone deformation mechanisms and conditions

Integration of microstructural and CPO data from rock-forming minerals has been widely applied to constrain deformation mechanisms and conditions in different minerals. Among them, quartz stands out due to its ubiquity and the existence of both experimental and natural calibrations (e.g., Mainprice et al., 1986; Hirth and Tullis, 1992; Okudaira et al., 1995; Kruhl, 1996; Stipp et al., 2002; Stipp and Tullis, 2003). Despite having some limitations (Law, 2014), thermometry based on quartz CPO textures and microstructures represents a useful tool, especially when combined with microstructures of other mineral phases in polycrystalline rocks (Dollinger and Blacic, 1975; Voll, 1976; Fitz Gerald and Stünitz, 1993; Pryer, 1993; Berger and Stünitz, 1996; Heidelbach et al., 2000; Rosenberg and Stünitz, 2003; Díaz Aspiroz et al., 2007).

In the case of the Tupambaé Shear Zone, quartz microstructures are indicative of subgrain rotation as the main dynamic recrystallization mechanism (Hirth and Tullis, 1992; Stipp et al., 2002), although the existence of larger sutured crystals may suggest conditions closer to the grain boundary migration zone. Quartz microstructures together with microfracturing, flame perthites, bent twins and recrystallization localized in tails recorded in feldspars may indicate deformation conditions of ca. 400-550°C (Voll, 1976; Passchier, 1985; Pryer, 1993; Stipp et al., 2002).

Microstructures and CPO data of the Sierra de Sosa Shear Zone reveal variable deformation conditions. Sutured quartz crystals and associated CPO textures revealing dominance of prism $\langle a \rangle$ slip point to deformation conditions in the grain boundary migration zone, probably near the transition to subgrain rotation (Passchier, 1985; Hirth and Tullis, 1992; Stipp et al., 2002), which are further supported by feldspar microstructures (Voll, 1976; Passchier, 1985; Pryer, 1993; Passchier and Trouw, 2005, and references therein). Nevertheless, the existence of large elongated relictic crystals with deformation lamellae, undulose extinction and only local subgrain formation reveal bulging recrystallization as the main mechanism in some samples, which would also account for the recorded basal $\langle a \rangle$ slip. In this case, deformation conditions can be thus constrained at ca. 300-400°C (Lloyd and Freeman, 1994; Hongn and Hippertt, 2001; Stipp et al., 2002).

In a similar way, higher conditions observed for the María Albina Shear Zone correspond to the grain boundary migration zone, as indicated by the presence of sutured grain boundaries and prism $\langle a \rangle$ as the main slip system (Passchier, 1985; Hirth and Tullis, 1992; Stipp et al., 2002). Nevertheless, subgrain rotation and bulging recrystallization are observable in some samples and may account for the recorded basal and rhomb $\langle a \rangle$, as in the Arroyo Corrales Shear Zone and the María Albina orthogneiss, indicating lower grade deformation conditions as well (Hirth and Tullis, 1992; Lloyd and Freeman, 1994; Hongn and Hippertt, 2001; Stipp et al., 2002).

On the other hand, microstructures from the Cordillera Shear Zone are indicative of deformation conditions below ca. 450°C, as quartz seems to be dominated recrystallized by bulging and subgrain rotation recrystallization, whereas feldspar shows only microfracturing (Voll, 1976;

Hirth and Tullis, 1992; Pryer, 1993; Lloyd and Freeman, 1994; Hongn and Hippertt, 2001; Stipp et al., 2002; Passchier and Trouw, 2005, and references therein; Sinha et al., 2010). This interpretation is further supported by the dominance of basal $\langle a \rangle$ recorded in one sample, which account for conditions at the boundary between subgrain rotation and bulging recrystallization zones. Comparable conditions for the Cordillera Shear Zone were also obtained by Oyhantçabal (2005) based on quartz CPO neutron diffraction data.

In contrast, the Cerro Amaro Shear Zone shows microstructures that indicate grain boundary migration and local subgrain rotation recrystallization (Hirth and Tullis, 1992; Stipp et al., 2002), whereas microfracturing and recrystallized tails in feldspars may suggest deformation at ca. 450–550°C (Voll, 1976; Passchier, 1985; Pryer, 1993; Passchier and Trouw, 2005, and references therein). Hence, deformation took place probably in the grain boundary migration zone close to the transition to the subgrain rotation recrystallization zone, as further supported by prism and minor rhomb $\langle a \rangle$ slip recorded by quartz CPO data (Passchier, 1985; Hirth and Tullis, 1992; Stipp et al., 2002).

Relictic quartz crystals in the Punta de las Palmas Shear Zone may indicate early grain boundary migration recrystallization, which was lately overprinted by subgrain rotation recrystallization. Despite subsequent static recrystallization partially overprinted quartz microstructures, this interpretation is further supported by quartz CPO data indicating conditions close to the transition between grain boundary migration and subgrain rotation recrystallization zones (Passchier, 1985; Hirth and Tullis, 1992; Stipp et al., 2002). Feldspar microstructures, in turn, point to deformation conditions of ca. 450–550°C (Voll, 1976; Pryer, 1993; Passchier and Trouw, 2005, and references therein).

Based on field observations, microstructural analysis and quartz CPO data, variable deformation conditions are documented for shear zones of the Dom Feliciano Belt. The dominance of grain boundary migration recrystallization, diffusion processes and prism $\langle a \rangle$ slip in quartz (Passchier, 1985; Jessel, 1987; Hirth and Tullis, 1992; Stipp et al., 2002; Passchier and Trouw, 2005) together with localized recrystallization and dislocation climb in feldspars (Voll, 1976; Pryer, 1993;

Passchier and Trouw, 2005, and references therein) point to maximum deformation conditions of ca. 450-550°C. Subsequent lower grade conditions between ca. 300-450°C are recorded by subgrain rotation and bulging recrystallization with associated basal and rhomb $\langle a \rangle$ slip in quartz as well as by microfracturing, twinning and dislocation glide and creep recorded in feldspars (Voll, 1976; Pryer, 1993; Lloyd and Freeman, 1994; Hongn and Hippertt, 2001; Hirth and Tullis, 1992; Stipp et al., 2002; Passchier and Trouw, 2005, and references therein; Sinha et al., 2010). Conditions below 300°C are observed as well, since most shear zones present local cataclastic reworking, pressure solution and phyllonite development (Rutter, 1983; Gibson, 1990; Shimizu, 1995; Stipp et al., 2002; Jefferies et al., 2006). Based on cross-cutting relationships indicating local lower grade deformation overprinting larger areas of higher grade deformation conditions, the variability of deformation conditions in shear zones can be interpreted as the result of progressive strain localization during exhumation and associated retrograde metamorphism (e.g., Sibson, 1977, 1983; Smith et al., 2007; Herwegh et al., 2008; Toy et al., 2008; Oriolo et al., 2015).

7.6.2. Strain partitioning and timing of deformation in the Dom Feliciano Belt

Despite variations of strain with time operate at all scales (Lister and Williams, 1983; Schulmann et al., 2003; Leever et al., 2011; Carreras et al., 2013), most documented examples of shear zones developed within transpressional orogens only consider strain partitioning processes, i.e., simultaneous heterogeneous deformation of different domains (e.g., Sanderson and Marchini, 1985; Teyssier et al., 1995; Fossen et al., 1994; Fossen and Tikoff, 1998; Jones et al., 1997, 2004; Sullivan and Law, 2007; Fernández et al., 2013; Massey and Moecher, 2013). One of the main problems may arise from the difficulty to assess the age of deformation, as it is difficult to be directly dated and geochronological data cannot be easily interpreted in terms of deformation processes (van der Pluijm et al., 1994; Dunlap, 1997; Mulch and Cosca, 2004). Hence, a methodological approach combining 3D macro- to microstructural data and geochronological data from different structural

domains is compulsory to provide robust evolutionary models of orogens (van der Pluijm et al., 1994; Carreras et al., 2013; Oriolo et al., 2016b; Wang et al., 2016).

Quartz-micaschists and marbles may comprise mostly metasediments of the Las Tetas Complex based on detrital zircon data (Hartmann et al., 2001; Oyhantçabal et al., submitted; Chapter 4), although the easternmost outcrops of quartz-micaschists near the Arroyo Corrales Shear Zone may represent remnants of the Lavalleja Group (Oyhantçabal et al., submitted; Chapter 4). Structural data from these units reflect double vergence, transected folds and associated gently-dipping lineations towards the SSE (Fig. 7.4, 7.5), which are similar to results obtained by Rossini and Legrand (2003) in the Zanja del Tigre Complex. Double vergence has been typically reported for transpressional settings (e.g., Cunningham et al., 1996; Giambiagi et al., 2011; Ellero et al., 2015), whereas transected folds may indicate a non-coaxial component of deformation during or after folding (Treagus and Treagus, 1992). Lineation orientations and fold geometries, in turn, point to pure-shear dominated deformation and orogen-parallel extension or lateral extrusion (Jones et al., 1997, 2004; Sengupta and Ghosh, 2004). Minor thrusts might be associated with fold development, although neither clear field relationships nor geochronological data are available.

In contrast, fold geometries, lineation orientations and the dominance of relative asymmetric CPO quartz [c]-axis textures indicate strike-slip dominated deformation for most shear zones (Fig. 7.4, 7.5; Schmid and Casey, 1986; Jones et al., 2004; Sengupta and Ghosh, 2004). Nevertheless, quartz [c]-axis textures observed in the shear zones of the eastern Dom Feliciano Belt show more symmetric textures, which may indicate a larger component of coaxial deformation (Schmid and Casey, 1986).

Amphibole Ar/Ar data from sample UY-57-14 show the oldest cooling age of the western Dom Feliciano Belt at ca. 640-630 Ma, which is well agreement with the oldest Ar/Ar and K-Ar mica data based on the expected cooling temperatures. Within error, this age probably indicates the onset of deformation and metamorphism at ca. 630 Ma based on comparison with all available data from the Dom Feliciano Belt (Fig. 7.16), which would be further supported by the Ar/Ar amphibole age of

604 ± 14 Ma of sample UY-40-14. Alternatively, this could be related to a metamorphic event at ca. 650 Ma, which is well recorded in the basement of the eastern Dom Feliciano Belt (Oyhantçabal et al., 2009a; Basei et al., 2011a; Lenz et al., 2011) and was not reported so far for the western Dom Feliciano Belt. The disturbed spectrum of this sample prevents from doing further interpretations and more data are required to evaluate the potential presence of a metamorphic event at ca. 650 Ma in the western Dom Feliciano Belt.

