

**Function of the α/β -hydrolase fold family
proteins Pummelig (CG1882)
and Hormone-sensitive lipase
in the *Drosophila melanogaster* lipid metabolism**

Dissertation
for the award of the degree
Doctor rerum naturalium
of the Georg-August-Universität Göttingen

within the doctoral program *Genes and Development*
of the Georg-August University School of Science (GAUSS)

submitted by
Philip Hehlert

from Berlin

Göttingen, 2016

Thesis Committee

Prof. Dr. Ernst Wimmer,
Dept. of Developmental Biology, Georg August University Göttingen

PD Dr. Ronald P. Kühnlein,
Research group Molecular Physiology, Max Planck Institute for biophysical
Chemistry

Assoz. Prof. Dr. Robert Zimmermann
Research group Molecular Enzymology, Institute of Molecular Biosciences (IMB) at
the University Graz

Members of the Examination Board

Referee: Prof. Dr. Ernst Wimmer,
Dept. of Developmental Biology, Georg August Universität Göttingen

2nd Referee: PD Dr. Ronald P. Kühnlein,
Research group Molecular Physiology, Max Planck Institute for
biophysical Chemistry

(if applicable) 3rd referee: Prof. Ahmed Mansouri,
Molecular Cell Differentiation, Max Planck Institute for
biophysical Chemistry

Further members of the Examination Board

Dr. Roland Dosch
Dept. of Developmental Biochemistry, Universitätsmedizin (UMG) Göttingen

Assoz. Prof. Robert Zimmermann
Research group Molecular Enzymology, Institute of Molecular Biosciences (IMB) at
the University Graz

Prof. Dr. Ivo Feußner
Dept. Biochemistry of the plant, Georg-August-University Göttingen

Date of oral examination: 3rd of August 2016

Danksagung

Diese Arbeit wurde am Max-Planck-Institut für biophysikalische Chemie (Göttingen) in der Arbeitsgruppe Molekulare Physiologie (in der Abteilung Molekulare Entwicklungsbiologie) unter der Betreuung von PD Dr. Ronald P. Kühnlein durchgeführt. Ich danke Prof. Jäckle für die Gelegenheit meine Dissertation in seiner Abteilung, mit ihren ausgezeichneten Bedingungen, durchführen zu können.

Mein besonderer Dank gilt PD Dr. Ronald Kühnlein für seine fortwährende Unterstützung und seine große und kritische Diskussions- und Hilfsbereitschaft, die zum Gelingen dieser Arbeit beigetragen haben. Außerdem bedanke ich mich für die Möglichkeit meine Dissertation in weiten Teilen selbständig gestalten und parallel noch Beiträge für Publikationen außerhalb meiner Promotion beisteuern zu können.

Weiter Dank gilt auch meinem erweiterten Betreuungsausschuss um Prof. Wimmer und Prof. Zimmermann für ihr ständiges Interesse an meiner Arbeit und den richtungsgebenden Diskussionen.

Im Besonderen danke ich dabei Prof. Zimmermann, für die Möglichkeit Experimente in seiner Arbeitsgruppe in Graz durchführen zu können. Großer Dank gilt auch Prof. Monika Oberer für die Möglichkeit in ihrer Arbeitsgruppe in Graz Experimente machen zu können.

Meinen Kooperationspartnern Dr. Christoph Heier, Dr. Harald Nagy und Lisa Maresch danke ich für Ihre Unterstützung bei den Experimenten in Graz.

Des Weiteren möchte ich meinen Kooperationspartnern Dr. Thomas Eichmann und Vinzenz Hofferek für die Zusammenarbeit bei den Lipidomics-Analysen danken. Dr. Dietmar Riedel gilt mein Dank für die elektronenmikroskopischen Aufnahmen. Großen Dank auch an Dr. Vlad Pena und Dr. Inessa De für die Möglichkeit der Nutzung ihrer Zellkulturräume am MPI-BPC.

Vielen Dank auch an alle aktuellen und ehemaligen Mitgliedern der Arbeitsgruppe Molekulare Physiologie. Im besonderen Iris Bickmeyer und Olga Babosova für ihre Unterstützung bei einigen Experimenten und ihren Beiträgen zu einer guten Laboratmosphäre.

Dr. Sebastian Grönke, Anna Takacs, Dr. Anja Hildebrandt und Jonathan Rosenberg danke ich für ihre Vorarbeiten am Hsl- und Pummelig-Projekt. Dr. Anita Sahu-Ohsen und Assoz. Prof. Dr. Ruth Birner-Grünberger danke ich für ihre Möglichkeit am Cyp1-Projekt mitwirken zu können.

Bei allen ehemaligen und aktuellen Mitarbeitern der Abteilung Molecular Developmental Biology möchte ich mich herzlich bedanken für die gute Atmosphäre, die diesen Ort zu wirklich etwas Speziellen machen! Im Besonderen gilt mein Dank Dr. Ralf Pflanz für seine erweiterte Diskussionsbereitschaft und Input sowie Material für Experimente, aber auch das durchsehen von Teilen meiner Dissertation. Besonderen Dank auch an Dr. Annekatrin König für ihre vielen Kommentare zu meiner Dissertation und das diskutieren vieler Aspekte.

Des Weiteren danke ich meinen Freunden Iro und seiner Familie, Ralf und Andres für die schöne Zeit hier in Göttingen, die langen Gespräche und manchmal sogar einen vollen Kühlschrank. Natürlich auch meinen Volleyballern vom TSV Roringen, die einen geistig und körperlich fordern und die die schon so kurze Zeit hier noch kürzer erscheinen lassen.

Zuletzt möchte ich meinen Eltern und meinem Bruder und natürlich meinen Großeltern danken für ihre ständige Unterstützung, ihr Verständnis und ihre Geduld.

Fruchtfliegen

Danke für Ihre Mitarbeit!

These are Kathryn and Jean-Luc two average fruit flies (female right, male left).

I. Summary

To maintain energy homeostasis, all organisms need to adjust the generation and mobilization of their energy stores. The key molecules for energy storage are neutral lipids, mainly triacylglycerides (TAGs), which accumulate in specialized tissues like the mammalian adipose tissue or the fat body of the fruit fly *Drosophila melanogaster*. Inside the cell neutral lipids are wrapped by phospholipid monolayer to form a unique organelle called lipid droplet (LD). A set of LD proteins act on the surface of these organelles to manage fundamental lipid homeostasis functions like lipid mobilization at this compartment border.

Remarkably, central mammalian LD proteins involved in storage fat mobilization like Perilipins or the Adipose triglyceride lipase (ATGL) have functional homologues in fruit flies (namely Plin1 and Brummer) suggesting an evolutionary conservation of factors and mechanisms of lipid mobilization between flies and men. In mammals the α/β -hydrolase fold family proteins Hormone-sensitive lipase (HSL) and α/β -hydrolase domain containing 5 (ABHD5 or CGI-58) are core components of the lipid mobilization module. ABHD5 acts as an activator of ATGL and HSL represents the main diacylglyceride (DAG) lipase.

In this work I characterized the functions of the related genes for mammalian *HSL* (*Hsl*) and *ABHD5* (*CG1882*, *pummelig*) in *D. melanogaster*.

Most findings for *Hsl*, are consistent with the published data for its mammalian homolog indicating an evolutionary conservation of its function. *DmHsl*¹ mutant flies have no altered body fat storage, as also observed in *HSL* deficient mice. A *DmHsl::GFP* fusion protein is conditionally localized on LDs and the substrate spectrum is very similar to mammalian HSL. However, whereas diacylglyceride amounts are increased in *HSL* deficient mice, this could not be observed in *DmHsl*¹ mutant flies. Also neither lipid mobilization nor fecundity were impaired in *DmHsl* deficient flies, leaving it open to identify a biological phenotype in *DmHsl*¹ flies.

pummelig mutant (*puml*¹) larvae had normal body fat storage but body fat stores (mainly TAGs) in adult *puml*¹ flies were increased in comparison to control flies. At the same time Glycogen stores in *puml*¹ flies were decreased by ~40% compared to control flies which was accompanied by a higher desiccation sensitivity. *puml*¹ flies survived significantly longer under starvation and surprisingly mobilized storage lipids faster than controls. *In vitro* assays using recombinantly expressed *pummelig* identified Puml as an active phospholipase with substrate affinities for Phosphatidic acid (PA), Phosphatidylglycerol (PG), N-Arachidonoyl-phosphatidylethanolamine (NAPE), Ethyl palmitate and Bis(monoacylglycerol)phosphate (BMP[R,R]). However, Puml cannot activate the main triglyceride lipase Brummer in flies.

Besides increased body fat storage, massive lipid accumulations in Malpighian tubules (the renal organs of the fly) could be observed in *puml*¹ flies. Further experiments indicated a tissue autonomous control of lipid storage in Malpighian tubules. Additionally, metabolic rate in *puml*¹ flies was similar to control flies. Interestingly, food intake of *puml*¹ flies was comparable to controls but the rate of lipogenesis was drastically increased.

Localization studies using Puml::mCherry fusion protein confirmed the LD localization in adult fat body tissue and additionally could show that Puml::mCherry co-localized with peroxisome-targeted eYFP. As peroxisomes are important for the breakdown of long-chain fatty acids (LCFAs) a lipidomics analysis was performed with Malpighian tubule samples that revealed increased TAG storage with a shift towards longer fatty acid sidechains and increased un-saturation grade of the esterified fatty acids. An extended working model is provided which explains the observed phenotypes in *puml*¹ flies. My findings contribute to a broader understanding of the complex network which controls lipid metabolism.

1 Introduction

1.1 Energy homeostasis

Living systems rely on a steady influx of energy to maintain metabolic processes. Whereas the external environment underlies a high variability, organisms try to keep a relatively constant internal energy level (**Figure 1**). In order to be able to adapt to the current energy needs highly ordered processes of energy uptake, storage and expenditure are taking place that combined are termed as energy homeostasis (WHO, 2014).

Figure 1 Factors that influence energy balance and control weight. The diagram depicts fundamental principles of energy balance and regulation. With high energy intake the energy and low energy expenditure energy balance becomes positive which promotes weight gain. The expenditure can vary greatly mostly by activity as the thermic effect of food (TEF) and basal metabolic rate (BMR) are relatively fixed parameters on the short term. It is commonly believed that the human body tends prevent undernutrition then protecting from nutrient overconsumption. However, environmental and societal influences have a great effect and may override this regulatory network. As genetic and biological factors (e.g. age and sex) cannot be control by oneself, dietary factors and physical activity provide an option to actively step into controlling energy regulation (Picture based on WHO report 894 on obesity)

Besides the basal metabolic rate energy demands of an organism can vary a lot. For instance, in resting state a 25-year-old man (1,80m, 70kg) has a basal metabolic rate of $\sim 7.400\text{KJ}/1761\text{cal}$ (Harris and Benedict, 1918) per day but metabolic rate can go

up to 25.000KJ during strenuous exercise (Berg *et al.*, 2007). Being chemotrophic organisms, animals rely on the uptake of nutrients to generate chemical energy by oxidation. As nutrient uptake is not always possible because of a discontinuous feeding behavior or maybe a specific developmental stage *e.g.* metamorphosis in insects or embryogenesis in chicken eggs, organisms developed systems to store energy.

Adenosine triphosphate (ATP) represents the universal currency of free enthalpy in biological systems (Berg *et al.*, 2007). However, despite its key role in metabolism an average human stores only ~100g ATP. Moreover, already in the resting state (~7400KJ per day) the body uses up 40kg of this molecule. Therefore, ATP needs to be regenerated continuously with energy from higher biomolecules (Berg *et al.*, 2007).

For this, humans store and mobilize three major macromolecules namely proteins, carbohydrates and lipids. Compared to carbohydrates and proteins, lipids can store up ~2,18x more energy per gram (38KJ/g). Additionally, the carbon atoms in lipids have a higher reductive state compared to carbon atoms in sugars so that more energy can be generated by oxidation lipids than sugars. Neutral lipids are nonpolar and self-organizing in order to lower surface tension and therefore lower entropy. This allows a high volumetric energy storage of lipids which can save 6.75 fold more energy per gram than hydrated glycogen. Last but not least lipids are relatively inert biomolecules. Taken together lipids provide an optimal form for carbon storage in cells and might be the reason why lipids are the dominant energy storage in humans. They constitute around 82.1% of the body energy stores, followed by proteins (17,4%), glycogen (0.42%) and glucose (0.08%) (Berg *et al.*, 2007). Lipid storage is a common theme to save energy as it can be found also in nematodes, insects (*e.g.* fat body tissue of *Drosophila melanogaster*), yeast, fungi but also plants (*e.g.* rapeseed or sunflowers). In higher animals specialized tissues exist for lipid storage *e.g.* white adipose tissue in mammals or fat body in insects like *Drosophila melanogaster*.

Energy storage underlies a complex regulation that is partially determined by genetic predisposition but also exogenous and endogenous factors. However, a chronic

imbalance of energy intake and expenditure can lead to a disruption of this system leading in the combination of a sedentary lifestyle and energy rich diet to obesity.

Obesity is defined as an excess storage of body fat that health may adversely effected. A crude but easy and relatively reliable categorization to classify if a person is obese is the body-mass-index (BMI) ($\text{mass}[\text{kg}]/(\text{height}[\text{m}])^2$). The BMI has different cut-off points. Normal weight is defined by a BMI between 18-25, followed by overweight (25-30) and obesity ($\text{BMI}>30$) (WHO, 2014). Obesity belongs to the non-communicable diseases (NCDs) that became the leading cause of death in the recent years. In 2012 ~68% of worldwide deaths (56 Mio.) were caused by NCDs, with more than 40% of deaths were premature (<70 years of age) (WHO, 2014). Obesity is increasing worldwide in both industrialized and developing countries. It even coexists with undernutrition in developing countries.

When it comes to gender specific prevalence woman a more prone to obesity than man, although rates of overweight men are higher (WHO, 2013). Another problem is a skewing in the BMI distribution that leads besides the average increase in mean population BMI to an even higher number of people with a high BMI (WHO, 2014). Besides its multifactorial elicitors obesity is associated with numerous detrimental health effects. Most importantly obesity contributes to chronic diseases like cardiovascular diseases (#3 leading cause of death) and hypertension, cancer (#2 leading cause for death) or diabetes but can have also less severe effects (WHO, 2014, WHO, 2016). As NCDs become more and more prominent also their consequences will have a bigger effect on the population (*e.g.* economic performance, financial costs of healthcare system). Therefore, it is necessary to understand the underlying regulatory networks of metabolism to fight these diseases.

In the recent years, big efforts have been undertaken to provide a better insight into metabolic regulation. Various animal model systems from human cell culture systems, over mice, nematodes (*C. elegans*), yeast (*S. cerevisiae*) to insects (most importantly *Drosophila melanogaster*) have been utilized to unravel the regulators of metabolism. This work will concentrate on lipid metabolism and will use *Drosophila*

melanogaster as a model system to analyze a few mostly uncharacterized modulators of the lipid metabolism in flies.

1.2 Lipid storage regulation in mammals

Figure 2 Physiological systems that regulates energy stores. The brain detects various afferent signals (nutrient state, diet, metabolites, hormones and neuronal) and generates a response to adapt food intake, physical activity and signalling (neuronal and hormonal) to the current needs. Additionally, the system directs the nutrient partitioning to a certain set point to ensure optimal energy availability. (Scheme bases on WHO report 894 on obesity)

Although the model in (Figure 1) implies a very simple cause for obesity (ENERGY INTAKE > energy expenditure) the physiological system that actually controls energy balance is quite complex (Figure 2). It includes various signalling molecules that enable the communication between various organs: the central nervous system, adipose tissue, liver, pancreas, muscles and the digestive tract (Friedman, 2004, Speakman, 2004, Cerk *et al.*, 2014).

As mentioned earlier the main energy storage in humans are lipids. Most in form of the neutral lipids: triacylglycerides (TAGs) in specialized cells the white adipose tissue. However, TAGs are not stored freely in the cytoplasm. Due to their non-polar character TAGs are packaged in a cellular organelle called lipid droplets. Together with other highly lipophilic substances like sterol esters, TAGs form the core of lipid droplets (LDs). This core is surrounded by a phospholipid monolayer that acts as an interphase border between the hydrophobic lipids and the aqueous cytosol (Figure 3). Furthermore, the phospholipid monolayer provides as a platform for specific proteins and serves as an intracellular compartment border to manage fundamental functions of lipid homeostasis like lipid mobilization.

Figure 3 Schematic illustration of the lipid droplet structure. An inner core of neutral lipids (triglycerides, cholesterol esters of ceramides) is surrounded by a phospholipid monolayer (polar head groups are shown in blue). Lipid droplets can be populated by specific proteins that can be found on the phospholipid monolayer. The left structure is a model for Triolein – three oleic acid residues are esterified with a glycerol molecule. (picture modified after(Kühnlein, 2011))

1.2.1 Lipolysis and β -oxidation

Lipid mobilization is a well-orchestrated processes that mobilizes lipids from its storage form TAG to other lipids that can be used for membrane synthesis, act as signalling molecules or are utilized for oxidative phosphorylation to generate ATP.

In mammals, catecholamines, natriuretic peptides and insulin are considered to represent the major regulators of lipolysis in humans (Lafontan and Langin, 2009). The activation via the β -adrenergic receptor by catecholamines has been studied extensively (Granneman, 2015, Heier *et al.*, 2016). By binding of *e.g.* adrenaline this G protein-coupled seven-transmembrane domain receptor (7TM GPCR) becomes activated and leads to the generation of cyclic-adenosine monophosphate (cAMP) by Adenylyl cyclase. cAMP activates Protein Kinase A (PKA) that phosphorylates and activates several enzymes involved in lipolysis (Figure 4) (Berg *et al.*, 2007).

Perilipin1 (PLIN1) a central modulator of lipid storage is localized on lipid droplets under basal conditions and binds to α/β -hydrolase domain containing 5 (ABHD5 / CGI-58). Upon PKA activation both proteins are phosphorylated by PKA (reviewed in (Londos *et al.*, 1999). This leads to the dissociation of ABHD5 to the cytoplasm that there binds to the adipocyte triglyceride lipase (ATGL) and the complex localizes on lipid droplets again (Granneman *et al.*, 2009). *In vitro* experiments showed, that this interaction is already sufficient to perform the first step in the mobilization of TAGs, the hydrolysis to Diacylglycerides (DAGs) and non-esterified fatty acids (NEFAs) (reviewed in (Oberer *et al.*, 2011). At the same time ABHD5 stimulates through an up to now unknown mechanism the activity of ATGL (Lass *et al.*, 2006).

Additionally, ABHD5 binds to fatty acids binding protein (FABP) (Boeszoermerenyi *et al.*, 2015). This enhances the Triacylglyceride hydrolase (TGH) activity of ATGL even more and provides a NEFA acceptor. Moreover, it has been shown that also ATGL is a phosphorylation target of PKA (Ser⁴⁰⁶) and that phosphorylation increases ATGL activity as well (Pagnon *et al.*, 2012). Antagonistically, phosphorylation of ATGL by AMPK lowers the activity of ATGL (Kim *et al.*, 2016).

The next step in lipolysis is the hydrolysis of DAG to Monoacylglyceride (MAG) which is performed by hormone-sensitive lipase (HSL) (Fredrikson *et al.*, 1981, Haemmerle *et al.*, 2002a). Under basal conditions HSL is localized in the cytoplasm but after phosphorylation it trans-locates to lipid droplets and interacts with the activated and now free (not bound to ABHD5) PLIN1 (Tansey *et al.*, 2003). Also HSL has been described to interact with FABP (Jenkins-Kruchten *et al.*, 2003). In the last step of lipid mobilization MAGs are degraded to free glycerol and NEFA by Monoacylglycerol-lipase (MAGL). The released glycerol is then transported to the liver and metabolised to pyruvate or used for gluconeogenesis (Berg *et al.*, 2007). The NEFAs now can be used for re-esterification or are utilized for oxidative phosphorylation.

Figure 4 Schematic overview of mammalian lipid mobilization for ATP regeneration. β -adrenergic signalling leads to elevated cAMP levels that activate PKA. Phosphorylation of PLIN1 leads to the release of ABHD5 that can interact with ATGL and FABP to catalyse the first step in lipid mobilization the hydrolysis of TAGs. PLIN1 and phosphorylated HSL can now interact that leads to trans-location of HSL the main DAG lipase from the cytoplasm to lipid droplets. In the last step the Monoacylglycerol

(MAG) generated by HSL is hydrolysed by MAGL. The released fatty acids from storage lipid mobilization are activated by Acyl/CoA-synthetase (ACS) and subsequently broken down in peroxisomes and mitochondria. All longer NEFAs (>C8) are transported into mitochondria via the carnitine-shuttle. The rate limiting step in the transport is catalysed by Acyl(palmitoyl)-transferase I (CPT1). The end-product of β -oxidation Acetyl-CoA can be utilized in the tri-carbonic acid cycle (TCA) to produce electron donors for oxidative phosphorylation (OXPHOS) to finally generate ATP. Peroxisome proliferator-activated receptor α (PPAR α) can sense NEFAs generated by ATGL and improve cellular substrate oxidation and respiration. Alternatively, this can be simulated by activated p-cAMP responsive element binding protein (CREB) or nuclear factor of activated T-cells (NFAT).

For the later NEFAs need to be activated, a process that actually needs energy in form of ATP. At the outer membrane of mitochondria, the NEFAs are bound to Coenzyme A by Acyl-CoA-synthetase (ACS) under the consumption of ATP. This two-step reaction is coupled with inorganic pyro-phosphatase cleaving the liberated pyrophosphate from the ATP into two separate phosphate ions consuming one molecule of water (Berg *et al.*, 2007). This shifts the reaction of NEFA to Acyl-CoA towards its end-product and makes it irreversible. Subsequently, Acyl-CoA is transported into the mitochondrial matrix by utilizing carnitine-shuttle. The activated NEFAs are conjugated to the zwitterion carnitine by carnitine acyl(palmitoyl)-transferase I (CPT1) that is located on the outer mitochondrial membrane as well. After that the acylated carnitine is shuttled to the inner mitochondrial membrane by a translocase by a simultaneous transport of one carnitine molecule to the outer side again. Arrived at the inner site the acyl carnitine is de-acylated by CPT2 (Berg *et al.*, 2007). Especially, the acylation of carnitine by CPT1 is rate limiting and tightly regulated as CPT1 is inhibited allosterically by Malonyl-CoA that is generated by Acetyl-CoA carboxylase (ACC) from Acetyl-CoA. As Malonyl-CoA is an intermediate of fatty acid synthesis, high amounts inhibit beta-oxidation in mitochondria and boost lipogenesis. Particularly, medium chain fatty acids (MCFAs) depend on the Carnitine shuttle to be available for β -oxidation and subsequently oxidative phosphorylation (Figure 5). However, various ACSs exist with different acyl-chain length specificities and cellular localization (Faust *et al.*, 2014). This mechanism is used in the hypothalamus in order to regulate food intake and glucose production (Lam *et al.*, 2005) (Figure 5).

Figure 5 Schematic overview of lipid breakdown for ATP synthesis and its regulation. Chemical reactions that happen during β -oxidation in mitochondria are shown in A. Peroxisome β -oxidation only differs in the first step lipid oxidation as shown in the box in A (modified after Faust et al.2012; red (best hit) and blue are predicted *Drosophila* genes coding for the depicted enzyme of this reaction). An electron transport chain over NADH-coenzyme Q oxidoreductase (complex I), Succinate-Q oxidoreductase (complex II), Q-cytochrome c oxidoreductase (complex III) and cytochrome c oxidase (complex IV) generates a proton gradient by transporting H^+ into the interluminal space of mitochondria. The stored energy in this gradient is used by ATP-Synthase to generate ATP (B). In the hypothalamus the generation of “activated” long-chain fatty acids (LCFA-CoA) lead to signalling for decreased food intake and glucose production, shown in C. Signalling by like insulin or leptin over AMPK lead to increased Malonyl-CoA amounts that block fatty acid transport into mitochondria by blocking CPT1 that enhances LCFA-CoA accumulation in the hypothalamus (picture C from (Aguilera et al., 2008))

Most of the NEFAs (90%) are directed to mitochondria for oxidative phosphorylation (OXPHOS). However, especially very-long chain fatty acids (VLCFAs) and poly-unsaturated fatty acids (acyl residues have numerous C=C double bonds) are processed in a different cell organelle the peroxisomes. These organelles have certain characteristics. The β -oxidation in peroxisomes terminates at Octanoyl-CoA and in the first reaction of β -oxidation the dehydrogenation of Acyl-CoA the Flavoprotein-dehydrogenase transfers electrons to oxygen and thereby generates H_2O_2 (Figure 5). Subsequently, hydrogenperoxide is broken down to oxygen and water by catalase. In contrast, the electrons are fixed in Flavin adenine dinucleotide hydrochinone (FADH_2)

in mitochondria. The following steps in β -oxidation take place as in mitochondria but are performed by different isoforms of the proteins (Berg *et al.*, 2007).

1.2.2 Control mechanisms of lipolysis

As described before one level of lipolysis control is the phosphorylation of several lipolytic proteins (PLIN1, ATGL, ABHD5 and HSL). The phosphorylation leads to the formation of a core module for the mobilization of TAGs consisting of at least ABHD5 and ATGL, where ABHD5 stimulates the TGH activity of ATGL. Additionally, it has been shown that ATGL changes its substrate specificity (from sn-2 to the sn-1 position of the glycerol backbone) upon activation by ABHD5, producing a more preferred substrate for HSL (Eichmann *et al.*, 2012). Equally important is also the inhibition of ATGL by long-chain acyl-CoA (Nagy *et al.*, 2014) and its competitive inhibitor GOS2-peptide (Cerk *et al.*, 2014). The binding to GOS2 affects the localization of ATGL to lipid droplets as well as its activity (Schweiger *et al.*, 2012). The strategy of spatial segregation can also be applied to HSL that only recruited to lipid droplets under lipolytic conditions.

Interestingly, the released NEFAs by ATGL (but not HSL) are essential mediators for the generation of ligands for the activation of peroxisome proliferator-activated receptor alpha (PPAR α). PPAR α activation (Figure 4) leads to improved cellular substrate oxidation and respiration (Haemmerle *et al.*, 2011). This provides a forward loop to ensure a proper utilization of the mobilized lipids.

On the cellular level, several pathways additionally modulate lipid mobilization. The energy/ATP sensor 5' AMP-activated protein kinase (AMPK) can inhibit ACC (as mentioned in the previous chapter) and therefore improve the transfer of Acyl-CoA into mitochondria (Wang *et al.*, 2011). On the other hand, insulin signalling acts antagonistically to β -adrenergic signalling (Figure 6). The binding of insulin to the insulin receptor starts a kinase cascade that leads to the phosphorylation of the insulin-receptor substrate (IRS-1) which activates Phosphoinositid-3-kinase (PI3K) that converts the secondary messenger Phosphatidylinositol-4,5-bisphosphate (PIP₂) to PIP₃. This again activates the PIP₃ dependent protein kinase (PDK1) which phosphorylates protein kinase B (PKB / Akt) (Berg *et al.*, 2007).

Activated Akt then improves the glucose uptake of cells and protein synthesis by enhancing target of rapamycin (TOR) signalling, increases lipogenesis while prohibiting gluconeogenesis and lipolysis. (Figure 6).

Figure 6 Schematic overview of intra-cellular energy balance regulation in mammals. Insulin signalling induces a signalling cascade that leads to increased uptake of glucose into the cells and promotes energy storage and decreased energy production by lipid breakdown in mitochondria.

1.2.3 Neutral lipid storage disease

Besides imbalances in energy storage caused by exogenous factors, this system is also compromised if the gene function of lipolytic genes is affected by mutations. For instance, neutral lipid-storage disease with myopathy, caused by ATGL deficiency, leads to systemic neutral lipid accumulation (Huijsman *et al.*, 2009). Neutral lipid-storage disease with ichthyosis, also known as Chanarin-Dorfman syndrome, is a rare autosomal recessive disorder that leads to a massive lipid accumulation in various tissues and is associated with impaired function of ABHD5 (Chanarin *et al.*, 1975). Both diseases additionally show neurological and various other phenotypes (Lefevre *et al.*, 2001, Massa *et al.*, 2016). However, some characteristics like ichthyosis are exclusive in ABHD5 indicating that not all functions of ATGL and ABHD5

are limited to their interaction but that especially ABHD5 has also ATGL independent functions (Radner *et al.*, 2011). Also, a knockout of HSL or PLIN1 leads to lipid phenotypes (Tansey *et al.*, 2001, Haemmerle *et al.*, 2002b).