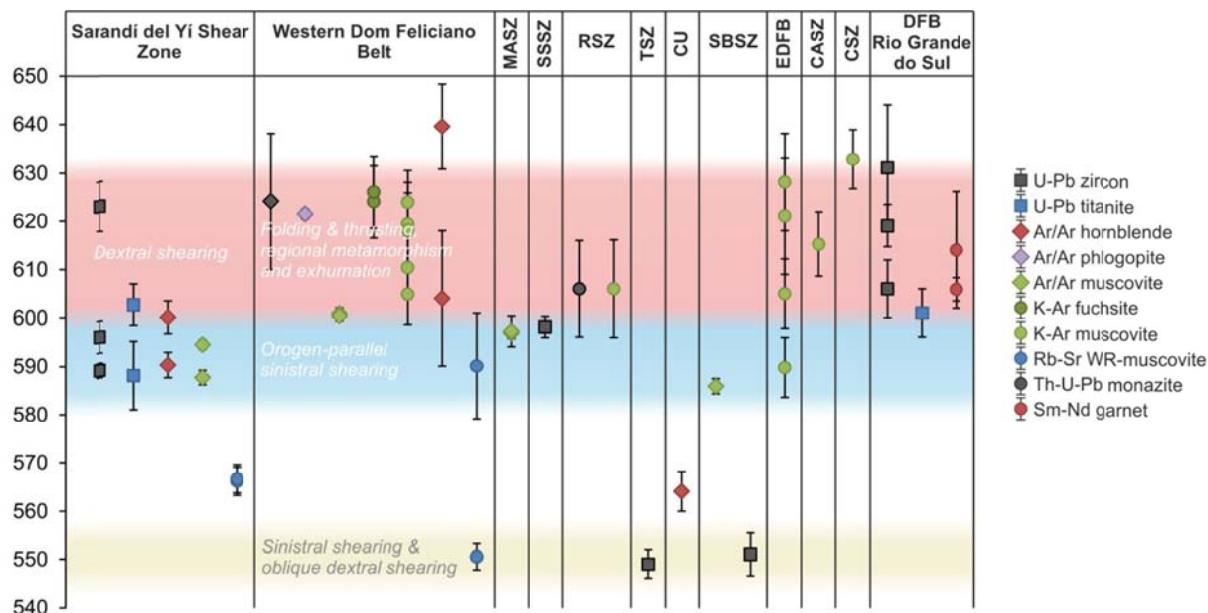

Fig. 7.16: Summary of geochronological constraints of the Dom Feliciano Belt of Uruguay after new and available data from the literature (U-Pb rutile, Passarelli et al., 2009; Campanero Unit and two K-Ar muscovite eastern Dom Feliciano Belt, Oyhantçabal et al., 2009a; Sierra Ballena Shear Zone Ar/Ar muscovite, Oyhantçabal et al., 2009b; Sierra Ballena Shear Zone U-Pb zircon, Oyhantçabal et al., 2011b; Rivera Shear Zone, Oyhantçabal et al., 2012). Geochronological data from the Dom Feliciano Belt in southernmost Brazil (Río Grande do Sul area) are included as well. U-Pb zircon metamorphic overgrowth data after da Silva et al. (1999), Chemale Jr. et al. (2011) and Philipp et al. (2015); U-Pb titanite data after Chemale Jr. et al. (2011) and Sm-Nd WR garnet data after Gross et al. (2006). MASZ: María Albina Shear Zone, SSSZ: Sierra de Sosa Shear Zone, RSZ: Rivera Shear Zone, TSZ: Tupambaé Shear Zone, CU: Campanero Unit, SBSZ: Sierra Ballena Shear Zone, CASZ: Cerro Amaro Shear Zone, CSZ: Cordillera Shear Zone. Data from the western and eastern (EDFB) Dom Feliciano in Uruguay and from the Dom Feliciano Belt in Rio Grande do Sul correspond to the timing of regional metamorphism and deformation.

On the other hand, the K-Ar fuchsite age is equivalent to the Ar/Ar phlogopite age and older than most K-Ar and Ar/Ar muscovite ages, excepting sample UY-54-14 (Fig. 7.16; Appendix 6). Both fuchsite and phlogopite samples were obtained from the Las Tetas Complex in close areas, whereas sample UY-54-14 was collected ca. 40 km to the NNE (Appendix 2). Although neither experimental nor theoretical constraints on Ar diffusion in fuchsite are available, these data suggest that the closure temperature for K/Ar in fuchsite may be slightly higher than in muscovite, probably close to the closure temperature of phlogopite for this system (Table 6.1). K-Ar and Ar/Ar muscovite ages, in turn, spread between ca. 624-600 Ma, which may indicate slightly differential cooling below muscovite closure temperature (Table 6.1) along the belt during exhumation and deformation (e.g., folding and thrusting of metasediments). Structural data from the Zapicán intrusion indicating emplacement during deformation of the belt further constraints regional deformation between ca. 630-600 Ma, as indicated by the 610.4 ± 2.5 Ma U-Pb LA-ICP-MS zircon age of the pluton (Oriolo et al., 2016a). This time span is equivalent to the timing of dextral shearing reported for the Sarandí del Yí Shear Zone (Fig. 7.16, 7.17; Chapter 6; Oriolo et al., 2016b), whereas coeval shearing along the Rivera Shear Zone at 606 ± 6 Ma was documented as well (Fig. 7.1, 7.16; Oyhantçabal et al., 2012). Furthermore, K-Ar data from the María Albina orthogneiss (sample UY-45-14, 619.4 ± 8.5 Ma) together with structural data indicating deformation during metasediment folding (Fig. 7.5) and CPO data asymmetry seem to indicate that a dextral shearing component might be also present during folding of the belt.

As late Neoproterozoic magmatism is widespread in the eastern Dom Feliciano Belt and may reset isotopic systems, the timing of metamorphism and regional metamorphism in this region is more difficult to assess. Nevertheless, K-Ar muscovite ages of ca. 630-620 Ma were obtained in pegmatites intruding the Cerro Olivo Complex (Oyhantçabal et al., 2009a), whereas a K-Ar muscovite age of 589.7 ± 6.2 Ma was obtained for the Puntas del Arroyo Rocha granite (Fig. 7.16). Muscovites from a pegmatitic dyke that cross-cuts a mylonitic granitoid yield a K-Ar age of 605.0 ± 7.2 Ma (Fig. 7.16), indicating deformation prior to pegmatite emplacement and subsequent cooling. Hence,

regional cooling of the eastern Dom Feliciano Belt below muscovite closure temperature might extend between ca. 630-590 Ma.

The María Albina Shear Zone yields Ar/Ar muscovite ages of 596.8 ± 11 and 597.2 ± 3.2 , whereas the Sierra de Sosa Shear Zones present a U-Pb LA-ICP-MS zircon age of 598.1 ± 2.2 Ma (Fig. 7.16). Maximum deformation conditions constrained for the María Albina Shear Zone were higher than the closure temperature for the K-Ar system in muscovite, and ages thus represent cooling after shearing. In the case of the Sierra de Sosa Shear Zone, the age seems to represent the crystallization age of the magmatic protolith, as zircons show dominance of prismatic habits with oscillatory zoning and $\text{Th}/\text{U} > 0.1$ (Hoskin and Schaltegger, 2003, and references therein). According to deformation conditions constrained for the shear zone, shearing probably took place shortly after emplacement of the protolith. In both cases, shearing might also predate the obtained ages, despite not being recorded by geochronological data, but similar ages were reported for sinistral shearing along the Sierra Ballena and the Sarandí del Yí shear zones (Fig. 7.16; Oyhantçabal et al., 2009b; Oriolo et al., 2016b). Sample UY-13-14 does not provide any clear constrain for deformation along the Sierra Ballena Shear Zone due to the strongly disturbed spectrum. Consequently, orogen-parallel sinistral shearing was active between ca. 598-584 Ma and clearly postdates regional deformation and metamorphism of the belt (Fig. 7.17). In the case of the eastern Dom Feliciano Belt, shear zone activity may also postdate the onset of regional deformation but might start prior to 600 based on the K-Ar of the Cerro Amaro and Cordillera shear zone. However, these shear zones show a large component of pure-shear, thus also supporting that deformation at ca. 630-600 Ma was dominated by pure shear as in the western Dom Feliciano Belt. However, more geochronological data are required to assess the timing of sinistral shearing in the eastern Dom Feliciano Belt.

A second event of shearing seems to be documented in the Tupambaé Shear Zone, indicating that oblique ENE-striking dextral shear zones were active at ca. 550 Ma (Fig. 7.16, 7.17). As in the case of the Sierra de Sosa Shear Zone, the age may represent the crystallization age of the magmatic protolith due to zircon habits, textures and Th/U ratios (Hoskin and Schaltegger, 2003, and

references therein). According to deformation conditions, deformation took place shortly after protolith emplacement. Contemporaneous shearing was documented for the Sierra Ballena Shear Zone (Oyhantçabal et al., 2011b), whereas cataclastic deformation since ca. 570 Ma up to the Cambrian was indicated for the Sarandí del Yí Shear Zone (Oriolo et al., 2015, 2016b). As in the latter, tectonic activity along other shear zones might be plausible during the late Ediacaran as well, but are probably not recorded by geochronological data. Evidences of cataclasis, pressure solution processes and phyllonite development could thus account for low-T deformation after shearing under ductile conditions constrained by geochronological data. Although Rb-Sr data from the folded metasediments do not reflect cooling paths as ages are younger than expected from closure temperatures, they may reflect resetting of the system during the two shearing events (Fig. 7.16). On the other hand, the Campanero Unit was probably exhumed during these late stages of the orogen, as indicated by the $^{40}\text{Ar}/^{39}\text{Ar}$ hornblende age of 564.0 ± 4.1 Ma (Fig. 16; Oyhantçabal et al., 2009a). Coeval low-grade metamorphism and subsequent cooling is recorded during the late Ediacaran in phyllites of the Lavalleja Group (545 ± 6 and 556 ± 8 Ma, K-Ar illite fine-fraction, Oyhantçabal et al., 2009a).