1.3 *Drosophila* a model system for lipid research

Insects like *Drosophila melanogaster*, also known as vinegar fly or fruit fly, are a very suitable model organism to study energy homeostasis. The energy homeostasis in flies is challenged by vast contrasts like the unavailability of nutrients during specific developmental stages (embryogenesis or metamorphosis) or in contrast rapid energy uptake during larval stages but also adult flies are faced with highly energy demanding situations like flight. Flies can be kept and handled easily and their small size allows breeding in large populations while being relatively inexpensive. Also, flies have a short generation time of 9-10 days (at 25°C) and a relatively small genome size (~144 Mio. base pairs with ~17700 genes distributed over 4 chromosomes) FB2015_01 (Dmel R6.04) (Attrill *et al.*, 2016). Furthermore, *Drosophila* shares many sequence homologues to human diseases (Reiter *et al.*, 2001, Chien *et al.*, 2002, O'Kane, 2003) which makes it an ideal model organism to study these diseases.

Additionally, the *Drosophila* system offers a giant genomic tool box. The easy generation of transgenic flies (Spradling *et al.*, 1999) and ectopic gene expression with the GAL4/UAS target system (Brand and Perrimon, 1993). Also site directed mutations (Crispr/Cas9 system) (Bassett *et al.*, 2013) or imprecise P-Element excisions (Spradling *et al.*, 1995, Spradling *et al.*, 1999) offer tools for the generation of mutants or modification of genes.

The lifecycle of *Drosophila* consists of four main stages that all have different requirements on energy storage regulation: embryo, larval stages, pupae and adults (see Figure 7). As mentioned before TAGs represent the main storage form of energy. Consequently, lipids are crucial for embryogenesis, as they total rely on the mobilization of energy stores during this non-feeding developmental stage. Thus, embryos with an impairment in mobilizing lipids (Grönke *et al.*, 2005) or generally low availability of lipids normally die (Buszczak *et al.*, 2002, Teixeira *et al.*, 2003). In the late stages of embryonic development a specialized tissue for lipid storage is

formed from the mesoderm (Bate *et al.*, 1993, Hartenstein, 1993) the *Drosophila* fat body that combines functions of mammalian liver and adipose tissue (Gilbert and Chino, 1974, Canavoso *et al.*, 2001). Larvae are continuous feeders (Zinke *et al.*, 2002) that accumulate a lot of body mass. The fat body grows up to ~2500 cells during this developmental stage and stores large amounts of TAGs that are partially mobilized during metamorphosis (Carvalho *et al.*, 2012). Simultaneously, the larval fat body dissociates in pupae and gives rise to ~800 immature adipocytes (Bodenstein, 1950) that float freely in the hemolymph in freshly eclosed flies. After 5-6 days these cells are replaced by the mature fat body tissue (Nelliot *et al.*, 2006).

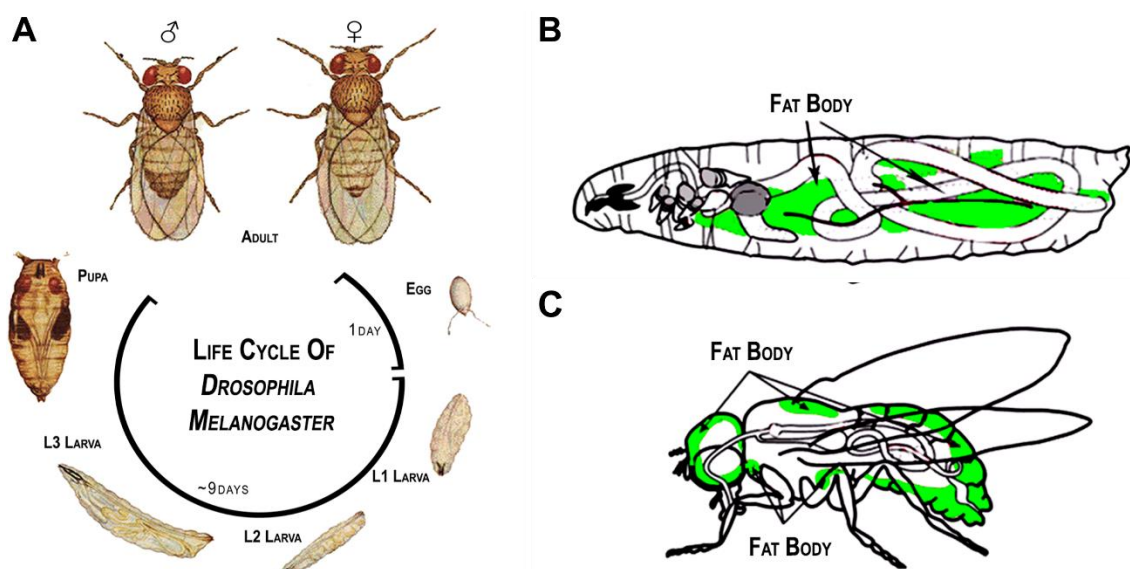

Figure 7 Life cycle of *Drosophila melanogaster* and distribution of the main lipid storage tissue the fat body in flies. The generation of flies is ~9-10 days at 25°C. 1st instar larvae hatch after ~24h from the fertilized egg. Several larval stages characterized by excessive accumulation of body mass and continuous feeding follow the hatching. ~5 days after the start of embryogenesis the larvae pupate. After ~4.5 days of metamorphosis the immature adult fly ecloses (A, Scheme modified after Carolina Biological Supply Company, 2006). The main lipid storage in larvae (B) and adult flies (C) is the fat body (pictures modified after Kuhnlein, 2011). Whereas the fat body is distributed in the whole larvae and represents the major tissue it mostly localized nearby the cuticle of the fly.

Like adult mammals, also adult flies exhibit a discontinuous feeding behavior that requires a flexible system to adapt energy storage and mobilization to the current metabolic needs. Indeed, the pathways that regulate energy storage and mobilization are evolutionary conserved between mammals and flies.

For instance, the insulin pathway described earlier (Figure 6), plays also an important role in the growth, stress resistance, reproduction, longevity and metabolism in fruit

flies (Broughton *et al.*, 2005, Edgar, 2006, Grandison *et al.*, 2009). The *Drosophila* genome encodes for seven insulin-like peptides (*Dilp1-7*) which have specific spatio-temporal expression patterns (Broughton *et al.*, 2005, Grönke, 2005). Prominently, *Dilp2*, 3 and 5 are expressed in the median neurosecretory cells in the adult brain of *Drosophila* (Broughton *et al.*, 2005, Grönke *et al.*, 2010). These cells are of great importance as an ablation leads increased lipid storage. Also the loss of these brain Dilps increased longevity in the presence of the parasitic gut bacterium *Wolbachia sp.* (Grönke *et al.*, 2010), indicating host-bacteria interaction in flies. The final mechanism between mammalian insulin and Dilps is conserved. Dilps bind to the Insulin receptor (InR) and activate the *Drosophila* IRS-1 (encoded by *chico*) starting a kinase cascade in flies. As a result, *Drosophila* Akt (DAkt) becomes activated and negatively regulates the activity of transcription factor Forkhead box O (FOXO), which has been described to enhance the expression of lipolytic genes like *Brummer* (*DmATGL*) or *pudgy* (*DmACS*) (Xu *et al.*, 2012). Knock outs of either *InR*, *chico* or *dilps* (e.g. *dilp2* or 3) *bmm* showed strong accumulations in body fat (Bohni *et al.*, 1999, Brogiolo *et al.*, 2001, Tatar *et al.*, 2001, Grönke, 2005). Yet, the phenomenon that an impaired insulin signalling (activated; induces lipogenesis) leads to elevated TAG storage as well seems to be counterintuitive, implicating that insulin signalling is not the only signalling pathway that regulates lipid storage in the fly.

Once stimulated by insulin, fat body cells start build up lipids and store them in lipid droplets (DiAngelo and Birnbaum, 2009). A common model for the lipogenesis is that lipid droplets originate from the endoplasmic reticulum (ER) (Ohsaki *et al.*, 2009). The nascent TAGs accumulated in the interspace of the bilayer leaflets of the ER. With further growing the outer ER membrane becomes the phospholipid monolayer for the final lipid droplets that at a certain size buds off from the ER (Tauchi-Sato *et al.*, 2002, Farese and Walther, 2009, Beller *et al.*, 2010). This model is supported by the finding of integral ER-membrane proteins on lipid droplets (Horiguchi *et al.*, 2008, Zehmer *et al.*, 2009). There is also evidence that further lipid droplet growth happens in the cytoplasm by the direct synthesis of TAGs into lipid droplets (Kuerschner *et al.*, 2008). A key enzyme of TAG synthesis in flies is Diacylglyceride acetyltransferase (DGAT1 encoded by *mdy*) that catalyses the last step in TAG synthesis by the

acetylation of DAG. An overexpression of *mdy* leads to obese flies whereas a deficiency has the opposite effect (Buszczak *et al.*, 2002, Beller *et al.*, 2010).

Figure 8 Schematic overview of the generation of neutral and phospholipids in *Drosophila melanogaster*. From Glucose or Acetate Acetyl-CoA can be generated that is used to build fatty acids which are combined with Glycerol-3-phosphate to generate Lyso-phosphatidic acid (LPA). Further incorporation of non-esterified fatty acids (NEFAs) leads to the synthesis of Phosphatidic acid (PA). PA is a precursor for phospholipids but can also be used to produce diacylglycerol (DAG) that is further acetylated to generate triacylglyceride (TAG) the main storage lipid. Alternatively, the Kennedy pathway can generate Phosphatidylethanolamine (PE) and Phosphatidylcholine (PC) with off-channelled DAG (Scheme was modified after (Igal and Coleman, 1996)).

Simultaneously with the synthesis of TAGs, also phospholipids need to be generated for the lipid droplet coat. Phospholipids are generated via the Kennedy pathway or channeled off from TAG synthesis (PA or DAG) (Figure 8). This interconnection is also emphasized by the finding that an imbalance in the phospholipid metabolism can also lead to increased amounts of TAG storage *e.g.* by a knock down of *Pect* (Figure 8) (Fullerton *et al.*, 2009, Lim *et al.*, 2012).

The phospholipid monolayer becomes of additional importance as it determines the size of lipid droplets (Guo *et al.*, 2008). A critical enzyme is CTP:phosphocholine cytidyltransferase 1 (CCT1) that is the only protein of the Kennedy pathway found on lipid droplets (Krahmer *et al.*, 2011). CCT1 conditionally localizes on growing lipid droplets (LD) and becomes activated on the LD surface. Concomitantly with TAG synthesis also PC is generated. This phospholipid is of particular importance as it affects the size of lipid droplets most effectively (Krahmer *et al.*, 2013).

1.3.1 Lipid mobilization in *Drosophila melanogaster*

In order to mobilize lipids *Drosophila* has a system that works similar to β -adrenergic signaling in mammals, the Adipokinetic hormone (Akh)-signaling pathway (Patel *et al.*, 2005, Grönke *et al.*, 2007, Galikova *et al.*, 2015). Akh is a short neuropeptide of eight amino acids that interacts specifically with the Akh receptor (AkhR) leading to lipid mobilization (Lee and Park, 2004, Galikova *et al.*, 2015). *Akh* is exclusively expressed in the corpora cardiaca (a portion of the ring gland) the major neuroendocrine organ in insects (Stone *et al.*, 1976, Noyes *et al.*, 1995) and Akh secretion is controlled by the extracellular trehalose concentration (Rulifson *et al.*, 2002). Interestingly, whereas Akh deficiency had no effect on ontogenesis, locomotion, oogenesis, lipid- and carbohydrate storage until the end of metamorphosis, in adults Akh regulates body fat as well as hemolymph sugar levels (Galikova *et al.*, 2015). Comparable to a *AkhR¹* mutant flies, also *Akh^A* mutants have increased lipid storage but glycogen stores were normal. Consistently, both mutants have a higher starvation resistance. However, lipids were still mobilized under starvation in both mutants, indicating a second system that stimulates lipid mobilization (Grönke *et al.*, 2007, Galikova *et al.*, 2015).

With the binding of Akh to the AkhR in a target tissue like the *Drosophila* fat body it activates this GPCR leading to the activation of the G protein α q subunit (G α q), G protein γ 1 (G γ 1) and Phospholipase C at 21C (Plc21C) and subsequently increasing the intracellular Ca^{2+} (*iCa²⁺*) and cAMP concentrations (Figure 9). An RNAi mediated knock down of *AkhR*, G α q, G γ 1 and Plc21C leads to decreased *iCa²⁺* levels (Baumbach *et al.*, 2014b) and finally resulted in increased lipid storage in the fat body. The same effect could also be observed by a knockdown of the *stromal interaction molecule* (*Stim*) or *Inositol-1,4,5,-tris-phosphate (IP3) receptor* (*Itpr83A/DmITPR*) (Baumbach *et al.*, 2014a).

Downstream of Akh-signalling we can find a similar pattern to mammals for the lipid mobilization (Figure 9). The activated PKA leads to the phosphorylation of *DmPlin1* (Patel *et al.*, 2005) which leads to elevated lipolytic activity (Arrese and Wells, 1994). Plin1 can be found primarily on larger “mature” lipid droplets (Beller *et al.*, 2010) and expression as well as translation is tightly correlated with the cumulative LD surface

area and thereby adjusts to the total fat storage in the fly (Beller *et al.*, 2010). *plin1¹* mutant flies have increased fat storage and a giant lipid droplet phenotype (LD diameter >30µm). However, *plin1¹* mutant flies still can mobilize storage lipids and have a higher starvation resistance than control flies. This indicates that *plin1* is not crucial for lipid mobilization but an important member of the AkhR-dependent lipolysis pathway (Beller *et al.*, 2010).

In *Drosophila* also a homolog of mammalian ATGL can be found namely Brummer (encoded by *brummer* or *bmm*). *bmm* knock out mutant (*bmm¹*) flies are obese whereas an overexpression leads to decreased body fat storage in adult flies (Grönke *et al.*, 2005). Like its mammalian relative that acts as the main TAG lipase in adipose tissue (Smirnova *et al.*, 2006) also Bmm catalyses the hydrolysis of TAGs to DAGs in flies but does not processes DAGs or MAGs (Grönke *et al.*, 2005). *bmm* expression correlates with the feeding state of the fly and is upregulated under nutrient deprivation (Grönke *et al.*, 2005). Like *AkhR¹* mutants also *bmm¹* mutant flies are still capable to mobilize lipids during starvation. On the other hand, *AkhR¹ bmm¹* double mutant as well as *bmm¹ plin1¹* double mutant flies cannot mobilize lipids anymore and exhibit severe obesity (Grönke *et al.*, 2007).

Figure 9 Schematic overview of storage lipid mobilization in *Drosophila melanogaster* for ATP synthesis. Adipokinetic hormone (Akh) binding to the Akh-Receptor (AkhR) induces a signal cascade that activates PKA and increases intracellular Ca²⁺ levels and subsequently activating cAMP responsive element binding protein (CREBP). The main triglyceride lipase Brummer lipase performs TAG hydrolysis. Phosphorylated Plin1 sequesters Hsl to lipid droplets to further catalyse storage lipid hydrolysis. The released fatty acids (NEFAs) are directed towards β-oxidation in peroxisomes (especially very-long and long chain fatty acids (VLCFAs and LCFAs) and mitochondria (here imported via carnitine-shuttle with the rate limiting step catalysed by Carnitine palmitoyltransferase I (CPT1)). Acetyl-CoA enters TCA and finally ATP is generated by oxidative phosphorylation (OXPHOS). Hepatic nuclear factor 4 (HNF4) can be activated by fatty acids and finally and improves cellular substrate oxidation and respiration.

However, it was not known if we can find also proteins with HSL and ABHD5 function and/or sequence similarity in the fly to see if the whole lipid mobilization pathway is evolutionary conserved. Indeed, unique sequence related proteins for HSL (Grönke, 2005) and ABHD5 (Takacs, 2007) could be found also in the fly namely Hormone-sensitive lipase ortholog (encoded by *Hsl*, CG11055) and Pummelig (encoded by *puml*, CG1882). Moreover, mutants had been generated for both genes in previous works (Grönke, 2005, Takacs, 2007).

DmHsl is expressed during all developmental stages with a strong enrichment in early embryogenesis indicating a strong maternal contribution (Grönke, 2005, Bi *et al.*, 2012). *Hsl*¹ mutant flies have normal body fat (Grönke, 2005), as so have *HSL*^{-/-}

knockout mice (Haemmerle *et al.*, 2002a). At the same time, starvation resistance of *DmHsl*¹ flies was not significantly different to control flies (Grönke, 2005).

Recently after I started with the further characterization of the *DmHsl*¹ mutants a different group published data on *DmHsl* (Bi *et al.*, 2012).

In larvae, *DmHsl* (as well as *bmm*) expression is upregulated during starvation (Bi *et al.*, 2012). Bi and colleagues also generated an independent knockout mutant called *DmHsl*^{b24} that was used in their experiments. The *DmHsl*^{b24} mutant larvae exhibited increased glyceride storage (+30%) and Bi *et al.* claimed that the mutant larvae had lipid mobilization defects. At least the larval lipid over-storage phenotype was incoherent with normal fat storage of *DmHsl*¹ mutant flies. Hence, it might be possible that the over-storage phenotype is restricted to the larval stage.

A fat body specific overexpression of *DmHsl::eGFP* in larvae showed the same characteristics as mammalian HSL. While being localized in the cytoplasm under basal conditions, abundance of *DmHsl::eGFP* on lipid droplets was increased during starvation (Bi *et al.*, 2012). Additionally, fat body overexpressed *DmHsl::eGFP* was unable to localize on Lipid droplets in *plin1*¹ larvae, leading to the assumption that, like in mammals, Plin1 sequesters *DmHsl::eGFP* onto the LD surface (Bi *et al.*, 2012). However, this studies focused mainly on larvae and indicated an evolutionary conserved function of *DmHsl* to mammalian HSL (Grönke, 2005, Bi *et al.*, 2012). Therefore, *DmHsl* was analysed further to characterize its function in adult flies and identify a possible biological phenotype in *DmHsl*¹ flies (see Supplement).

1.3.2 Pummelig the single sequence related protein to mammalian α/β -hydrolase domain containing 4 and 5 in *Drosophila melanogaster*

A BLAST research with the protein sequence from ABHD5 revealed only a single sequence related 454 amino acids long protein in *Drosophila* (e-value $5.58 \cdot 10^{-93}$) which was named Pummelig (encoded by the gene *pummelig / puml*) by me. Hence, a reverse BLAST search with the Puml sequence in mammals showed also a very high similarity to mammalian ABHD4 the paralog of ABHD5.

Figure 10 Phylogenetic analysis of Pum1, conservation of the catalytic center and PKA phosphorylation site. *Drosophila Pum1* was compared to *Danaus plexippus*, *Anopheles gambiae*, *Homo sapiens*, *Mus musculus*, *Rattus norvegicus*, *Danio rerio*, *Gallu gallus*, *Meleagris gallopavo*, *Egretta garzetta*, *Aptenodytes forsteri*, *Tyto alba*, *Taeniopygia guttata*, *Xenopus laevis*, *Nematostella vectensis*, *Caenorhabditis elegans*, *Arabisopsis thaliana* and *Sacharomyces cerevisiae* (left). Numbers in brackets are %sequence identity and % sequence similarity. A point mutation can be found in the catalytic center (GxSxG-motif) from Pum1 relatives in vertebrates and in *C. elegans* (middle). The majority of these proteins also have PKA phosphorylation site (KYSS-motif) (right). Many vertebrates with a Pum1 relative with an inactive catalytic center also have a second Pum1-like protein with an active center (ABHD4-like). The evolutionary history was inferred by using the Maximum Likelihood method based on the JTT matrix-based model. The bootstrap consensus tree inferred from 500 replicates is taken to represent the evolutionary history of the taxa analyzed. Branches corresponding to partitions reproduced in less than 50% Bootstrap replicates are collapsed. Initial tree(s) for the heuristic search were obtained by applying the Neighbor-Joining method to a matrix of pairwise distances estimated using a JTT model. The analysis involved 32 amino acid sequences. All positions containing gaps and missing data were eliminated. There were a total of 212 positions in the final dataset. Evolutionary analyses were conducted in MEGA6.

A phylogenetic tree analysis with proteins present in: *Drosophila melanogaster*, *Danaus plexippus*, *Anopheles gambiae*, *Homo sapiens*, *Mus musculus*, *Rattus norvegicus*, *Danio rerio*, *Gallu gallus*, *Meleagris gallopavo*, *Egretta garzetta*, *Aptenodytes forsteri*, *Tyto alba*, *Taeniopygia guttata*, *Xenopus laevis*, *Nematostella vectensis*, *Caenorhabditis elegans*, *Arabisopsis thaliana* and *Sacharomyces cerevisiae*

(Figure 10) showed that most organisms that coded for only one Pum1-like protein had an active catalytic GxSxG-motif. On the other hand, in organisms with ABHD4 and ABHD5-like proteins also the PKA-target sequence “KYSS” was preferentially conserved in the ABHD5-like proteins. The closest homologue outside the *Drosophilidae* is *Anopheles gambiae* with 77% similarity. In vertebrates a clustering can be observed for the ABHD4- and ABHD5-like proteins while ABHD4-like proteins had a slightly higher similarity to Pum1.

Figure 11 *In silico* prediction of phosphorylation sites in Pum1. Analysis of Pum1-PA protein sequence by DISPHOS1.3 identified 75 phosphorylation targets (serines in red, threonines in blue and tyrosine in green). The software scored six serines and 1 threonine (marked by asterisks) as potential *in vivo* phosphorylation sites. Most of these sites are located at the c-terminus of Pum1 (grey box indicates α/β -hydrolase domain). The underlined amino acids represent predicted catalytic centers in Pum1.

Pum1 belongs to the α/β -hydrolase domain containing (ABHD) protein family. The core of the protein consists of eight β -sheets that are connected via α -helices. Another characteristic are the two catalytic motifs in the serine-hydrolase motif (GxSxG) at Ser¹⁹⁰ and an additional HxxxD-motif (Asp³⁷¹) that has been associated with Acyltransferase activity in other species (Ghosh *et al.*, 2009, Montero-Moran *et al.*, 2010, McMahon *et al.*, 2014b). An *in silico* analysis of possible phosphorylation sites (using DISPHOS 1.3 from the Temple university, PA, USA) predicted 6 serine- and 1 threonine phosphorylation sites. However, the PKA-targeted site found in ABHD5 of mammals (KYSS-motif) was not conserved in Pum1 (Figure 11). Also the characteristic point-mutation in the GxSxG-motif found in mammalian ABHD5 that leads to an inactive center could not be found in Pum1 (Figure 10).

1.3.3 Genomic locus of *pummelig* and Pum1 constructs

Several tools to analyze *puml* function were established by previous workers on this project. A *puml* knock out mutant covering the protein coding site had been generated, as well as a genomic rescue construct with an c-terminal mCherry-tag (Figure 12) (Takacs, 2007). Additionally, several UAS-constructs for the expression of Pum1-PA, -PB and also for both in combination with c-terminal fusions to mCherry were created beforehand (Takacs, 2007) and used to characterize *puml* function (Figure 12).

Figure 12 Genomic locus of *puml*, constructs and proteins available. A *puml^l* mutant had been generated that covers the protein coding sequence of *puml*. A genomic rescue construct was generated that covers the extended genomic region of *puml* and contains a c-terminal fused mCherry-tag. His-HRV3c-fused Pum1 variants were recombinantly expressed for enzymatic assays.

1.3.4 Main findings from previous contributors to the characterization of *pummelig*

The *puml.puml-PA::mCherry* transgene gene product localized on lipid droplets in larval fat body tissue as well as on LDs in adipocytes of freshly eclosed flies and exhibited a characteristic ring-localization indicating a homogenous distribution over the LD-monolayer (Takacs, 2007). The same localization behavior could be also observed if *puml-PA::mCherry* was overexpressed in the fat body. On the other hand, an overexpression of *puml-PB::mCherry* and the resulting Pum1-PB::mCherry could not be found on LDs anymore but was localized punctually in the cytoplasm (Takacs, 2007).

The *puml*¹ mutant flies exhibited no difference in starvation time when compared to control flies and *post mortem* TAG content was insignificant from control flies (Takacs, 2007). In a later work also the TAG content of adult *puml*¹ flies was quantified and showed no significant difference to control flies (Rosenberg, 2012). Also, fecundity of *puml*¹ flies was not impaired (Rosenberg, 2012). However, a screening for lipid storage phenotypes in various tissues in *puml*¹ larvae and adults revealed a strong increase in lipid storage in the Malpighian tubules in both developmental stages (Rosenberg, 2012).

Taken together *puml*¹ flies exhibited no significant change in body fat but had ectopic lipid storage in the malpighian tubules. Therefore, I concentrated in this work on the further characterization of *puml* to identify the biological function of *puml*.

2 Material and Methods

2.1 Molecular Biology

2.1.1 PCR

Polymerase Chain reaction (PCR) enables the rapid *in vitro* amplification of a DNA template. For this work, PCR was used to generate amplicates for cloning or genotyping of flies and plasmids. In order to avoid the introduction of mutations into the amplicates DNA polymerases with a 3'-5' proof reading activity were used (Takara LA Taq.[Clonetech, Cat. #: RR002A], Phusion Taq. [Thermoscientific, Cat. #: F-548L], Q5 High-Fidelity DNA Polymerase [NEB, Cat. #: M0491S]) for PCR products that were subsequently used for cloning. For genotyping Qiagen Hot Start Master Mix (Qiagen, Cat. #: 203443) or Phire Tissue Direct PCR 2X Master Mix (Thermo Scientific, Cat. #: F-170L) were used. If not stated otherwise Primers were used at 0.5µM final concentration. PCR reactions were set up and run in the PCR machine according to the manufacturer recommendations of the polymerase used.

2.1.2 Genotyping of flies using PCR

In order to select for specific genotypes, single flies or fly batches were disintegrated and used as a template for PCR specific to the DNA sequence of interest. DNA preparation for PCR was performed after Gloor *et al.* (Gloor *et al.*, 1993). In detail,

flies were collected in 1.5mL Eppendorf tubes and snap frozen in liquid nitrogen. Then samples were smashed with a 200µL Pipette-tip containing 50µL (per fly in the vial) squishing buffer (10mM Tris-HCl pH8.2, 1mM EDTA, 25mM NaCl; freshly added 200µg/mL Proteinase K [Sigma, Cat. #: P6556-100MG]) in an Eppendorf tube. After smashing the buffer was expelled from the tip. Samples were then incubated for 20-30min at room temperature. Proteinase K was inactivated by heating to 95°C for 2min in a water bath. 1µL of the crude fly DNA extract was used for a PCR reaction (15-20µL recommended as minimal PCR reaction volume due to inhibitory effects of the extract on the PCR reaction).

2.1.3 Colony PCR

In order to identify correct genotypes of cloned plasmids in transformed *E.coli* colony PCRs were performed. For this, single bacteria colonies were picked with a sterile pipet tip and mixed in sterile 1xPBS in separate 200µL PCR vials (*e.g.* Biorad, Cat. #: TBC-0802). 1µL was used as PCR template. Positive clones were used for culturing in 6mL LB-media (with added selective antibiotics) and plasmid preparation.

2.1.5 Reverse transcribed quantitative Polymerase Chain reaction (RT-qPCR) for gene expression analysis

2.1.5.1 RNA extraction

RNA was extracted with Quick-RNA MircoPrep-Kit (Zymo Research; Cat. #: R1054) according to the manufacturer's protocol. In detail: Replicates of ten flies were collected in the provided 2mL collection tubes and immediately snap frozen in liquid nitrogen and stored at -80°C or processed directly. For RNA extraction 600µL RNA-Lysis-Buffer was added to the and flies were homogenized with twenty 1,4mm ceramic beads (Peqlab) using a mixer mill (Retsch, MM400) at 30s⁻¹ for 45sec. The lysate was centrifuged at 16000 x g for 1min to remove cellular debris and supernatant was transferred into a new RNase-free vial. 600µL of Ethanol (95-100%) was added to the supernatant, mixed well and the whole mixture was then transferred to a Zymo-Spin IC Column (2 x 600µL) and the column was centrifuged for 30s (16000 x g). The flow through was discarded. In the next step, 400µL RNA-Prep Buffer was added on the column, centrifuged (30s, 16000 x g) and the flow through was discarded. Then, 700µL RNA-Wash buffer was added, centrifuged (30s, 16000 x g) and flow through was discarded again. In the last washing step 400µL RNA-Wash

buffer was used and centrifuged as described before. To ensure complete buffer removal the column was centrifuged for additional 2min (16000 x g) and the column was transferred into a new RNase-free tube. RNA was eluted with 30µL preheated (~95°C) H₂O (RNase-free) by centrifugation (30s, 16000 x g). RNA concentration was measured with a NanoDrop1000 and used directly or stored at -80°C.