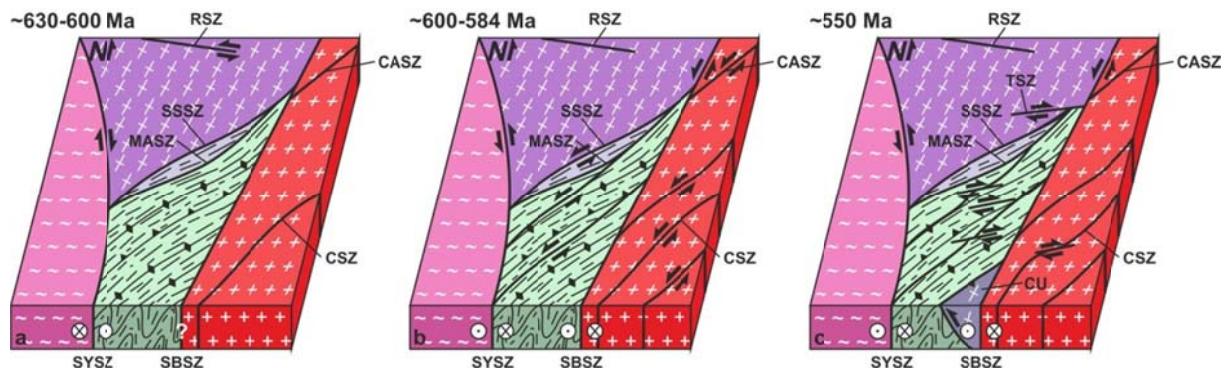

Fig. 7.17: Schematic structural evolution of the Dom Feliciano Belt (SYSZ: Sarandí del Yí Shear Zone, SBSZ: Sierra Ballena Shear Zone, RSZ: Rivera Shear Zone, SSSZ: Sierra de Sosa Shear Zone, MASZ: María Albina Shear Zone, CASZ: Cerro Amaro Shear Zone, CSZ: Cordillera Shear Zone, TSZ: Tupambaé Shear Zone). a) Main phase of regional metamorphism and deformation of the Dom Feliciano Belt (e.g., folding of the metasedimentary units) coeval with dextral shearing along the Sarandí del Yí Shear Zone. b) Sinistral shearing along N- to NNE-striking shear zones. c) Dextral shearing along ENE-striking shear zones and further sinistral shearing along N- to NNE-striking shear zones.

7.6.3. Structural evolution and regional implications

Structural data from the Dom Feliciano Belt indicate inclined transpression with partitioning into different deformational domains (Jones et al., 1997, 2004). Nevertheless, regional metamorphism and deformation in the Dom Feliciano Belt clearly predates deformation along localized shear zones. Hence, pure shear-dominated deformation related to crustal shortening was probably succeeded by strike-slip simple shear-dominated deformation, being the evolution of the Dom Feliciano Belt thus comparable with the Chongshan Shear Zone in the Himalayas (Zhang et al., 2010) and the eastern Pyrenees in the Cap de Creus area (Carreras and Druguet, 1994). Moreover, this model might account for the development of transected folds (Treagus and Treagus, 1992). Although strike-slip simple shear-dominated deformation is recorded along most shear zones of the Dom Feliciano Belt, coeval pure-shear dominated deformation was reported for the Sierra Ballena and Sarandí del Yí shear zones (Oyhantçabal et al., 2009b; Oriolo et al., 2015), indicating strain partitioning to some extent. On the other hand, late deformation along oblique ENE-striking dextral shear zones, which are antithetic regarding sinistral shearing along main N- to NNE-striking shear zones, also matches proposals that indicate late activation of antithetic oblique structures regarding orogen-parallel structures (Cembrano et al., 2005).

New and available geochronological data from the Dom Feliciano Belt places the onset of deformation and metamorphism at ca. 630 Ma (Fig. 7.16). These results match the onset of the collision between the Río de la Plata craton and the Nico Pérez Terrane/Congo Craton system along the Sarandí del Yí Shear Zone at 630-625 Ma (Chapter 6; Oriolo et al., 2016b) as well as ages of metamorphism and syncollisional magmatism reported for the Dom Feliciano Belt in Río Grande do Sul in southernmost Brazil (Fig. 7.16; da Silva et al., 1999; Gross et al., 2006; Chemale Jr. et al., 2011; Philipp et al., 2013, 2016). The collisional phase of the Dom Feliciano Belt in the Santa Catarina region, in turn, was alternatively placed between ca. 650 and 600 Ma (Basei et al., 2008; Chemale Jr. et al., 2012; Florisbal et al., 2012). Likewise, post-collisional magmatism since ca. 630 Ma is

ubiquitously recorded along the belt (Oyhantçabal et al., 2007; Florisbal et al., 2009, 2012; Sacks de Campos et al., 2012; de Oliveira et al., 2015).

7.7. Conclusions

The Dom Feliciano Belt records inclined transpression and strain partitioning processes. The main phase of deformation, metamorphism and associated exhumation below muscovite closure temperature conditions is recorded between 630 and 600 Ma, which is related to the collision of the Río de la Plata and Congo cratons. Subsequent sinistral shearing along N- to NNE-striking shear zones gave rise to further deformation up to ca. 584 Ma. These shear zones record progressive strain localization and retrograde conditions of deformation during crustal exhumation. Dextral ENE-striking shear zones were subsequently active at ca. 550 Ma, coeval with further sinistral shearing along N- to NNE-striking shear zones to some extent.

-CHAPTER 8-

Discussion: Implications for the tectonic evolution of Western Gondwana

8.1. Pre-Gondwana configuration

Several contributions attempted to elucidate the Mesoproterozoic paleogeography (e.g., Powell et al., 1993; Dalziel et al., 2000; Kröner and Cordani, 2003; Pisarevsky et al., 2003; Tohver et al., 2006; Li et al., 2008; Evans, 2009), which represents a key point to understand the history of Gondwana amalgamation. Despite most authors agree on the fact that the Amazonas and West African cratons were part of Rodinia (Dalziel et al., 2000; Tohver et al., 2006; Li et al., 2008; Evans, 2009), the participation of southwestern Gondwanic blocks is still under discussion. Kröner and Cordani (2003) indicated that the Río de la Plata and Congo-São Francisco cratons were not part of Rodinia, which was further supported by Tohver et al. (2006) and Rapalini et al. (2013). In contrast, Evans (2009) included both blocks within Rodinia. In the case of the Río de la Plata Craton, the pre-Brasiliano geological record is restricted to the Paleoproterozoic (Cingolani, 2011; Oyhantçabal et al., 2011a), pointing to lack of Mesoproterozoic events and isolation of the Río de la Plata Craton during Rodinia evolution. The Congo-São Francisco Craton, in turn, exhibits several distinct Mesoproterozoic magmatic events at ca. 1.50, 1.38 and 1.10 Ga (Ernst et al., 2013). Although the youngest event is almost coeval with the timing of Rodinia assembly, it is unclear if it is related to a convergent or an intraplate setting (Ernst et al., 2013; Debruyne et al., 2015). A different situation can be observed in the Kalahari Craton, which was clearly part of Rodinia based on the existence of the Namaqua-Natal Belt (e.g., Thomas et al., 1994; Dalziel et al., 2000; Cornell et al., 2006; Eglington, 2006; Spencer et al., 2015). In any case, most reconstructions do not consider Mesoproterozoic connections of the Congo-São Francisco and Kalahari cratons, even if the former was part of Rodinia (Evans, 2009), which is further supported by detrital zircon data from the Damara Belt (Foster et al., 2015) and paleomagnetic data (Bartholomew, 2008). Hence, the Río de la Plata, Congo-São Francisco and Kalahari cratons did not interact with each other prior to their incorporation into Gondwana, being only the latter part of Rodinia.

On the other hand, new data presented herein further supports the allochtony of the Nico Pérez Terrane regarding the Río de la Plata Craton and its derivation from the Congo Craton, previously suggested by Oyhantçabal et al. (2011a) and Rapela et al. (2011). The oldest Neoproterozoic record in the southern Dom Feliciano Belt, in turn, is constituted by the high-grade rocks of the Cerro Olivo Complex, which contains zircons yielding U-Pb concordant ages of ca. 800–750 Ma (Hartmann et al., 2002; Oyhantçabal et al., 2009a; Basei et al., 2011a; Lenz et al., 2011). Due to similar ages reported in the Coastal Terrane of the Kaoko Belt (Kröner et al., 2004; Konopásek et al., 2008), both regions were correlated and these ages were interpreted as the timing of rifting-related magmatism during the Rodinia break-up (Kröner et al., 2004; Oyhantçabal et al., 2009a; Basei et al., 2011a; Frimmel et al., 2011; Rapela et al., 2011; Konopásek et al., 2014), although some contributions indicated a convergent setting for this event (Lenz et al., 2013; Koester et al., 2016). Hence, the African crustal affinity of the Nico Pérez Terrane together with correlations between the Cerro Olivo Complex and the Coastal Terrane point to Cryogenian rifting of the Nico Pérez Terrane from the Congo Craton margin as indicated by Rapela et al. (2011), in contrast to contributions interpreting the Cerro Olivo Complex as the basement of a distinct terrane (Bossi and Gaucher, 2004; Gaucher et al., 2010; Basei et al., 2011a). Similarities in the detrital zircon pattern of the southwestern Dom Feliciano Belt metasediments (Chapter 4) and a quartzite of the southeastern Dom Feliciano Belt basement (Nedrebø, 2014) would further support that the underlying Nico Pérez Terrane basement and the Cerro Olivo Complex, respectively, comprised a single African block.

Further to the north, the Nico Perez Terrane extends up to the Taquarembó block in Río Grande do Sul, southeastern Brazil (Fig. 1.4; Oyhantçabal et al., 2011a). To the east of this block, isolated outcrops of gneisses of the Encantadas Complex within the Pelotas Batholith record Paleoproterozoic magmatism at ca. 2.3–2.0 Ga (Hartmann et al., 2000b, 2003a; Leite et al., 2000; Saalmann et al., 2011), which is comparable to magmatism recorded in the Nico Pérez Terrane in Uruguay (Chapter 3) and the Taquarembó Block. Sm-Nd model ages in the area are mostly Archean and Paleoproterozoic (Gastal et al., 2005), being also similar to those recorded in the Nico Pérez

Terrane (Oyhantçabal et al., 2011a). Cryogenian magmatism is recorded as well (da Silva et al., 1999; Hartmann et al., 2000a; Koester et al., 2016). Archean-Paleoproterozoic magmatism with Archean Hf and Sm-Nd model ages is also recorded in the Camboriú Complex in the Santa Catarina region (Hartmann et al., 2000c, 2003b; Basei et al., 2013b), thus allowing possible correlations with the Nico Pérez Terrane. Independently of whether Archean-Paleoproterozoic basement inliers of the Dom Feliciano Belt comprised a single block or not, the existence of Cryogenian magmatism may suggest that all these blocks were rifted during Rodinia break-up from the southwestern Congo Craton (Rapela et al., 2011). If so, the first rifting phase reported by Li et al. (2008) also extended up to the Congo Craton margin (Fig. 8.1).