2.1.5.2 Reverse Transcription

Reverse Transcription and DNase digestion was performed with the Qiagen QuantiTect Reverse Transcription Kit (Qiagen, Cat. #: 205311) according to the manual. gDNA Wipeout buffer was warmed to room temperature before use. 1µg total RNA was used with 1x gDNA Wipeout buffer (7x stock) in a final volume of 14µL. The reaction was incubated for 2min at 42°C and afterwards immediately stored on ice. Then, 4µL RT Buffer (5x), 1µL PrimerMix and 1µL of reverse Transcriptase was added to the mix on ice. The complete mix was then incubated for 15min at 42°C followed by 3min of heat inactivation (95°C). The generated cDNA was directly used or stored at -20°C. For the negative control and possible detection of genomic DNA contamination an additional replicate from the same total RNA was treated the same way except the addition of 1µL water instead of reverse transcriptase (-RT control).

2.1.5.3 qPCR

The generated cDNA was used as template for quantification of gene expression. Samples were diluted (1:25) in H₂O_{dd} for the reaction. For the PCR reaction the Rotor-Gene SYBR Green PCR Kit (Qiagen, Cat. #: 204076) was used. 10µL SybrGreen-Mix were added to 2µL cDNA template. Gene-specific primers (finally 2mM in reaction) were added and H₂O_{dd} was added to a total reaction volume of 20µL.

Following primers were used:

Table 2 qPCR Primers

Symbol	Gene	Efficiency	Amplicon size / bp	Ordering #/ Sequence
RpL32	Ribosomal protein L32	~100% (Qiagen)	115	QT00985677
Act5c	Act5c	100% (Bauer <i>et al.</i> , 2009)	151	5` GTGCACCGCAAGTGCTTCTAA 3` 5` TGCTGCACTCCAAACTCCAC 3`

EF1	Elongation Factor 1 alpha100; Tm ~60°C	106% (Ponton <i>et al.</i> , 2011)	125	5' GCGTGGGTTTGTGATCAGTT 3' 5' GATCTTCTCCTTGCCCATCC 3'
bmm	<i>brummer</i> (CG5295)	100%	104	QT00964460
puml	<i>pummelig</i> (CG1882)	97%	68	QT00941493
Hsl	<i>DmHsl</i> (CG11055)	~100%	78	PPD05253A-200

Amplification cycles and analysis was performed on a Qiagen Rotor-Gene Q System. Technical triplicates were run for each tested cDNA sample and Primer combination. Reactions were performed in 0.1mL tube stripes (Qiagen, Cat. #: 981103). Following standard program was used: 5min at 95°C followed by 40 amplification cycles (5sec at 95°C → 10sec at 60°C). Finally, a melting curve was generated (65-95°C; 1°C-steps; 5sec duration of each step). Cycle of quantification (Cq) was determined in the Rotor-Gene Q Software. Further calculations were performed using Microsoft Excel 2013. Relative gene expression levels were calculated with $\Delta\Delta^{Cq}$ method (Pfaffl *et al.*, 2002) using two reference genes (chosen after (Ponton *et al.*, 2011)).

2.1.6 Restriction of DNA

For cloning and size analysis DNA templates were subjected to a restriction digest with restriction endonucleases (type II). For size analysis ~1µg DNA template was incubated for 1h with 2U of a selected restriction enzyme in a reaction volume of 20µL (buffer and incubation temperature according to the manufacturer).

DNA fragments were separated by gel electrophoresis in a 1xTBE-Buffer system (90mM Tris-borate, 1mM EDTA; pH ~8.3). Gel percentages were adjusted to the needed resolution range (0,5 - 2,5% Agarose). Gels were incubated in Ethidium bromide in order to visualize nucleic acids under UV light.

2.1.7 Gel extraction of DNA fragments

In order to extract size separated DNA fragments from an Agarose Gel, pieces with the wanted fragment were cut out. Extraction of DNA was performed with the QIAquick Gel Extraction Kit (Qiagen, Cat. #: 28706) according to the manufacturer protocol.

2.1.8 Gibson assembly cloning

Gibson assembly was used to join overlapping DNA fragments in a single-tube isothermal reaction. In this work it was used to clone various genes into the 14His-HRV3C-pFL-vector for Baculovirus expression in Sf-9 and Hi-5-cells.

The needed primers were designed with the NEBuilder Assembly Tool (<http://nebuilder.neb.com/>). PCR reaction was performed with a high fidelity polymerase as mentioned above. For all constructs the same touch-down PCR program was used: (1x 95°C for 3min followed by a cycle of 95°C for 30s → step-wise-gradient from 62-54°C (-1°C/cycle) for 30s → 72°C for 3min. Then followed by 10 cycles with the lowest annealing temperature and a final amplification step with 72°C for 10min. Total reaction volume was 50µL. As templates existing plasmids or according cDNA was used for the wanted genes.

PCR amplicates were separated by gel electrophoreses and extracted from the gel. The 14His-HRV3C-pFL vector (gift from (Trowitzsch *et al.*, 2010)) was linearized using EcoRI (NEB), separated on an Agarose gel and extracted from the gel. Gibson assembly was performed according to the manufacturer protocol. The assembled DNA template was then transformed into bacteria and screened for positive integrations. Positively confirmed clones (via colony PCR) were cultured and subjected to a plasmid preparation (midi-prep). Final vectors (14His-HRV3C-GOI-pFL) were analysed by a restriction digest and DNA-fragment size analysis. Vectors with expected fragment sizes were kept and sequenced in order to ensure correct DNA sequences for a successful expression.

2.1.9 Transformation of *E.coli*

2.1.9.1 Transformation with chemically competent cells

50µL (in a 1.5mL Eppendorf tube) of chemically competent cells were thawed on ice. Desired DNA template (2µL) was added and gently mixed by flicking the tube. The mix was incubated for 30min on ice. Afterwards a heat shock was performed for 30s! at 42°C (do not mix the sample). The tube was then immediately transferred on ice for 2min. Then 950µL of SOC-medium (pre-warmed to 37°C) were added (without antibiotics) and bacteria were cultured for 1h at 37°C under vigorous shaking. Finally,

100µL of the culture were spread on LB-Agar plates with the needed selective antibiotics and incubated over night at 37°C.

2.1.9.2 Transformation with electro competent cells

50µL of electro competent cells were thaw on ice and transferred into an electro- poration cuvette (pre-chilled on ice). 2µL of DNA template were added to the cells and mixed gently by pipetting up and down. Electroporation was performed in a Biorad Electroporator (Program Ec2). After the electro pulse cells were taken up in 950µL SOC and incubated for 1h at 37°C under vigorous shaking. Finally, 100µL were distributed homogenously on a LB-Agar plate with the needed selective antibiotics and incubated over night at 37°C.

2.2 Fly husbandry

If not stated otherwise flies were propagated on a complex corn flour-soy flour-molasses medium (corn flour and barley malt each 69,57g/L; soy flour 8,7g/L; molasses/beet syrup 19,13g/L; yeast 15,65g/L; agar-agar 5,7g/L; propionic acid 5,43mL/L; methyl 4-hydroxybenzoate/nipagin 1,3g/L) furthermore referred to as

Göttingen food (Gö-food). Flies reared at 25°C (60% humidity; 12/12 light/dark cycle) in midsize vials (Greiner, PS-Dosen, 68mL, 36/83mm Cat. #:217101) with a few added crumbs of live-yeast and a filter paper placed in the food (Macherey-Nagel, Filterpaper folded Ø7cm; Cat. #:531007). Vials were enclosed with mite proof plugs (Ø36mm Mite proof plug, K-TK). Density was only controlled for flies used for experiments.

2.3 Genetics

2.3.1 Ectopic gene expression via the GAL4/UAS-System

The GAL4/UAS-System allows the selective ectopic expression of a cloned gene in various tissue and cell-specific patterns. The two-part system consists of the GAL4 yeast transcription factor and its corresponding DNA target site the UAS-element (upstream activating sequence) (Brand and Perrimon, 1993). To achieve the spatiotemporal specificity, the Driver/GAL4-line carries a specific enhancer sequence upstream of the GAL4 gene. Fly effector lines carry downstream of the UAS-site a gene of interest. The F1 generation offspring of the Driver/Effector-interbreed expresses the GAL4 protein depending on the enhancer sequence of the Driver. As the UAS-target site is available GAL4 can now bind to it and induce gene expression of the target gene.

2.3.2 Backcrossing

In order to avoid inbreeding effects and random genomic modifiers leading to unwanted phenotypes within the population and getting a genetically similar control fly stock, flies were crossed with an isogenic host strains (*e.g.* w^{1118} from VDRC). Virgin females of each generation were collected and selected for allele of interest and crossed again with male flies from the isogenic host strain. Due to recombination during oogenesis, genetic variability was increased in the fly population. After ~9 generations fly lines were established again and the isogenic host strain could be used as the genetically matched control strain.

2.4 Fly stocks

Table 4 Fly stock list

Flystock #	Genotype	Cyt.	Description	Reference

2.5 Physiology

2.5.1 Lifespan

Lifespan assays were performed, in order to analyse possible biological effects of the interfered genes used in this study. For this, male flies were collected in the first 24h after eclosure (derived from a density seeding with 150 embryos/ midsize vial) and kept under standard adult feeding conditions for ten days (40 flies / midsize vial);

12h/12h-light/dark cycle). Flies were transferred into a new vial every second day. Then, all intact and viable flies were transferred into new midsize vials (40 flies / vial). Flies were kept upright and food was exchanged every 2,5 days (change on early Monday, Wednesday and late Friday; kept at 25°C; 12h/12h-light/dark cycle; ~60% relative humidity). Dead animals mostly stuck to the old food and were not transferred to a new vial during food replacement. Dead flies were scored at the day of food change until all flies died. Each tested genotype was kept in six replicates ($n_{\text{total population}}=240$ male flies). In order to avoid positional effects of the vial or bias each vial obtained an arbitrary number and positions were alternated randomly within the box after each food exchange. Survival analysis was performed in OriginPro 9.1 using the Kaplan-Meier analysis and a Log Rank test.

2.5.2 Capillary feeding (CAFÉ) assay for quantification of food uptake

Prandial behaviour of male flies was addressed by measuring food intake for six days, using six-day-old adult male flies, in a modified CAFÉ system (Ja *et al.*, 2007) at *ad libitum* feeding condition. Male flies, deriving from controlled density seeding (150 embryos/ midsize vial) and collection within the first 24 hours after eclosure. 40 flies were kept in a midsize vial for the following days. For the assay, flies were then transferred into individual chambers of the CAFÉ system (based on a 24-well cell culture plate) and kept at very high humidity (~100%) at 25°C at a 12h/12h-light/dark cycle. To exclude positional effects, flies from the different tested genotypes were allocated randomly to the chambers. One chamber of each plate was dedicated for the evaporation control at random and no fly was put into this chamber. The liquid diet (5% sucrose, 5% yeast extract in H₂O) was provided in 5µL capillaries (ring caps, Hirschmann, Cat. #: 9600105). Capillaries were substituted every day and measured volume of consumed food was corrected by the evaporation control. Statistical analysis of the food intake was performed in OriginPro 9.1 as indicated in the figure caption.

2.5.3 Lipogenesis experiment

Lipogenesis in adult flies was followed by incorporation of Glucose D-[14C(U)] into neutral lipids(Katewa *et al.* 2012; 2012). Adult flies (10 days after eclosure; from density seeding; 150 embryos/midsize vial, cohorts of 40 males after eclosure; food

changed every second day; 25°C; 12/12h light/dark-cycle, 50% humidity) were transferred to 1% Agar with an 200µL gel-block of labelled food: 5% Yeast extract, 5% Sucrose, 1% Agar and additional 325mM Glucose with 2µCi ¹⁴C-labeled Glucose (Glucose D-[¹⁴C(U)], Perkin Elmer, NEC042X050UC [Glucose dissolved in 500µL Ethanol by manufacturer]).

A first set of flies was collected after 24h (pulse) and another after 60h (chase; kept on unlabelled food after the 24h “pulse”-period) - snap frozen in liquid nitrogen. The frozen samples (20 flies per replicate, 3 replicates per genotype and time point) were homogenized in 1,5mL chloroform. Lipids were fractionated by solid phase extraction (SPE) using DSC-NH2 columns (DISCOVERY DSC-NH2 6mL Tube 1GM, Sigma Aldrich, Cat. #: 52640-U) (Kaluzny *et al.*, 1985).

Homogenates were loaded on the columns and flow through was discarded. Neutral lipids were eluted with 1,5mL Chloroform:2-Propanol (2:1). Then fatty acids were eluted with 2% Acetic acid in diethyl ether (1,5mL used). In a last step, Phospholipids (PLs) were eluted with 1,5mL Methanol (100%). Elution buffers should be prepared freshly to ensure high extraction yield and very high specificity to targeted lipid class. Solvents from the lipid fractions were evaporated under a stream of nitrogen_(g).

After that, lipids were resuspended in scintillation fluid (Ultima Gold scintillation cocktail, Perkin Elmer, Cat. #:6013326) and radiometrically analysed with a Liquid Scintillation Analyzer (Tri-Carb 2100TR, Packard). Statistical analysis was performed with OriginPro9.1.0 as indicated in the figure caption.

2.5.4 Osmotic stress resistance

In order to address the survivability under osmotic stress, adult male flies from controlled density (150 embryos / midsize vial) were collected at the day of eclosure and kept for six days under standard feeding conditions (40 flies / midsize vial; 12h/12h-light/dark cycle; 60% relative humidity). Flies were then transferred (25 flies / vial) to standard food that was supplemented with additional 4% sodium chloride (NaCl) and kept as described before. Food was changed every second day. Dead flies were scored at least every 24 hours. Kaplan-Meier analysis and Log Rank test for statistical comparison of the survival times were performed in OriginPro 9.1.

2.5.5 Starvation resistance

Total starvation was performed with adult male flies (six days after eclosure) deriving from density seedings (150 embryos / midsize vial). Flies were kept under standard feeding conditions (40 flies / midsize vial; 12h/12h-light/dark cycle). To address starvation resistance, flies were transferred into new vials (25 flies / vial) or into individual tubes of the *Drosophila* activity monitor (DAM) system. Water was supplied in form of 2% agarose gel. Flies were kept at 25°C, 12h/12h-light/dark cycle and ~60% relative humidity. Dead flies were scored by manual counting (in vials) or by the last time point of measured activity in the DAM-system. Survival analysis was performed in OriginPro 9.1 using the Kaplan-Meier analysis and a Log Rank test.