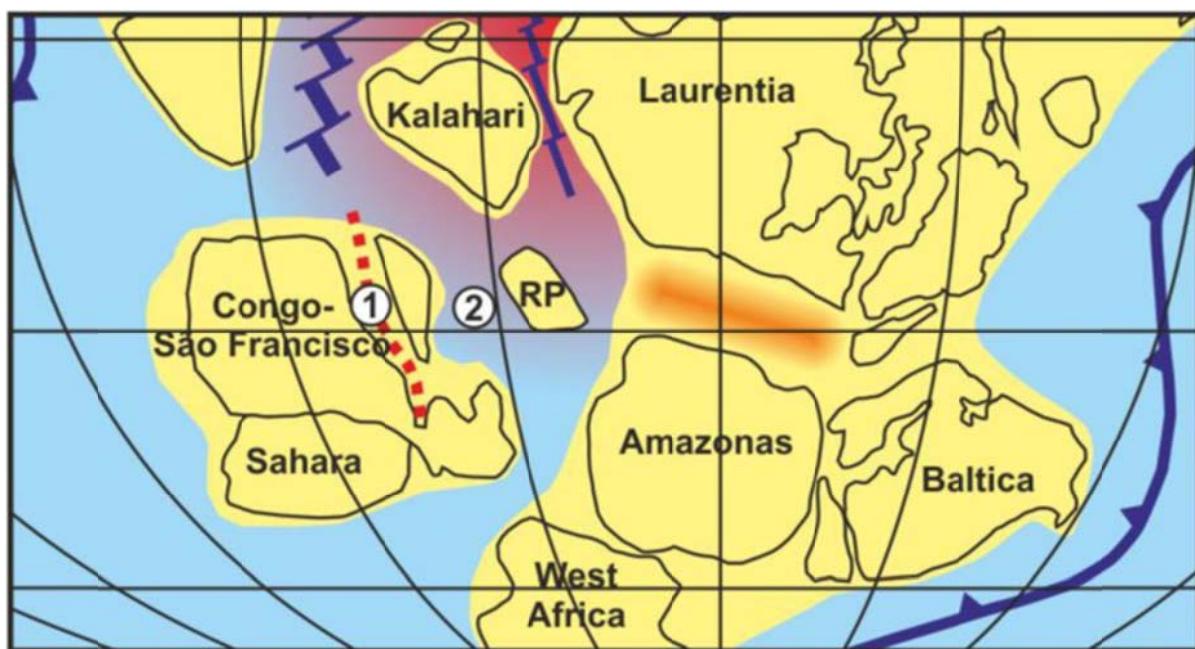

Fig. 8.1: Schematic paleogeography showing main crustal block distribution during Rodinia break-up at ca. 720 Ma (see Fig. 1.1 for comparison; modified after Li et al., 2008). The red line shows the position of the rifting of Congo-derived blocks amalgamated to the Río de la Plata Craton margin during the Ediacaran (e.g., Nico Pérez Terrane). Two possible positions after the redefinition of the Adamastor Ocean are presented as well (1: proto-Adamastor developed during Cryogenian crustal extension after Rapela et al., 2011; 2: Adamastor as a pre-Cryogenian remnant ocean separating the Río de la Plata Craton and the Congo-derived blocks after Cordani et al., 2003). Subduction zones and spreading ridges are indicated in blue, whereas the red area indicates the possible location of a mantle plume. The rifting zone at ca. 600 Ma between Laurentia and Amazonas is shown in orange.

Rapela et al. (2011) considered that the rifting gave rise to the opening of the Adamastor Ocean. Nevertheless, the Adamastor Ocean was originally defined by Hartnady et al. (1985) for the ocean closed during the evolution of the Gariep and Damara belts, and was afterwards extended to the Dom Feliciano Belt (Fragoso Cesar, 1991). Fragoso Cesar (1991) considered that the Adamastor Ocean separated the Río de la Plata and Kalahari cratons prior to the collisional phase of the Dom Feliciano Belt, which gave rise to the closure of the oceanic basin. Considering new and available evidences summarized in this work (e.g., Chapter 3, 6, 7; Section 8.2), this phase was related to the Río de la Plata and Congo collision, which also included the amalgamation of minor crustal blocks such as the Nico Pérez Terrane. Likewise, the definition of the Río de la Plata Craton after Oyhantçabal et al. (2011a) also differs from the definition considered by Fragoso Cesar (1991), as the Sarandí del Yí Shear Zone comprises its eastern boundary. Hence, the existence of the Adamastor Ocean can be questioned, or it should be at least redefined. If the Adamastor is regarded as the ocean located to the east of the Río de la Plata Craton as indicated by Fragoso Cesar (1991), it may thus represent a probable pre-Cryogenian remnant ocean (Fig. 8.1; Cordani et al., 2003), ruling out that its opening was related to the beginning of a “Brasiliano Wilson Cycle” (Fragoso Cesar, 1991) or to Cryogenian rifting (Rapela et al., 2011). On the other hand, if Cryogenian magmatism records crustal extension that triggered the ocean development, the Adamastor would have separated the Congo Craton from the Congo-rifted blocks (Fig. 8.1), and not from the Río de la Plata Craton as originally defined by Fragoso Cesar (1991). However, no evidences of Cryogenian oceanic crust generation were founded so far as Cryogenian rocks show Sm-Nd Paleo- to Mesoproterozoic T_{DM} ages, and some contributions even indicated that this magmatism could be associated with a convergent setting (Lenz et al., 2013; Koester et al., 2016). In order to test the validity of these hypotheses, more data are nevertheless required.

8.2. The Brasiliano–Pan-African Orogeny in southwestern Gondwana

Since early contributions recognized the existence of late Neoproterozoic tectonic events in South America and Africa and first correlations across the Atlantic Ocean were established (Almeida et al., 1973, 1981; Miller, 1983; Porada, 1985, 1989; Brito Neves and Cordani, 1991; Fragoso Cesar, 1991), works focused on the Brasiliano–Pan-African Orogeny have diversified. Nevertheless, the amalgamation of Western Gondwana and the evolution of the Dom Feliciano Belt are a matter of ongoing debate. Some hypotheses have linked the Dom Feliciano with the Gariep Belt, thus indicating that tectonic processes recorded in both areas were related to convergence and subsequent collision between the Río de la Plata and Kalahari cratons (Basei et al., 2005; Frimmel et al., 2011, 2013). Other proposals, in contrast, have indicated first assembly of the Río de la Plata and Congo cratons, favoring correlations between the Dom Feliciano and Kaoko belts (Prave, 1996; Alkmim et al., 2001; Goscombe and Gray, 2007; Oyhantçabal et al., 2011b; Rapela et al., 2011; Konopásek et al., 2014; Oriolo et al., 2016b).

New and available data point to collision at ca. 630 Ma of the Río de la Plata and Congo Craton, which also implied the amalgamation of minor blocks located at the attenuated Congo Craton margin (i.e., the Nico Pérez Terrane and the Cerro Olivo Complex/Coastal Terrane; Chapter 3, 6, 7). Several contributions demonstrated the correlation between the Coastal Terrane in Africa and the Cerro Olivo Complex in Uruguay (Gross et al., 2009; Oyhantçabal et al., 2009a; Basei et al., 2011a; Lenz et al., 2011; Rapela et al., 2011; Konopásek et al., 2014), as they both record Cryogenian rifting-related magmatism and high-grade metamorphism at ca. 650 Ma (Hartmann et al., 2002; Kröner et al., 2004; Konopásek et al., 2008; Oyhantçabal et al., 2009a; Basei et al., 2011a; Lenz et al., 2011). Goscombe and Gray (2007, 2008) and Konopásek et al. (2014) indicated an arc/barck-arc domain at ca. 650-630 Ma at the attenuated Congo Craton margin, implying subduction towards the east and a trench located to the west of the Coastal Terrane. Consequently, metamorphic conditions of the Cerro Olivo Complex and the Coastal Terrane could be explained by arc-related high-grade metamorphism and magmatism followed by the accretion of the Nico Pérez Terrane and the Río de

la Plata Craton (Fig. 8.2a, 8.2b). Similar P-T conditions in arc settings were reported by Tibaldi et al. (2013) and Maki et al. (2014) in the Famatinian arc (Western Sierras Pampeanas) and the Higo metamorphic terrane (central Kyushu), respectively.

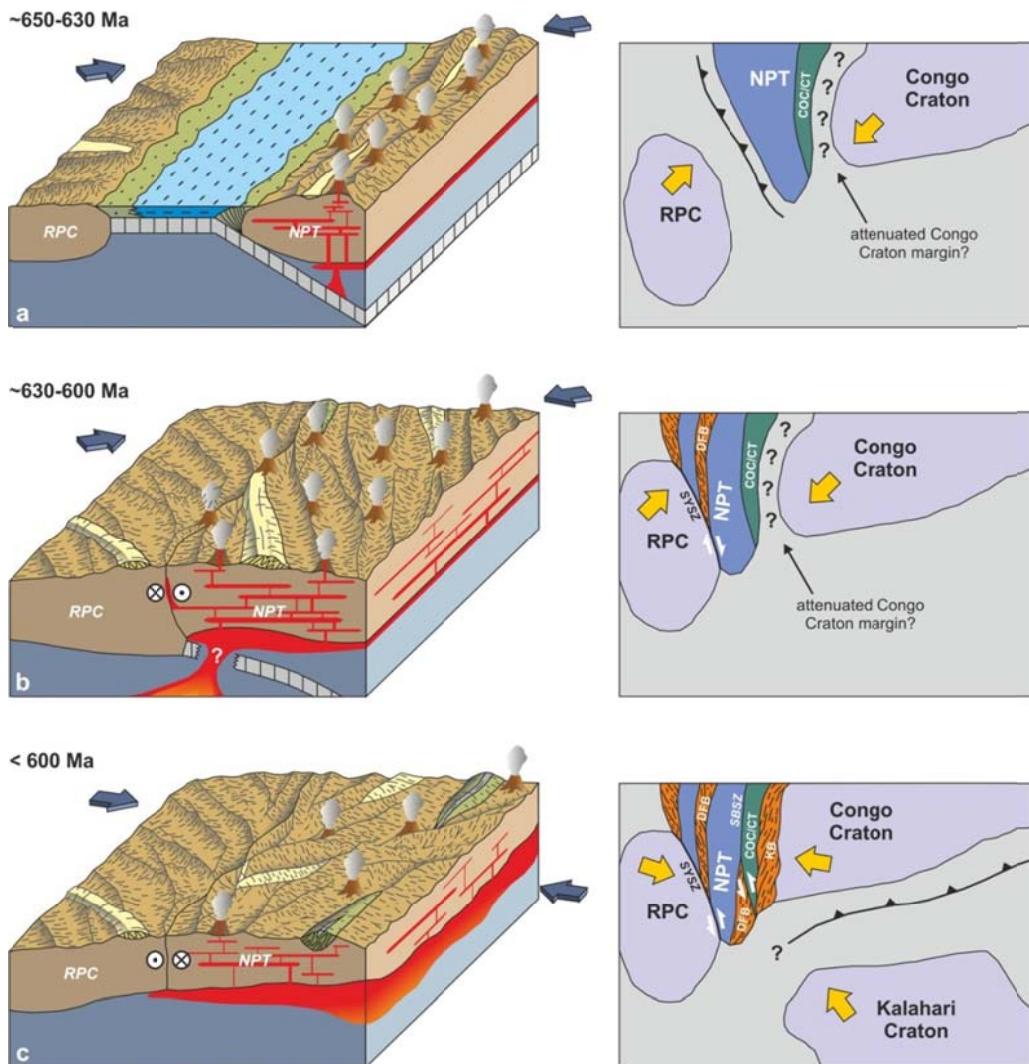

Fig. 8.2: Tectonic evolution model for the Sarandí del Yí Shear Zone and adjacent crustal blocks. The paleogeographic framework is schematized on the right. RPC: Río de la Plata Craton, NPT: Nico Pérez Terrane, COC/CT: Cerro Olivo Complex/Coastal Terrane, DFB: Dom Feliciano Belt, KB: Kaoko Belt, SYSZ: Sarandí del Yí Shear Zone, SBSZ: Sierra Ballena Shear Zone. a) Subduction under the Nico Pérez Terrane, which was probably part of the attenuated margin of the Congo Craton margin. b) Juxtaposition of the Río de la Plata Craton and the Nico Pérez Terrane and consequent onset of deformation along the Sarandí del Yí Shear Zone at ca. 630 Ma. During the post-collisional phase and associated slab break-off, dextral shearing along the shear zone was coeval with deformation, metamorphism and magmatism in the Dom Feliciano Belt. c) Sinistral shearing in the Sarandí del Yí Shear Zone after ca. 600 Ma. Further post-collisional magmatism and sinistral shearing along the shear zones of the Dom Feliciano Belt are also recorded. The switch to sinistral shearing was related to the onset of the convergence of the Kalahari Craton.

Oblique collision and associated deformation, metamorphism and exhumation extended up to ca. 600 Ma in the Dom Feliciano Belt, as indicated by geochronological data (Fig. 7.16). The Kaoko Belt, in turn, records this phase since 580 Ma as it comprised a foreland domain, indicating deformation and exhumation migration towards the east (Goscombe et al., 2005a; Konopásek et al., 2005; Goscombe and Gray, 2007, 2008; Foster et al., 2009; Ulrich et al., 2011). This is further supported by docking of the Coastal Terrane to the Kaoko Belt western margin at 645-580 Ma (Goscombe and Gray, 2007).

Widespread post-collisional magmatism is recorded in the Nico Pérez Terrane and the Dom Feliciano Belt after ca. 630 Ma (Oyhantçabal et al., 2007; Florisbal et al., 2009, 2012; Sacks de Campos et al., 2012; de Oliveira et al., 2015). Likewise, minor post-collisional magmatism is recorded in the Piedra Alta Terrane at 587.1 ± 7.9 Ma (Cingolani et al., 2012), whereas hydrothermal activity at ca. 620-590 Ma was reported for the Tandilia Belt (Martínez et al., 2013). Asthenospheric upwelling due to slab break-off after collision could account for this process (Figure 8.2b; Oyhantçabal et al., 2007), as in the Western Kunlun orogenic belt in the Tibet Plateau (Ye et al., 2008) and the Alps (von Blanckenburg and Davies, 1998), giving rise to thinning of the lithospheric mantle under the Nico Pérez Terrane and consequent thermal destabilization (Black and Liégeois, 1993; Liégeois et al., 2013), which is supported by cooling age patterns (Figure 6.6c; Oyhantçabal et al., 2011a). Moreover, significant post-collisional synkinematic magmatism is recorded along the Sarandí del Yí Shear Zone (Figure 6.6a) and is thus comparable with the magmatism along the Periadriatic Lineament (Steenken et al., 2000; Rosenberg, 2004; Stipp et al., 2004), which also represents a first-order tectonic boundary (Schmid et al., 1989).

The switch from dextral to sinistral shearing along the Sarandí del Yí Shear Zone together with sinistral shearing along NNE-striking shear zones of the Dom Feliciano point to a geodynamic change at ca. 600 Ma (Fig. 6.6a, 7.16; Oyhantçabal et al., 2009b; Oriolo et al., 2016b), postdating the main crustal shortening and metamorphism phase. In a similar way, sinistral shearing along main shear zones in the Kaoko Belt was recorded after ca. 570-550 Ma (Goscombe et al., 2005; Konopásek

et al., 2005; Goscombe and Gray, 2007, 2008; Foster et al., 2009; Ulrich et al., 2011), providing further evidences of deformation migration towards the foreland.

The onset of convergence between the Kalahari and Río de la Plata-Congo cratons along the Damara Belt at ca. 600 Ma provides a satisfactory explanation for ubiquitous sinistral shearing in the Dom Feliciano Belt (Figure 8.2c; Lehmann et al., 2015; Oriolo et al., 2016b). This plate reorganization could be further supported by the sudden change in the apparent polar wander path of the Congo Craton observed after ca. 590 Ma (Moloto-A-Kenguemba et al., 2008). Consequently, the assembly of the Río de la Plata and Congo cratons clearly predates the incorporation of the Kalahari Craton in Western Gondwana, which is further supported by detrital zircon data of the eastern Dom Feliciano and Kaoko belts (Section 4.5.3). In the Dom Feliciano Belt, the final incorporation of the Kalahari Craton gave rise to the closure of the Rocha basin, which was located at the southeastern margin of the Dom Feliciano Belt and represented the western counterpart of the Gariep basin (Basei et al., 2005; Blanco et al., 2009; Frimmel et al., 2011, 2013).

8.3. The diachronous assembly of Gondwana

Comparison of available data allows characterizing the amalgamation of the Río de la Plata and Congo cratons as the earliest collisional phase recorded during the Brasiliano–Pan-African Orogeny (Fig. 8.3, 8.4a), indicating that they probably comprised the first Gondwana nucleus. Subsequent collisional processes up to 600 Ma are recognizable further to the north along the Transbrasiliano-Kandi Lineament (Ganade de Araujo et al., 2014a, 2014b, 2014c; Ganade et al., 2016), the Ribeira and Brasilia belts (Bento dos Santos et al., 2010; Campos Neto et al., 2010) and the LATEA metacraton (Berger et al., 2014). This implied the incorporation of the Amazonas and West African cratons as well as of the Saharan Metacraton into Gondwana during this period (Fig. 8.3, 8.4b), revealing that the first stages of Gondwana assembly are contemporaneous with the last events related to Rodinia break-up, which were related to the opening of the Iapetus Ocean at 610-

600 Ma (Fig. 8.3; Cawood et al., 2001; Hartz and Torsvik, 2002; Li et al., 2008; O'Brien and van der Pluijm, 2012; Johansson, 2014; Lubnina et al., 2014).

Interestingly, all collisional orogens between 630 and 600 Ma show some similarities. Although the timing of collision is slightly diachronous, they are all bounded to the west by crustal-scale dextral shear zones, namely the Transbrasiliano-Kandi Lineament (Ganade de Araujo et al., 2014a, 2014b, 2014c) and the Sarandí del Yí Shear Zone (Chapter 5, 6; Oriolo et al., 2015, 2016b), which separate them from cratonic areas (i.e., West African, Amazonas and Río de la Plata cratons). They also record Cryogenian magmatism and subsequent arc/back-arc magmatism with subduction to the east since ca. 660 Ma up to the collisional phase, probably implying the existence of one of the largest collisional zones in the geological history (Fig. 8.4a; Goscombe and Gray, 2007, 2008; Rapela et al., 2011; Berger et al., 2014; Ganade de Araujo et al., 2014c; Konopásek et al., 2014; Ganade et al., 2016; Oriolo et al., 2016b). The subsequent collision gave rise to the birth of Western Gondwana and the consequent amalgamation of African-derived crustal blocks to the South American Archean-Proterozoic nuclei (Fig. 8.4b; Rapela et al., 2011; Chapter 3).

Available O and Hf isotopic data combined with geological evidences reveal that juvenile continental crustal addition took place to some extent during Tonian to Cryogenian subduction, mostly related to island arc or back-arc systems associated with northwestern Gondwanic cratons (Fig. 8.5; Matteini et al., 2010; Fortes de Lena et al., 2014; Ganade de Araujo et al., 2014c; Ali et al., 2015). In contrast, coeval magmatism recorded in southwesternmost Gondwanic blocks show higher $\delta^{18}\text{O}$ values and Meso- to Paleoproterozoic Hf model ages, indicating a dominant crustal source (Rapela et al., 2011; Frimmel et al., 2013). However, Archean to Mesoproterozoic Hf model ages and high $\delta^{18}\text{O}$ values in zircons younger than ca. 650 Ma reveal that the timing of Gondwana amalgamation was ubiquitously dominated by crustal reworking processes (Fig. 8.5). This is further supported by geological evidences, as deformation, metamorphism and voluminous post-collisional magmatism and shear zone activity that reworked basement units were elsewhere recognized (Abdesalam et al., 2002; Liégois et al., 2003; Neves, 2003; da Silva et al., 2005; Oyhantçabal et al.,

2007, 2011a, 2011b, 2012; Teixeira et al., 2010; Berger et al., 2014; Ganade de Araujo et al., 2014a), indicating the importance of metacratonization processes during Gondwana assembly (Fig. 8.4b; Liégois et al., 2013). This also agrees with proposals indicating that accretional tectonics favour crustal growth in comparison with collisional tectonics, which are dominated by crustal reworking processes (Collins et al., 2011).