2.5.6 Desiccation

Desiccation resistance was addressed in adult male flies (six days after eclosure, from density seeding with 150 embryos / midsize vial, 12/12h-light/dark cycle; 60% relative humidity on standard food). Flies were transferred into an empty midsize (20 flies / vial) vial or as individuals into a tube of the *Drosophila* activity monitor (DAM) system and were kept at 25°C, a 12/12h-light/dark cycle and 60% relative humidity. Dead flies were scored by manual counting (in the vials) or by the last time point of detected activity in the DAM-system. Survival analysis was performed in OriginPro 9.1 using the Kaplan-Meier analysis and a Log Rank test.

2.5.7 Metabolic Rate

Metabolic rate was determined as described in (Yatsenko *et al.*, 2014). In detail, 3 male flies (six-day-old from density seeding with 150 embryos / midsize vial kept at 12h/12h-light/dark cycle and 60% relative humidity on standard food) were placed in one freshly build measurement chamber. The chamber was assembled by adding a 50µL capillary to the tip of a 1mL plastic pipette tip. The junction was sealed airtight with glue (Power-Pritt-Gel, Henkel). Then a small piece of foam/cotton wool was placed inside the chamber and Soda lime was added on top to adsorb the generated CO₂ generated by the flies. Another piece of foam was added to separate the flies from soda lime. After loading of the chamber with three flies, it was sealed airtight with modelling clay (Künstlerbedarf Schulze). The metabolic rate chamber was then placed in a thin layer chromatography (TLC) chamber. The capillary tip was

submerged into Eosin/H₂O-solution and images were taken every 30min for a period of three hours. In order to avoid artefacts, let the chambers settle for 5min after the start of the experiment and start image acquisition. It is crucial that TLC- and metabolic rate-chambers are equilibrated to the same temperature. Ensure constant atmospheric conditions during the measurement (experiments were performed in a fly incubator). Consumed oxygen was measured indirectly by the generated CO₂ that was absorbed by the soda lime thereby reducing the gas volume in the measurement chamber. The pressure difference was balanced draft of the coloured water. Images were analysed in Image J. For each picture the white markings on the capillaries were used to set a scale for the picture. The volume was calculated by the difference in volume from the black marking (representing the calibrated 50µL scale for the capillary) to the meniscus from two following time-points. For each tested condition/genotype 3-6 replicates were measured at three different time points (zeitgeber +0h, +4h, 8h). For normalization one metabolic rate chamber was incubated with three dead flies. Calculations were performed in Excel and results were analysed statistically in OriginPro 9.1 as indicated in the figure caption.

2.5.8 Startle induced climbing assay

In order to address the startle induced climbing activity flies were scored as described in (Greene *et al.*, 2003).

In detail, 20 male flies (from density seeding 150 embryo/ midsize vial; 12/12h light/dark cycle; 60% humidity; standard food; cohorts of 40 flies per midsize vial after eclosure) were placed in the first chamber of a counter current apparatus (Benzer, 1967). Flies were tapped down, then given a time frame of 30s to climb a distance of 10cm. Successors were transferred into the second vial and the cycle was repeated. After five replications flies were counted in the six vials. The climbing index was calculated as:

$$Climbing\ index = \frac{\sum(\#\ flies \times index\ \# \ vial)}{4 \times total\ flies\ in\ assay}$$

Measurements were repeated as duplicates per genotypes and repeated in four independent experiments. Calculations were performed in Excel. Statistical analysis was executed in OriginPro 9.1 as indicated in the figure caption.

2.5.9 Fecundity assay

Fecundity was measured by the scoring of egg laying of individual females during over a period of 25 days. Virgins were collected from a density seeding and individual virgins were paired with 2 male flies and kept in a small fly vial for 48h. The males were then removed and females were kept alone in small vials for the next six days. Then again 2 male flies were paired with the female for another 2 days. This cycle was repeated four times. Flies were transferred to a new vial (with standard fly food and a drop of yeast (~200µL)) every day. Laid eggs were counted under a stereo-microscope. Fecundity is expressed as mean cumulative number of laid eggs per female. Statistical analysis was performed as described in the figure caption.

2.5.10 Hatchability assay

Eggs laid by females in the fecundity assay were kept for 48h at 25°C. Then hatched eggs were scored and compared to the total number of laid eggs to get % of hatched eggs. Statistical analysis was performed as described in the figure caption.

2.5.11 Viability assay

Vials from the hatchability assay were kept for ten additional days at 25°C and number of pupae and eclosed flies (empty pupae counted) were scored. Statistical analysis was performed as described in the figure caption.

2.5.12 Coupled colorimetric assay (CCA) for lipid determination

Lipids were measured as described in (Hildebrandt *et al.*, 2011).

2.5.12.1 Generation of fly homogenates

4 replicas of 5 flies were collected in 1,2mL collection tubes (Qiagen, Cat. #: 19560; Caps: Cat. #: 19566) and immediately snap frozen in liquid nitrogen and either stored at -20°C or processed directly. To each replicate a 5mm metal bead and 600µL homogenization buffer (0,05% Tween in H₂O) was added. Samples were then homogenized with a mixer mill (Retsch, MM400) at 30s⁻¹ for 45sec. and heat-inactivated in a water bath (70°C, 5min). After that, samples were pelleted (2500 x g;

5min) and the supernatant was transferred to a 1mL Master block (96-well, Greiner bio-one) and covered with Silver seal sealer (Aluminium, Greiner bio-one). Homogenates were stored at -20°C or used directly.

2.5.12.2 Lipid determination

Homogenates were preheated to 37°C, mixed and pelleted (2500 x g, 5min). A 50µL aliquot of homogenate was used for lipid and protein measurement. Supernatant was transferred into a 96-well microtest plate (Sarstedt, Cat. #: 82.1581) and absorbance was measured at 540nm to get the baseline absorbance. Afterwards 200µL of CCA-Mix (Triglycerides; Microgenics, Cat. #: 981786) for lipids. Samples were incubated at 37°C for 30min (120rpm). Finally, samples were re-measured at 540nm. Absorbance values were then corrected by the baseline absorbance. In order to quantify the amount of lipid Thermo Trace Triglycerides standards (used 0, 5.5, 11, 22, 33, 44µg in 50µL) solved in homogenization buffer were used to generate a standard curve. Lipid data were normalized to protein levels measured separately from the same fly homogenate. Data were analysed as indicated in the figure captions.

2.5.12.3 Protein determination

Homogenates were preheated to 37°C, mixed and pelleted (2500 x g, 5min). A 50µL aliquot of homogenate was used for protein measurement. Supernatant was transferred into a 96-well microtest plate (Sarstedt, Cat. #: 82.1581) and absorbance was measured at 570nm. Afterwards 200µL of BCA-Mix (prepared according to manual; BCA Protein Assay Kit; Pierce, Thermo Scientific; Cat. #: 23225) were added. Samples were incubated at 37°C for 30min (120rpm) and absorbance was measured again (at 570nm). In order to quantify the amount of protein BSA standards (provided by the BCA Protein Assay Kit; used: 0, 1.3, 6.3, 12.5, 25, 37.5µg in 50µL) solved in homogenization buffer were used to generate a standard curve.

2.5.13 Non-esterified fatty acid (NEFA) assay

Non-esterified fatty acids (NEFAs) were measured colorimetrically with the HR Series NEFA-HR (2) Kit (Wako chemicals, Cat. #: 434-91795 and 436-91995). 10-50µL of sample were transferred into a 96-well microtest plate and absorbance was

measured at 552nm to get the baseline before the reaction. Then, 150µL of NEFA R1 Mix were added and samples were incubated at 37°C (10min, 120rpm). Afterwards, 75µL of NEFA R2 solution were added and samples were incubated again at 37°C (10min, 120rpm; avoid strong light exposure). Finally, absorbance at 552nm was measured a second time (T30). In order to quantify the amount of NEFAs, oleic acid was solubilized in H₂O with 0,05% Tween and used as standard (0, 0.25, 0.625, 1.25, 2.5, 3.75, 5, 7.5 and 14µg). With an additional protein measurement (see BCA-assay in CCA-Assay paragraph) NEFA data could be normalized. Independent experiments were performed at least three times. Data were analysed as indicated in the figure captions.

2.5.14 Carbohydrate analysis

Fly homogenates for Glycogen measurements were prepared as described before (2.5.12.1). Avoid multiple freezing of homogenates. Glycogen measurements were performed by using Amyloglucosidase (Amyloglucosidase from *A. niger*, Sigma, Cat. #: A1602-25MG) for glycogen hydrolysis followed by the detection of free glucose (Glucose Assay (GO) Kit, Sigma, Cat.: GAGO20-1KT) as described in (Tennessee *et al.*, 2014). Homogenates from fed animals were diluted 1:3 in homogenization buffer whereas homogenates derived from starved animals were used directly for the assay. This is necessary to ensure that the detected glucose amounts are within the linear range of the assay (0,25 - ~5µg).

Homogenates were measured in two separate reactions – one with added amyloglucosidase (total glucose determination) and a second without the enzyme (free glucose). 30µL of the un-/diluted homogenate were transferred into a Microtest plate 96-well (Sarstedt, Cat. #: 82.1581) and absorbance was measured (T0) at 540nm. Afterwards 100µL of GO Assay mix was added to each sample (in the first reaction with additional 0.3U amyloglucosidase (1µL from 4,3mg/mL stock solution, lyophilized powder ~70 U/mg, Sigma, 10115-1G-F). Samples were incubated at 37°C for 30min (120rpm). Then 100µL of 12N H₂SO₄ were added to terminate the reaction and enable colour development (stable end product quantified) and absorbance was measured again at 540nm (T30). Final absorbance of the samples was corrected by the measured T0 values.

In order to quantify the amount of glycogen glucose (D-(+)-Glucose, Sigma, G8270-100G) and bovine liver glycogen (Glycogen from bovine liver - Type IX, Sigma, G0885-1G; used: 0, 0.3, 0.6, 1.2, 2.4, 4.8 μ g) were used to generate a standard curve. Total glycogen was calculated by the subtraction of the free glucose amount and was normalized to protein content. Measurements were performed as quadruplicates of 5 flies and repeated at least three times. Data were analysed as indicated in the figure captions.

2.5.15 Body weight measurements

Wet weight of flies was measured in adult male flies (6-day-old; deriving from density seeding; 150 embryos/midsized vial; cohorts of 40 males after eclosure; food changed every second day; 25°C; 60% humidity; 12/12h light/dark cycle). Flies were collected and snap frozen in liquid nitrogen. For weighing flies were equilibrated to room temperature. Cohorts of ten flies (at least 3 technical replicates) were measured on a weighing scale (Mikrowaage MC5, Sartorius). Each cohort was measured three times and average weight was calculated afterwards. Weighing was performed in three independent experiments. Statistical analysis was done in OriginPro 9.1.0 as indicated in the figure caption.

2.5.16 TLC analysis of neutral lipids

Thin layer chromatographic (TLC) of the lipid content of collected samples was performed with small modifications as described by Baumbach *et al.* (Baumbach *et al.*, 2014b). In general, lipids were extracted according to Bligh and Dyer (Bligh and Dyer, 1959). Three biological replicates of five flies each were homogenized in 285 μ L buffer (150 μ L methanol, 75 μ L chloroform, 60 μ L H₂O_{dd}) were homogenized by ten 1,4mm ceramic beads (PeqLab) using a mixer mill (Retsch, MM400) at 30s⁻¹ for 45sec. Afterwards, samples were incubated in a water bath (1h, 37°C). In the next step, first 75 μ L chloroform and then 75 μ L KCl (1M) were added to the samples (vortexed for 20s). Subsequently, phase separation was achieved by centrifugation (1000 x g, 2min). The organic phase (lower) was collected in a new 1,5mL tube. Solvent was evaporated in a SpeedVac concentrator (7min). Lipid pellets were stored at -20°C or used directly.

Lipid pellets from control flies were resuspended in 100µL buffer (chloroform: methanol, 1:1). Buffer volumes of samples were normalized to protein amounts of control flies. Protein amounts were determined from sibling flies as described in chapter (2.5.12.3)

Finally, 20µL of each sample were applied on a high performance thin layer chromatography (HPTLC) plate (Merck, Cat. #: 105633). For lipid class assignment following lipid standards were used: 40 µg of glyceryltriolate, 40 µg of 1,3-diolein, 40 µg of 1,2-dioleoyl *rac*-glycerol, 40 µg of mono-olein (provided as mix in SUPELCO Mono-, Di-, Triglyceride Mix, SIGMA 1787-1AMP) supplemented with 4 µg oleic acid (FA; CALBIOCHEM #4954).

Lipids were separated using n-hexane / diethyl ether / acetic acid (70:30:1, v/v/v; Merck) as mobile phase. Running phase was stopped ~1cm before the mobile phase reached the border of the TLC-plate followed by air-drying of the plated. Afterwards, plates were immersed in 8% (w/w) H₃PO₄ containing 10% (w/v) copper (II) sulphate pentahydrate. Excess liquid on the glass-carrier was removed and plates were then charred for ≤5min (180°C), avoiding too much background. After cooling, plates were finally imaged using a Canon LiDE220 scanner. Amounts of lipids were calculated by comparison to loaded standards on the same plate both measure by densitometry using ImageJ v1.49m.

2.5.17 Lipidomics analysis of Malpighian tubules

Lipidomic analyses were performed to identify which lipid species were accumulated in Malpighian tubules of *pum1¹* in comparison to control flies. The flies used for these experiments derived from a density seeding (150 larvae/ midsize vial) and were kept at standard conditions. 6d old flies were dissected in cold Ringer's solution using forceps. Malpighian tubules were removed from the intestinal tissue by pulling away the ureter. Tissue was collected in Ringer's solution and pelleted (4°C, 1000 x g, 10min). Afterwards, the buffer was removed by careful pipetting. Samples were snap-frozen in liquid nitrogen and stored at -20°C.

For the pilot experiment 5 x 10 Malpighian tubule pairs per genotype were analysed. Lipid extraction and mass spectrometry and lipid annotation was performed as

described by Hoffereck (Hofferek, 2016). Additional analyses were performed using 3 x 100 Malpighian tubule pairs per genotype. Lipid extraction, mass spectrometry and lipid annotation was performed as described in Knittelfelder *et al.* (Knittelfelder *et al.*, 2014). Calculations for relative comparison of TAG species were performed in MS Excel 2013. Graphs and heat maps were generated using OriginPro9.1.0.