As previously outlined, the Kalahari Craton was lately incorporated into Western Gondwana, as indicated by the timing of collision in the Gariep, Saldania, Damara and Zambezi belts (Fig. 8.3, 8.4d, 8.4e; Frimmel and Frank, 1998; John et al., 2004; Gray et al., 2006; Frimmel et al., 2011, 2013; Schmitt et al., 2012). However, the onset of the Kalahari convergence with the already amalgamated Western Gondwana is recorded since ca. 600-590 Ma in both Damara and Dom Feliciano belts (Section 8.2; Lehmann et al., 2016; Oriolo et al., 2016b).

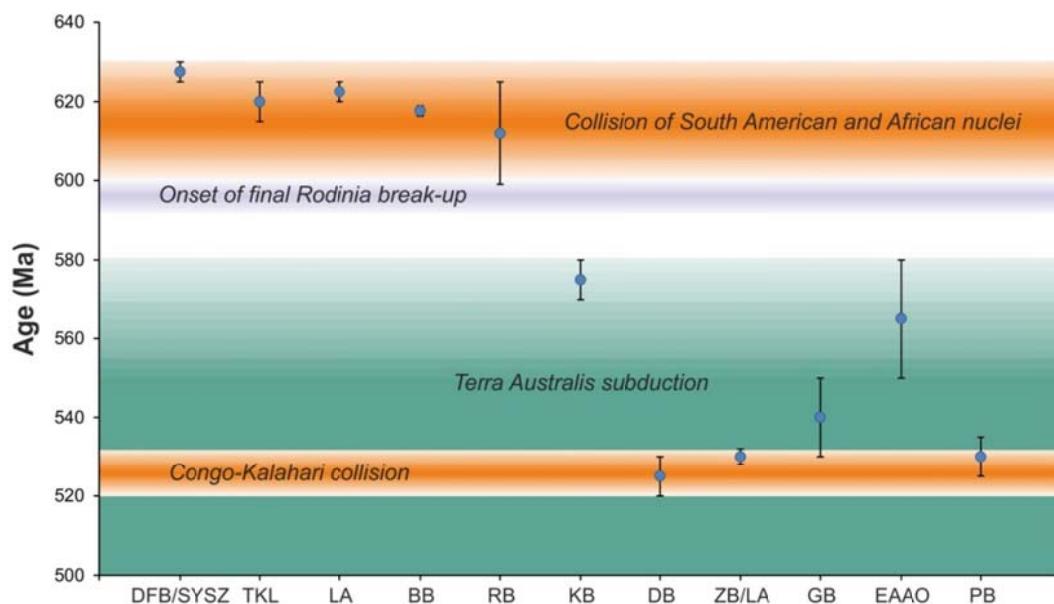

Fig. 8.3: Timing of Gondwana-related collisional events summarized from available data. DFB/SYSZ: Dom Feliciano Belt/Sarandí del Yí Shear Zone (this work), TKL: Transbrasiliiano-Kandi Lineament (Ganade de Araujo et al., 2014a, 2014b, 2014c), LA: LATEA Metacraton (Berger et al., 2014), BB: Brasilia Belt (Campos Neto et al., 2010), RB: Ribeira Belt (Bento dos Santos et al., 2010), KB: Kaoko Belt (Goscombe et al., 2005; Goscombe and Gray, 2007, 2008; Foster et al., 2009), DB: Damara Belt (Gray et al., 2006; Schmitt et al., 2012), Zambezi Belt/Lufillian Arc (John et al., 2004), GB: Gariep Belt (Frimmel and Frank, 1998; Frimmel et al., 2011), EAEO: East African-Antartic Orogen (Jacobs and Thomas, 2004; Viola et al., 2008), PB: Pampean Belt (Rapela et al., 1998, 2007; Siegesmund et al., 2010). Onset of final Rodinia break-up after Li et al. (2008) and subduction along the Terra Australis Orogen after Cawood (2005) and Cawood and Buchan (2007) are shown as well. See text for further explanations.

Collisional processes at 580-550 Ma were reported in the East African-Antarctic Orogen (Fig. 8.4d; Jacobs and Thomas, 2004; Viola et al., 2008; Fritz et al., 2013), indicating that the assembly of Western and Eastern Gondwana predates the final incorporation of the Kalahari Craton into the former. Nevertheless, the accretion of the juvenile Arabian-Nubian Shield to the Congo Craton/Saharan Metacraton margin was constrained at ca. 650-620 Ma (Fig. 8.4a; Fritz et al., 2013).

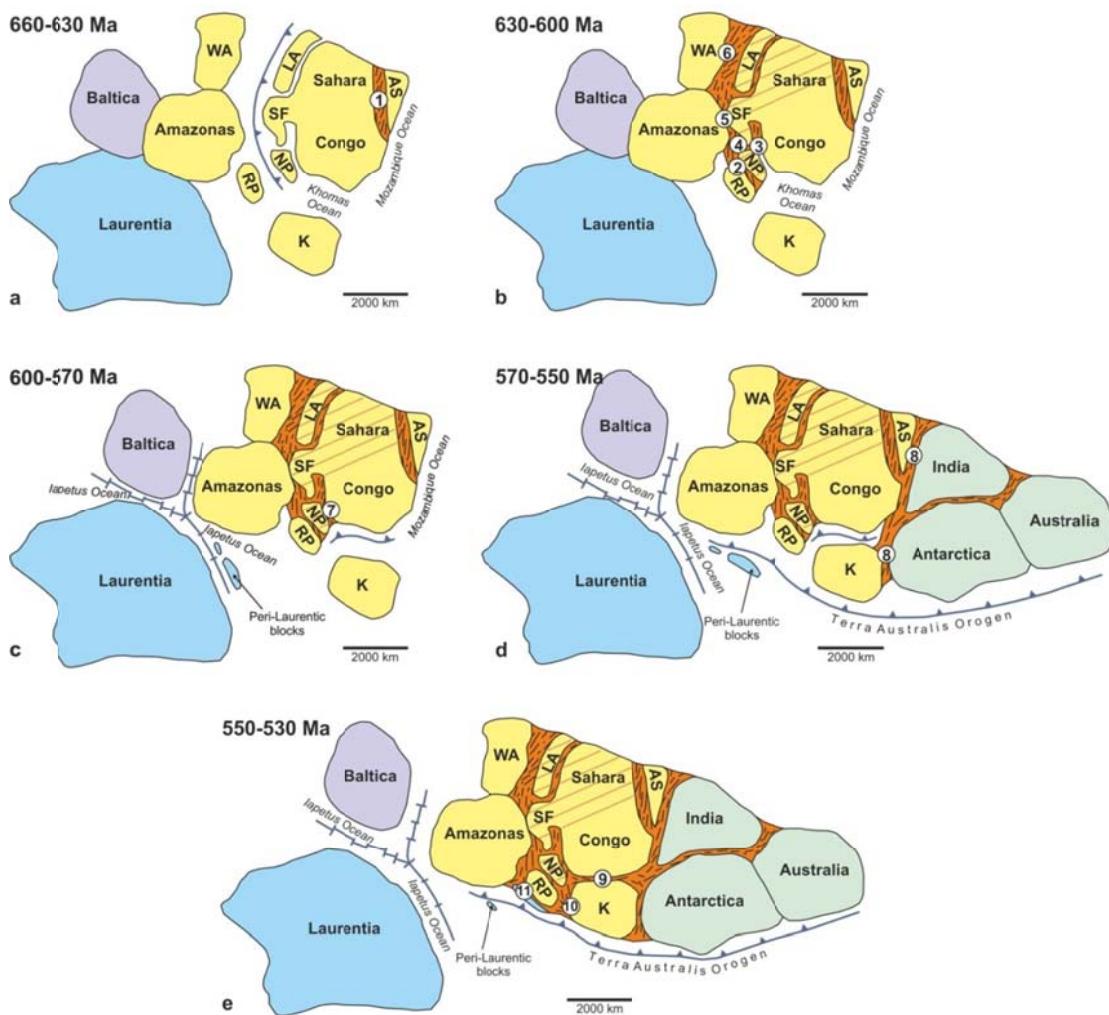

Fig. 8.4: Schematic tectonic and paleogeographic evolution of main crustal blocks (WA: West Africa, RP: Río de la Plata, K: Kalahari, NP: Nico Pérez, SF: São Francisco, LA: LATEA, AS: Arabian-Nubian Shield). Gondwana reconstructions modified after Meert and Lieberman (2004), Collins and Pisarevsky (2005), Tohver et al. (2006), Li et al. (2008), Pisarevsky et al. (2008), Pradhan et al. (2009) and Johansson (2014). Evolution of Laurentia, Baltica and Iapetus Ocean after Cawood et al. (2001), Hartz and Torsvik (2002), O'Brien and van der Pluijm (2012) and Lubnina et al. (2014). Terra Australis Orogen after Cawood (2005) and Cawood and Buchan (2007). See text for further explanations. Red dashed lines indicate areas that underwent metacratonization. 1: northern East African Orogen, 2: Dom Feliciano Belt, 3: Ribeira Belt, 4: Brasilia Belt, 5: Transbrasiliano Lineament, 6: Kandi Lineament, 7: Kaoko Belt, 8: East African-Antarctic Orogen, 9: Damara Belt, 10: Gariep and Saldania belts, 11: Pampean Belt.

On the southeastern margin of Western Gondwana, late Ediacaran-Cambrian subduction is recorded along the Terra Australis Orogen, which also extended up to the southern Eastern Gondwana margin (Cawood, 2005; Cawood and Buchan, 2007). Along this margin, several peri-Laurentic blocks were rifted away during the opening of the Iapetus Ocean and subsequently juxtaposed to the Gondwana margin during the Paleozoic (e.g., Dalla Salda et al., 1992; Dalziel et al., 1994). Among them, Pampia was one of the first amalgamated blocks (Ramos et al., 2010), which collided with the Río de la Plata Craton during the early Cambrian Pampean Orogeny (Fig. 8.3, 8.4e; Rapela et al., 1998, 2007; Siegesmund et al., 2010).