2.6 Microscopy

2.6.1 Used fluorophores, dyes and concentrations

If not stated otherwise, for standard imaging samples were explanted in 1X PBS and directly mounted on microscope slides (Menzel-Gläser, Thermo Scientific, AAAA000001##12E) in the staining solution. Samples were not fixed. Images were acquired within 1 hour after mounting. All samples were covered with a small cover slide (10mm, circular, #1, Menzel-Deckgläser, VWR; CAT. #:631-1340) that was sealed by nail polish. For embedding 1X PBS was used containing the following dyes:

Table 5 Dyes and fluorophores used for laser scanning microscopy

Dye/Fluorophore	Excitation/Emission (nm)	Concentration	Manufacturer
DAPI	405 / 415-470	1:1000 (6,3mM)	Invitrogen; D1306
Cellmask	633 / 635-670	1:1000 (5mg/mL)	Invitrogen; C10046
Bodipy493/503	488 / 490-540	1:1000 (38mM)	Invitrogen; D3922
Nile Red	488 / 490-620	1:1000 (100µg/mL)	Invitrogen; N1142
LD540	514 / 520-570	1:250 (2µg/mL)	Gift from C. Thiele (Spandl <i>et al.</i> , 2009)
LipidTOX DeepRed	633 / 635-670	1:500 (2X)	Invitrogen; H34477
EGFP	488 / 490-540	-	-
mCherry	561 / 570-712	-	-
ECFP	405 / 450-550	-	-
EYFP	514 / 515-552	-	-

2.6.2 Lipid staining with Oil Red O

In order to visualize storage lipids, the lysochrome dye Oil Red O was used. Fresh tissue samples were obtained from anaesthetized animals. Dissection was executed in 30% Glycerol/1xPBS on ice. Samples were fixated in 4% Paraformaldehyde/1xPBS for 10min (gentle shaking).

Afterwards, fixative was removed and samples were washed with equal volumes of 1xPBS (repeated three times, each washing step 5min). Then samples were

permeabilized with 0.01% Digitonin in 1xPBS (20min, 30rpm). This was followed by three washing steps with equal volumes of 1xPBS (5min each step).

Staining solution was prepared freshly by mixing 6mL of 0.1% Oil Red O in 100% Isopropanol (pelleted at 2500 x g, 4°C, 5min prior use) with 4mL H₂O (4°C). Staining solution was filtrated and warmed up to RT in a water bath. Samples were incubated in staining solution for 25min (RT, 30rpm) followed by three washing steps with 1xPBS as described before. Finally, samples were mounted in 30% Glycerol in 1xPBS and imaged.

Fixation and the lysochrome dyes lead to increased fusion of lipid droplets. Therefore, it is recommended to acquire images soon after sample preparation. Images were acquired with an Axiophot epifluorescence microscope (Zeiss) and a 40x Objective (Zeiss). Images were analysed in ImageJ v1.49m.

2.6.3 Imaging of Malpighian tubules and gut-ring fat body

In order to explant Malpighian tubules or gut-ring fat body, flies (from density seeding; 150 embryos/midsized vial) were raised for six days (kept in cohorts of 40 males; food changed every second day) upon eclosion. Flies were transferred into an empty vial and anesthetized by chilling on ice. For dissection, flies were grabbed at the thorax with the dorsal side directed upwards to the viewer. First the head was removed with forceps. In the next step, a fine tweezer was stabbed into the fly with one end between abdominal tergite 4 – 5. Then the tweezer was closed to grab the cuticle and the whole abdomen was bend over into ventral direction in order to break up the abdomen. Then the posterior end was pulled away slowly along the anteroposterior axis. As the digestive tract should have been still connected to the anus it was possible to pull out the complete digestive system including the gut-ring fat body (in close distance to the transition from the mid- to the hindgut), posterior and anterior Malpighian tubule pairs and maybe even the crop. Tissues were mounted as described above with the added dyes, according to the caption of the figure.

2.6.4 Imaging of adult cuticle attached fat body

For imaging of adult fat body tissue 6-day-old male flies (deriving from density seeding; 150 embryos/midsized vial; cohorts of 40 males after eclosion; food changed every second day) were dissected in 1X PBS. First flies were mechanically fixed by thrusting a preparation pin through the thorax into a silicone gel matrix with the ventral side facing upwards. Then the abdomen was sliced in transversal plane between abdominal tergite 6-7 using a fine scissor. Additional slices were performed in coronal plane along the tergital-sternal intersections. In order to expose the cuticle-attached fat body the ventral tissues (sternal parts, digestive and reproductive system, trachea) were removed. Finally, tissues were mounted. With its high hydrophobicity cuticle fat body samples had the tendency to flip in the small liquid volume on the slides. Therefore, instead of a microscope slide a cover slide (cover slide 22x22mm, VWR, Cat. #: 631-0653) was used and samples were covered as described above. In order to ensure a proper and fast distribution of the dyes the carcass was flushed slowly with mounting medium using a pipette, then covered, and sealed with nail polish.

2.6.5 Image acquisition

If not stated otherwise, images were acquired with a Zeiss LSM710 microscope and a C-Apochromat 40x/1.20 W Korr. FCS M27 objective in 12-bit mode. Each image was adjusted for a dynamic signal range. Standard resolution was: 2000x2000 pixel mode, pixel acquisition time 12 μ s/pixel, 70nm/pixel (in ImageJ 13.48 pixel/ μ m).

2.6.6 Lipid Droplet Size quantification

In order to quantify the size of lipid droplets the areas of lipid droplets were measured from single optical sections (tissues from different animals, multiple cells from one animal and various z-positions) for fat body tissue. In Malpighian tubules it was possible to acquire 3D-Z-stacks from various positions along the tubules (intersection of the tubules into the ureter, mid-segment and tip) and a maximum intensity projection was used for the analysis. Lipid droplet area quantification was performed in ImageJ v1.49m.

A lipid droplet is defined by the area from the fluorescence signal that is distinguishable from the background due to accumulated lipophilic dye. Due to inhomogeneity of the lipid droplet composition and variable diffusion, lipid droplet staining normally suffers from strong differences in fluorescent signal intensities. Therefore, a good contrast (defined as the slope of the fluorescence intensity between background and a lipid particle) especially in the low-signal range is crucial for a successful detection of lipid droplets. For this, first the lookup table was changed to “HiLo” in ImageJ. Then the contrast was adjusted. The “Minimum” pixels were increased until the background becomes blue in the image. The exact values depend on the bit-depth of the picture and background intensity of the sample. Then a different lookup table was applied to the picture using an s-log curve to the picture (ImageJ macro available on request; macro was developed with Andres Hertel (MPI-BPC, Göttingen)). Depending on the slope, signal intensities in the low-signal range were increased while higher intensity values were not modified (use the same slope-parameter for all analysed samples). By this, the contrast of lipid particles can be enhanced and intra-lipid droplet fluorescence signals become more homogenous. This enables a more reliable detection of lipid droplets in the following steps and ensures the detection of weaker stained lipid droplets (s-log curve should only be applied for applications that finally want to discriminate “signal-positive” areas. Signal intensities cannot be used during further analysis!).

In the next step, a “Gaussian blur” filter (2.0-pixel range, picture resolution: 13,5 pixel / μm) was applied to the picture to smooth out the edges of lipid droplets. Afterwards a FFT-Bandpass Filter (40 pixels, 3 pixels, none, 40% settings in ImageJ) was applied to improve contrast of the lipid droplet fluorescence signal. A binary image was created by thresholding using “Moments B&W” algorithm. Due to inhomogeneous intra-lipid droplet staining signal, thresholding may provide holes that were filled (Process->Binary->Fill holes). Clustered lipid droplets were separated by the “watershed” tool. Finally, the particle analyser was applied on the picture (size (μm^2): 0.15 – Infinity; circularity: 0.01-1.0; exclude edges; show outlines) for area determination of discrete particles. Lipid droplet diameters and volumes were

calculated assuming that lipid droplets are ideal spheres. Statistical analyses of lipid droplet size distributions were performed in OriginPro 9 using Mann-Whitney test.

2.6.7 Electron Microscopy

Ultrastructural analysis of lipid storage was performed in dissected Malpighian tubules from 6-day-old male flies (from density seeding; 150 embryos/midsized vial, cohorts of 40 males after eclosion; food changed every second day; 25°C; 12/12h light/dark-cycle, 50% humidity). Flies were dissected in 1x PBS.

Samples were placed in a 150µm flat embedding specimen holder (Engineering Office M. Wohlwend GmbH, Sennwald, Switzerland) and subsequently frozen in a Leica HBM high pressure freezer (Leica Microsystems, Wetzlar, Germany). Afterwards the vitrified samples were embedded using an Automatic Freeze Substitution Unit [AFS] (Leica).

Substitution was performed at -90°C in: anhydrous acetone with 0.1% tannic acid and 0.5% glutaraldehyde for 72h. This was followed by an incubation in anhydrous acetone, 2% OsO₄, 0.5% glutaraldehyde for 8h and additional 18h at -20°C. Afterwards samples were warmed up to +4°C and washed with anhydrous acetone. Further on, samples were embedded in Agar 100 (Epon 812 equivalent) at room temperature and polymerized for 24h (60°C).

Images were acquired with a Philips CM120 electron microscope (Philips Inc.) equipped with a TemCam 224 A slow scan CCD camera (TVIPS, Gauting, Germany). Sample processing and image acquisition was done by Dr. Dietmar Riedel (Max Planck Institute for biophysical chemistry, facility for Transmission Electron Microscopy).

2.6.8 Measurement of Mitochondrial diameter

In electron microscope pictures mitochondria were measured with the ruler tool in ImageJ v1.49m. The maximal spread was measured for each discrete mitochondrion. Statistical analyses of lipid droplet size distributions were performed in OriginPro 9.1.0 using Mann-Whitney test.

2.7 Protein expression

2.7.1 Baculovirus-system

The MultiBac system (Berger *et al.*, 2004, Trowitzsch *et al.*, 2010) was employed for recombinant protein expression. pFL-acceptor vector was modified (in this work) to have an 14His-tag and HRV3C-protease cleavage site N-terminal of the expressed gene of interest. Genes were inserted into the 14His-HRV3C-pFL vector by Gibson assembly cloning (chemo-transformation of DH10 α *E. coli*). Positive clones, the so-called expression constructs, were identified via colony PCR and verified by DNA sequencing. Expression constructs (~100ng) were transformed (electroporation) into *DH10MultiBacY E. coli* cells (gift from I. Berger). Clones were selected by antibiotics and blue/white selection (disrupted β -galactosidase-gene indicated a successful acceptor vector integration). Recombinant bacmids were isolated from a 5mL overnight LB-culture (with selective antibiotics, 37°C, shaking). Cells were harvested at 4000 x g (4°C, 15min) and resuspended in 250 μ L suspension buffer (ROCHE; Qiagen or Machenery-Nagel). 250 μ L of lysis-buffer were added and carefully mixed by inverting Eppendorf tubes several times. The mix was then incubated for 5min. After that 350 μ L neutralisation-buffer were added and mixed by inverting the tube several times. Precipitated protein was pelleted by centrifugation (4000 x g, 10min, 4°C). Supernatant was transferred to a fresh Eppendorf vial and pelleted again (4000 x g, 10min, 4°C). Supernatant was again transferred to a new Eppendorf vial and 700 μ L Isopropanol were added. Mix was incubated for 30min at -20°C and then pelleted at 17000 x g for 15min (4°C). Liquid was removed and the DNA pellet was washed carefully with 70% Ethanol. After centrifugation (17000 x g, 10min, 4°C) liquid was removed and the pellet was washed with 30 μ L 100% Ethanol and again pelleted (17000 x g, 10min, 4°C). The DNA pellet was air-dried and finally 20 μ L of sterile H₂O were added for resolubilization (no strong mixing by pipetting or vortexing).

Recombinant proteins were produced in insect cells as described earlier (Trowitzsch *et al.*, 2010).

2.7.1.1 Virus production and protein expression in Sf-9 cells

Generated recombinant bacmids (see above) were transfected into Sf-9 cells (in Sf-900™ III SFM culture medium, 27°C) for initial virus production in a 6-well-plate format (use 1Mio cells/well) using Xtreme Gene transfection reagent (ROCHE, Cat. #: 06365779001). After passaging and dilution cells should rest for at least 15min prior transfection.

200µL of cell culture medium were added to the 20µL Bacmid preparation. Then 100µL culture medium were mixed with 10µL Xtreme Gene reagent and added to the 220µL Bacmid-cell culture medium solution. This was mixed by gently flipping of the vial and incubated for 1h at 27°C (without movement; avoid strong light exposure). 150µL of the transfection mix were then used for one vial of a 6-well-plate. For this the mix was expelled slowly from the tip and the single drops were distributed over the whole well homogenously.

Cells were incubated for 60-72h at 27°C. Virus production (V_0 virus) was monitored by GFP expression of the cells. After incubation time the V_0 virus (located in the medium) was used to inoculate a 25mL suspension culture of SF-9 cells ($0,5 \times 10^6$ cells/mL, 27°C, 120rpm). Cell density and viability was measured every 24h with a cell counter. Samples of ~1Mio cells were collected and cell pellets (centrifugation at 10000 x g, 10min, 4°C) were stored for later analysis of protein expression. From the time point the cells stopped proliferation (Day of proliferation arrest; DPA) cells were incubated until DPA+60-72h to collect the V_1 virus (cell culture medium was collected in a 50mL Falcon tube, pelleted [4000 x g, 10min, 4°C] and supernatant was sterile filtered [20µm]). V_1 was stored at 4°C (avoid light exposure of the virus; long-term storage at -20°C possible but with lower MOI).

2.7.1.2 Protein expression in Hi-5 cells

In order to achieve a higher protein yield expression was performed in Hi-5 cells (using Express Five® SFM culture medium, Life technologies, Cat. #: 10486-025 supplemented with 20mL L-Glutamine (200mM), Life technologies, Cat. #: 25030-032). 25-100mL suspension cultures ($0,5 \times 10^6$ cells/mL;) were inoculated with various volumes of V_1 virus (virus volume should not exceed 2µL/mL culture). Normally a 100mL culture was inoculated with 100µL V_1 virus. Cell viability and density were measured every 24h and samples of 1Mio cells were collected as described above. Cells were harvested when being in cell cycle arrest and a drop of the cell viability ≤ 70 took place (~DPA+ 48-72h). Normally, this was accompanied by a plateau in the GFP-intensity of the harvested samples.

2.7.2 *E. coli* expression system

For protein expression of proteins cloned into the pASK-IBA5+ vector *E.coli* BL-21 were transformed with the respective vector (**Table 3**) as described recently (Nagy *et al.*, 2014). Protein expression was induced at OD_{600nm}=0.5-0.6 by addition of 200ng/mL anhydro-tetracycline (AHTC). Cultures were kept at 22°C for 3h (180rpm, 300mL) until cells were harvested.