8.4. Implications for the supercontinent cycle

Late Neoproterozoic-Cambrian collisions leading to the final Gondwana assembly and coeval subduction along the Terra Australis Orogen suggest a coupling between internal collisional and marginal subduction processes, as indicated by Cawood and Buchan (2007). Likewise, these processes seemed to be strongly linked to the final stages of Rodinia break-up, particularly to the opening of the Iapetus Ocean (Pisarevsky et al., 2008). Hence, the evolution of Gondwana emphasizes the need to reevaluate the classical concept of supercontinent cycle (Nance *et al.*, 2014, and references therein), as supercontinent assembly and break-up do not necessarily represent alternating episodic processes but may overlap in time (Condie and Aster, 2013). As a first conclusion, the proposed Gondwana evolution (Fig. 8.4) allows ruling out the existence of the supercontinent Pannotia (Powell and Young, 1995; Dalziel, 1997), as Laurentia, Western and Eastern Gondwana were not part of a single supercontinent during the late Neoproterozoic. Indeed, Laurentia and Amazonas connections just represented remnants of the Rodinia assembly.

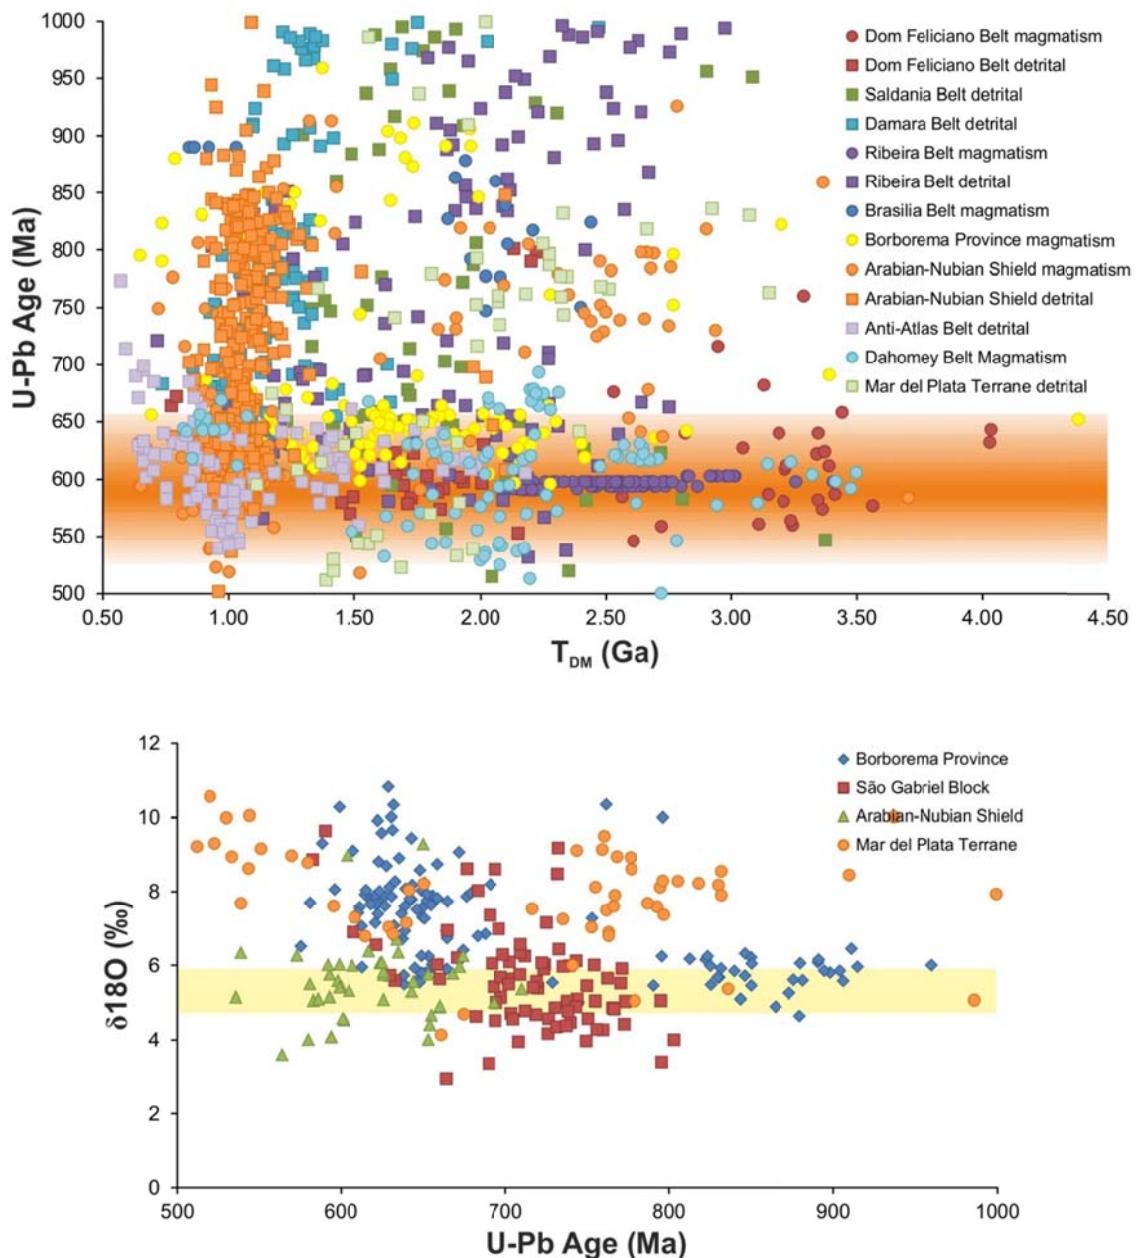

Fig. 8.5: Synthesis of available isotopic data from Neoproterozoic zircons of Brasiliano–Pan-African belts. a) Hf T_{DM} vs. U-Pb data after this work, Be’eri-Shlevin et al. (2010), Matteini et al. (2010), Morag et al. (2011), Rapela et al. (2011), Abati et al. (2012), Ali et al. (2012, 2013, 2015), Basei et al. (2013b), Frimmel et al. (2013), Ganade de Araujo et al. (2014c), Fernandes et al. (2015), Foster et al. (2015), Janasi et al. (2015), Pertille et al. (2015b) and Ganade et al. (2016). The timing of Gondwana amalgamation is indicated in orange. b) U-Pb vs. $\delta^{18}\text{O}$ data after Rapela et al. (2011), Ganade de Araujo et al. (2014c), Fortes de Lena et al. (2014) and Ali et al. (2015).

Two end-member processes were proposed for the formation of supercontinents, namely introversion and extroversion, depending on whether internal or external oceans of a supercontinent are closed to form the next one, respectively (Fig. 8.6; Nance et al., 1988; Hartnady, 1991; Hoffman,

1991; Murphy and Nance, 2003, 2005, 2013; Mitchell et al., 2012; Evans et al., 2016). In terms of paleogeography, introversion implies that the location of a supercontinent is the same of its predecessor, whereas the successor is located in the opposite hemisphere in the case of extroversion (Mitchell et al., 2012). For this purpose, large databases of U-Pb, Hf, Sm-Nd and O isotopic data have been typically analyzed (Murphy and Nance, 2003, 2005; Kemp et al., 2006; Collins et al., 2011; Roberts, 2012; Condie and Aster, 2013), as internal oceans comprise juvenile crust that formed after break-up of the previous supercontinent and external oceanic crust predates the previous supercontinent (Murphy and Nance, 2003, 2005). In the particular case of Gondwana, an extroversion model was proposed (Murphy and Nance, 2003, 2005, 2013; Evans et al., 2016).

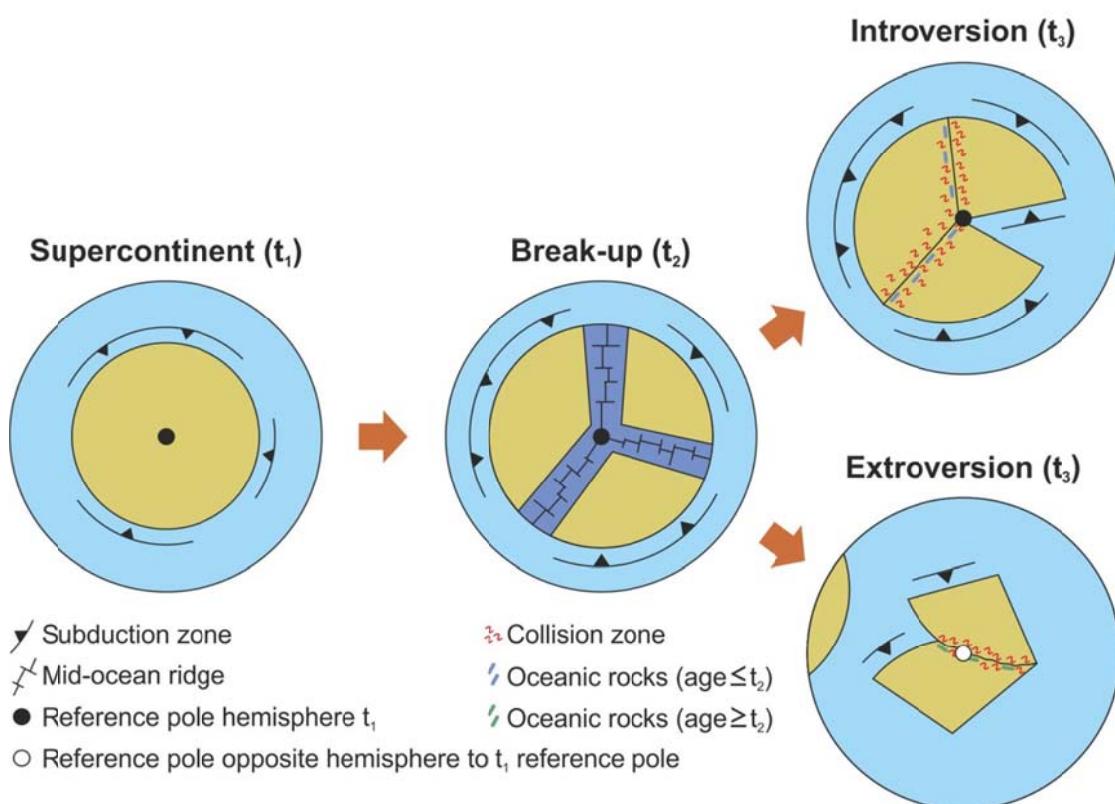

Fig. 8.6: Cartoons illustrating two end-member processes for the formation of supercontinents (modified after Murphy and Nance, 2003).

However, some points regarding Gondwana evolution have to be carefully considered. Though scarce, Tonian-Cryogenian mafic and ultramafic rocks showing ϵ_{Nd} values between ca. +3.5 and +7 are recorded between western Gondwanic blocks and indicate post-Rodinia oceanic crust

formation (Pedrosa-Soares et al., 1998; Saalmann et al., 2005; Paixão et al., 2008), although in some cases older remnants of oceanic crust are spatially associated as well (Pimentel et al., 2006). The presence of oceanic lithosphere older than the Cryogenian Rodinia break-up could be explained by geological evidences supporting that neither the Río de la Plata nor the Congo-São Francisco Craton was part of Rodinia (Fig. 8.1), thus being possible that the age of oceanic rocks predates Rodinia break-up. On the other hand, all paleogeographic reconstructions indicate that the amalgamation of Western Gondwana cratons took place in almost the same place where they were positioned since Rodinia break-up (Li et al., 2008; Evans, 2009; Evans et al., 2016). Hence, the amalgamation of Western Gondwana resulted from introversion, although extroversion can still be considered valid for the amalgamation of Western and Eastern Gondwana based on paleogeographic reconstructions (Tohver et al., 2006; Li et al., 2008; Evans, 2009) as originally indicated by Hoffman (1991). Consequently, the assembly of Gondwana resulted from a combination of introversion and extroversion.

-CHAPTER 9-**General conclusions**

Based on the aims presented in Section 1.1, the main conclusions are summarized in this chapter. These results and interpretations are partially included in contributions that resulted from this work, and are thus integrated herein.

The Nico Pérez Terrane mostly originated from Archean episodic crustal growth and underwent crustal reworking during the Proterozoic, which is recorded by the dominance of Archean Hf model ages and several Proterozoic magmatic events. In contrast, U-Pb and Hf data reveal that the Piedra Alta Terrane (i.e., Río de la Plata Craton) is made up of juvenile Paleoproterozoic continental crust, thus supporting the allochthony of the Nico Pérez Terrane regarding the Río de la Plata Craton. The Archean crust of the Nico Pérez Terrane underwent multistage magmatism at ca. 2.2-2.0 Ga and subsequent high- to medium grade metamorphism, prior to magmatism at 1.7 Ga. Metavolcano-sedimentary units indicate the existence of Mesoproterozoic events, which could be related to intracontinental magmatism. During the Brasiliano–Pan-African Orogeny, the Nico Pérez Terrane underwent further crustal reworking recorded by widespread late Neoproterozoic magmatism, metamorphism and deformation. Based on similarities in terms of tectonostratigraphy as well as isotopic fingerprint, the Nico Pérez Terrane shows an African crustal affinity and probably derived from the southwestern margin of the Congo Craton. After Cryogenian rifting from the Congo Craton, the Nico Pérez was accreted to the eastern Río de la Plata Craton and underwent further crustal reworking during the evolution of the Dom Feliciano Belt.

Detrital zircon data from the metasedimentary sequences of the southwestern Dom Feliciano Belt indicate a Neoproterozoic deposition age older than ca. 600 Ma for the schist belt, predating deposition of late Ediacaran post-collisional sequences of the foreland basin. U-Pb

detrital zircon age distributions and model ages indicate that the basement of the Nico Pérez Terrane was the main source of both sequences. Similarities of Archean and Proterozoic events recorded in the Nico Pérez Terrane basement and the overlying metasedimentary cover of the western Dom Feliciano Belt further support an African derivation. Comparison with available detrital zircon data from the southeastern Dom Feliciano Belt suggests that the Congo-Río de la Plata amalgamation predates the accretion of the Kalahari Craton during Gondwana assembly, as the input of Kalahari-derived detritus is only recorded during the late Ediacaran in the southeasternmost post-collisional sequences.

The evolution of the Sarandí del Yí Shear Zone records progressive strain localization under retrograde metamorphic conditions during crustal exhumation. The onset of the deformation is related to the collision of the Río de la Plata and Nico Pérez Terrane at 630-625 Ma, giving rise to dextral shearing up to 596 Ma along the Sarandí del Yí Shear Zone under upper to middle amphibolite conditions in a post-collisional setting. Subsequent sinistral shearing took place between 594-584 Ma under lower amphibolite to upper greenschist facies conditions, which was followed by emplacement of the Sierra de las Ánimas Complex and the Cerro Caperuza granite. Further deformation under brittle conditions was recorded after ca. 570 Ma. On the other hand, strain partitioning and localization, magmatism and fluid circulation were identified as key processes that have to be evaluated when assessing the timing of deformation of crustal-scale shear zones.

The Dom Feliciano Belt records inclined transpression and strain partitioning. The main phase of deformation, metamorphism and associated exhumation is recorded at ca. 630-600 Ma, resulting from to the collision of the Río de la Plata and Congo cratons. Subsequent sinistral shearing along N- to NNE-striking shear zones gave rise to further deformation up to ca. 584 Ma, and is also contemporaneous with sinistral shearing along the Sarandí del Yí Shear Zone. All these

shear zones record progressive strain localization and retrograde conditions of deformation during crustal exhumation. The onset of sinistral shearing in the Dom Feliciano Belt is related to the onset of convergence between the Kalahari Craton and Río de la Plata-Congo cratons, which is well-documented in the Damara Belt. The Kaoko Belt comprised the foreland domain of the Dom Feliciano Belt and its evolution resulted from deformation migration towards the foreland. Therefore, the Kaoko Belt also records sinistral shearing postdating the main phase of crustal shortening, being both phases younger than their respective counterparts in the Dom Feliciano Belt.

An integral model for the amalgamation of Gondwana is presented based on available geological, geochronological, isotopic and paleomagnetic data. The amalgamation of the Río de la Plata and Congo cratons at ca. 630 Ma gave rise to the first Gondwana nucleus and was succeeded by the assembly of the Amazonas and West African cratons up to 600 Ma. These first collisional phases were coeval with the beginning of the Iapetus Ocean opening during late stages of Rodinia break-up. The Kalahari Craton was lately incorporated into Western Gondwana, succeeding collisional orogenies along the East African/Antarctic Orogen between Western and Eastern Gondwana since 580 Ma. The latter took place contemporaneously with the onset of subduction along the Terra Australis Orogen, which implied the accretion of several peri-Laurentic blocks to the margin of Gondwana during the Paleozoic. As a corollary, the existence of Pannotia can be ruled out, as the final amalgamation of Gondwana postdates latest Laurentia-Gondwana connections.

-CURRICULUM VITAE-

1. PERSONAL INFORMATION

Name: Sebastián Oriolo
Date of birth: 30.07.1987
Place of birth: Buenos Aires, Argentina

2. EDUCATION

Since October 2013. PhD Student Geosciences. Georg-August-Universität Göttingen, Germany.

2007-2012. Licenciatura Ciencias Geológicas. Universidad de Buenos Aires, Argentina.

3. SCHOLARSHIPS AND DISTINCTIONS

2013-2016. Deutscher Akademischer Austauschdienst (DAAD) scholarship for PhD students.

2016. Göttingen International travel grant. Georg-August-Universität Göttingen, Germany.

2015. PROMOS DAAD travel grant. Georg-August-Universität Göttingen, Germany.

2012. Licenciatura Ciencias Geológicas, average grade: 9.96 (maximum 10.00). Universidad de Buenos Aires, Argentina.

2011-2012. Research scholarship for undergraduate scientists. Centro Interuniversitario Nacional (CIN), Argentina. Project: *Analogue modelling of shear zones controlled by previous anisotropies.*

2006-2011. Scholarship for undergraduate students of Engineering and Geosciences. Roberto Rocca Education Program, Techint Group.

2011. Grant to attend the course *Principles of structural and tectonic analysis: their application to vein-type ore deposits.* XVIII Argentinian Geological Congress, Argentina.

4. PUBLICATIONS

Oriolo, S., Oyhantçabal, P., Wemmer, K., Basei, M.A.S., Benowitz, J., Pfänder, J., Hannich, F., Siegesmund, S. 2016. Timing of deformation in the Sarandí del Yí Shear Zone, Uruguay: Implications for the amalgamation of western Gondwana during the Neoproterozoic Brasiliano-Pan-African Orogeny. *Tectonics* 35, 754-771.

Oriolo, S., Oyhantçabal, P., Basei, M.A.S., Wemmer, K., Siegesmund, S. 2016. The Nico Pérez Terrane (Uruguay): from Archean crustal growth and connections with the Congo Craton to late Neoproterozoic accretion to the Río de la Plata Craton. *Precambrian Research* 280, 147-160.

Japas, M.S., Ré, G.H., **Oriolo, S.**, Vilas, J.F. 2016. Basement-involved deformation overprinting thin-skinned deformation in the Pampean flat-slab segment of the southern Central Andes, Argentina. Geological Magazine, doi: 10.1017/S001675681600056X.

Oriolo, S., Oyhantçabal, P., Heidelbach, F., Wemmer, K., Siegesmund, S. 2015. Structural evolution of the Sarandí del Yí Shear Zone, Uruguay: kinematics, deformation conditions and tectonic significance. International Journal of Earth Sciences 104, 1759-1777.

Japas, M.S., Ré, G.H., **Oriolo, S.**, Vilas, J.F. 2015. Palaeomagnetic data from the Precordillera fold and thrust belt constraining foreland evolution of the Pampean flat slab segment (Central Andes, Argentina). In: Pueyo, E.L., Cifelli, F., Sussman, A.J., Oliva-Urcia, B. (Eds.) Palaeomagnetism in fold and thrust belts: new perspectives. Geological Society of London, Special Publication 425, doi: 10.1144/SP425.9.

Oriolo, S., Cristallini, E.O., Japas, M.S., Yagupsky, D.L. 2015. Neogene structure of the Andean Precordillera, Argentina: insights from analogue models. Andean Geology 42, 20-35.