For bmm-GST *E. coli* BL-21 were transformed with the vector and protein expression was induced at OD_{600nm}=0.5-0.6 by addition of IPTG (1mM). Bacteria were cultured for 3h at 22°C (180rpm, 300mL) until cells were harvested.

2.7.3 COS-7 expression system

Expression of proteins in COS-7 cells was performed as described principally (Zimmermann *et al.*, 2004) with minor modifications (Schweiger *et al.*, 2014). In detail, SV-40 transformed monkey kidney cells (COS-7, ATCC CRL-1651) were transfected with pCDNA4/HisMax vector coding for the protein of interest (**Table 3**). Cells were seeded one day before transfection (9,5*10⁵ cells / 10cm Petri dish) and kept in DMEM (4,5g/L Glucose) with 10% foetal calf serum (FCS) and 5% antibiotics (penicillin, streptomycin) at 37°C (5% CO₂).

Per transfection 300µL DMEM (serum-free) medium were mixed with 6µg Plasmid DNA. 27µL of Metafectene (Biontex GmbH, Cat. #: T020-1.0) were added to the solution and mixed. Afterwards the transfection mixture was incubated for 20min at RT. For transfection standard culture medium was replaced by 4mL serum- and antibiotic-free DMEM and transfection mixture was added to the cells. After incubation for 4h the medium was changed back to 6mL standard culture medium.

Cells were harvested after 48h incubation. For this culture medium was removed and cells were washed with 1xPBS. Cells were mechanically removed (with a scraper) in 3mL 1xPBS. Finally, cells were pelleted by centrifugation (3min, 1200 x g, RT) and 1xPBS was removed.

2.8 Lysate preparation for recombinantly expressed proteins

Cell pellets were resuspended in 300 μ L lysis buffer (250mM Sucrose, 1mM EDTA, 1mM DTT, 1x Protease inhibitor [ROCHE; Cat. #: 04693116001]) and kept on ice. Disruption of cells was done by sonication (Branson; S-450A with a micro-tip). In order to remove cellular debris, the lysate was pelleted (1000 x g, 4°C, 15min). The supernatant was collected and stored at -20°C for further use. Protein expression was assayed by Western blot and protein concentration was determined by Bradford protein assay according to the manufacturer (ThermoFisher scientific, Cat. #:23200). Finally, substrate concentration was adjusted to 2mg protein/mL using lysis buffer.

2.9 Western Blot and Immunohistochemistry

In order to detect proteins a western blot was performed. Protein samples were dissolved in sample buffer (final 1x; Stock 3x: 150mM Tris [pH 6.8], 6% SDS, 0.3% Bromophenol blue, 30% Glycerol, 300mM DTT). Sample mix was then incubated for 3min in a water bath (95°C) and stored back on ice. Protein size separation was performed by SDS-PAGE (12%).

Afterwards samples were transferred onto a nitrocellulose membrane (Thermo scientific, Cat. #: 80018) by electro-blotting (20W, 2h, 4°C). Afterwards, the blots (membrane with transferred protein on it) were washed in 1xTBST (20mM Tris pH 7.5, 150mM NaCl, 0.1% Tween20). In order to reduce unspecific binding of the used primary antibodies the blots were blocked with 1xTBST+5%BSA (2h, RT, 30rpm).

Then blots were incubated with the primary antibodies (used concentrations in the table) in 1xTBST+5%BSA for 1h (RT, 30 rpm). After washing with 1xTBST blots were incubated with secondary antibodies (30min, RT, 30rpm). In order to remove unbound secondary antibody that provide unspecific- and background signal blots were washed another time with 1xTBST.

For detection of HRP-conjugated secondary antibody an luminol-based enhanced chemiluminescent substrate was used (Super Signal West Pico Chemiluminescent Substrate; Cat. #: 34080). Membrane was incubated with working solution for 5min (RT, 100 μ L/cm² membrane). Excess liquid was removed and membrane was placed

between to plastic foils to prevent drying. Finally, chemiluminescence was detected with a Fujifilm LAS-1000 CH Plus CCD Camera System. Images were analysed with ImageJ v1.49m.

Table 6 Antibodies

Name / Antigen	Host; Subclass	used concentration	Supplier
β -tubulin	<i>mouse; IgG1</i>	<i>1:5000</i>	Hybridoma Bank #E7
α -mouse IgG-HRP	<i>goat</i>	<i>1:1000</i>	Pierce, Cat. #: 31430, used with β -tubulin
α -His	<i>rabbit</i>	<i>1:10000</i>	gift from Görlich department
α -rabbit-HRP	<i>goat</i>	<i>1:12000</i>	Pierce, Cat. #: 31460
α -GFP(SySy)	<i>rabbit</i>	<i>1:7000</i>	Synaptic Systems, Cat. #:132002
α _Strep-tag II	<i>mouse, IgG</i>	<i>1:5000</i>	IBA, Göttingen
α -mouse IgG-HRP	<i>sheep</i>	<i>1:10000</i>	GE Healthcare Amersham; used with α _Strep-tag II

2.10 Immunohistochemistry in larvae

Larval were dissected in phosphate buffer saline (PBS) for analysis of subcellular localization of proteins. Isolated fat bodies were carefully washed with PBS and fixed in 4 % formaldehyde for 15-20 minutes at room temperature. After fixation fat bodies were washed with BBT solution (10 mM Tris, 55 mM NaCl, 40 mM KCl, 7 mM MgCl₂, 20 mM glucose, 50 mM sucrose, pH 7.0 and 0.1% Tween-20) and 0.2% BSA. Afterwards samples were blocked in 3% (v/v) horse serum (diluted in BBT) for 2 hours at room temperature. Than fat bodies were incubated with the primary antibody over night at 4°C. After washing with BBT the samples were incubated with the secondary antibody in 1:500 dilution for 2 hours at room temperature. In the last step fat body was mounted with DAPI and LipidTox as described earlier (2.6.1) and images were acquired.

2.11 Enzymatic assays

2.11.1 Triglyceride hydrolase assay

Hydrolase activity of proteins on triglyceride was measured as described in (Schweiger *et al.*, 2014) based on a protocol from Holm *et al.* (Holm *et al.*, 2001).

For the assay needed amounts for finally 1.67mM Triolein (Sigma-Aldrich, Cat. #: T-7140) were dosed with 10 μ Ci/mL ³H-Triolein ([9,10(N)-3H]-Triolein, Perkin Elmer, Cat. #: NET431L005MC, dissolved in toluene) and 190 μ M PC/PI [ratio 3:1] (PC from egg yolk and PI [Cat. #: P-3556] from soybean [Cat. #: P-0639], Sigma Aldrich, dissolved in Chloroform) were added to a reaction tube. The solvents were evaporated under a stream of nitrogen_(g).

2mL of 0.1M potassium phosphate buffer (KPB; pH 7.0) were added initially and sonicated (30s, 20% output power, on ice). Ideally, the substrate mix should become turbid. Then the remaining KPB was added to get the final concentrations mentioned above (keep in mind that BSA still needs to be added). Samples were then sonicated again (15s, 20% output power, on ice). Afterwards the fatty acid (FA) acceptor fat-free BSA (20% stock solution in KPB, Sigma Aldrich, Cat. #: A6003) was added to a final concentration of 5%. One aliquot of substrate was measured to determine the specific substrate activity (should be $\sim 1 \times 10^6$ dpm/100 μ L).

For hydrolysis assay 100 μ L sample (2mg protein/mL) were mixed with 100 μ L substrate. As blank 100 μ L substrate were mixed with 100 μ L lysis buffer. Protein amounts for the assay need to be optimized in order to be in the linear range of the assay. Samples were tested at least as triplicates. The reaction mix was then incubated in a water bath (1h, 37°C, continuous shaking). The reaction was terminated by the addition of 3.25mL Methanol: Chloroform: n-heptane (10:9:7 v/v/v). Then 1.05mL of 0.1M potassium carbonate (pH 10.5 [adjusted with saturated Boric acid) were added and mixed vigorously for 5s by vortexing. Phase separation was achieved by centrifugation (1000 x g, 10min, RT). 200 μ L of the aqueous (upper one) phase were mixed with 2mL of scintillation cocktail and radiometrically analysed. Statistical analysis was performed in OriginPro 9.1.0 as described in the figure caption.

The rate of Triglyceride hydrolase activity is represented as:

$$\frac{nmol_{released\ fatty\ acid}}{h \times mg\ protein}$$

A partition coefficient of 1.9 (71,5% recovery) for the extraction of released fatty acids into aqueous phase was used (Schweiger *et al.*, 2014). For the calculation of the activity rate following equation was applied:

$$\frac{nmol_{released\ fatty\ acid}}{h \times mg\ protein} = \frac{(dpm\ sample - dpm\ BLANK) \times \left(\frac{V_{total\ aqueous\ phase}}{V_{used\ for\ scintillation\ counting}} \right)}{\left(\frac{dpm\ substrate}{nmol\ fatty\ acids} \right)^1 \times mg\ protein \times 0,715 \times t_{incubation}}$$

For 1,67mM Triolein $n_{fatty\ acids} = 501nmol\ fatty\ acids/100\mu L$ substrate were used.

2.11.2 Hitfinder assay

In order to identify possible substrates a screen testing different neutral and phospholipids was used.

In reaction volume of 25 μ L different substrates (see table) were tested at 1mM concentration and released fatty acids were measured colorimetrically with the NEFA HR(2)-Kit (Wako Chemicals, Cat. #: 434-91795 and 436-91995). Samples lysates were prepared as described before. The 2mg/mL samples were diluted 1:3 in Assay buffer (2,5mM EDTA, 250mM KCl, 12,5mM CHAPS and finally 5% BSA) and 15 μ L were used for a reaction. Samples were run as duplicates in one well of a 96-well plate.

Substrates were prepared as a stock-solution for the assay. Needed amounts (prepare 400 μ L with 2.5mM) of substrate were placed in a 1.5mL Eppendorf tube and organic solvent was evaporated under a stream of nitrogen. Then substrate was dissolved in 300 μ L assay buffer and sonicated (20% output power, 2 x 20s, on ice). Then 100 μ L of 20% of fat-free BSA (in Assay buffer, Sigma Aldrich, Cat. #: A6003) were added as fatty acid acceptor and mixed thoroughly.

10 μ L of substrate-solution were added to the 15 μ L of prepare sample and incubated (30min, 37°C, 120rpm). Plate should be covered to avoid evaporation. Released fatty acids were measured by the NEFA assay (described before).

2.11.3 List of substrates

Table 7 Substrates for Enzymatic assays

Symbol	Substance	Manufacturer
PC	1,2-dioleoyl-sn-glycero-3-phosphocoline	Sigma Aldrich
PA	1,2-dioleoyl-sn-glycero-3-phosphate (sodium salt)	Enzo Life Sciences
PG	1,2-dioleoyl-sn-glycero-3-phospho-(1'-rac-glycerol) (sodium salt)	Sigma Aldrich
NAPE	1,2-dioleoyl-sn-glycero-3-phosphoethanolamine-N-arachidonoyl (ammonium salt)	Enzo Life Sciences
MCPG	1,2-dioctanoyl-sn-glycero-3-phospho-(1'-rac-glycerol) (sodium salt)	Sigma Aldrich
MCPC	1,2-dioctanoyl-sn-glycero-3-phosphocholine	Sigma Aldrich
BMP(R,R)	sn-(3-oleoyl-2-hydroxy)-glycerol-1-phospho-sn-1'-(3'-oleoyl-2'-hydroxy)-glycerol (ammonium salt)	Avanti Polar Lipids
LPC	1-oleoyl-2-hydroxy-sn-glycero-3-phosphocholine	Sigma Aldrich
LPA	1-oleoyl-2-hydroxy-sn-glycero-3-phosphate	Avanti Polar Lipids
LPG	1-oleoyl-2-hydroxy-sn-glycero-3-phospho-(1'-rac-glycerol) (sodium salt)	Sigma Aldrich
MO	1-(9Z-octadecenoyl)-rac-glycerol	in Stock
Cardiolipin	1,3-bis(sn-3'-phosphatidyl)-sn-glycerol (in bovine heart mainly C18:2)	Sigma Aldrich
pNPB	para-Nitrophenylbutyrate	Sigma Aldrich
PE	1,2-dioleoyl-sn-glycero-3-phosphoethanolamine	Sigma Aldrich
PS	1,2-dioleoyl-sn-glycero-3-phospho-L-serine (sodium salt)	Sigma Aldrich
PI	1,2-dioleoyl-sn-glycero-3-phospho-(1'-myo-inositol) (ammonium salt)	Sigma Aldrich
CL	1',3'-bis[1,2-dioleoyl-sn-glycero-3-phospho]-sn-glycerol (sodium salt)	Sigma Aldrich
BMP(S,s)	sn-(3-oleoyl-2-hydroxy)-glycerol-1-phospho-sn-1'-(3'-oleoyl-2'-hydroxy)-glycerol (ammonium salt)	Avanti Polar Lipids
LPS	1-oleoyl-2-hydroxy-sn-glycero-3-phospho-L-serine (sodium salt)	Sigma Aldrich
LPE	1-oleoyl-2-hydroxy-sn-glycero-3-phosphoethanolamine	Sigma Aldrich
LPI	L- α -lysophosphatidylinositol (Liver, Bovine) (sodium salt)	Sigma Aldrich
MP	Methylpalmitate	Sigma Aldrich
EP	Ethylpalmitate	Sigma Aldrich
PP	2-propyl palmitate	Sigma Aldrich
BP	1-Butyl palmitate	Sigma Aldrich
DO (rac)	1,2-dioleoyl-sn-glycerol	Sigma Aldrich
TO-C18:1	1,2,3-(9Z-octadecenoyl)-glycerol	Sigma Aldrich
TO-C8	Glyceroltrioctanoate	Sigma Aldrich

MGDG	1,2-diacyl-3-O-β-D-galactosyl-sn-glycerol	Sigma Aldrich
RE	Retinylpalmitate	Sigma Aldrich
CO	Cholest-5-en-3β-yl octadecanoate	Sigma Aldrich
WE	Arachidyl laurate	Sigma Aldrich
PlasmaPC	1-(1Z-octadecenyl)-2-oleoyl-sn-glycero-3-phosphocholine	Sigma Aldrich
BDP (S,S)	sn-[2,3-dioleoyl]-glycerol-1-phospho-sn-1'-[2',3'-dioleoyl]-glycerol (ammonium salt)	Sigma Aldrich
PMG	1-O-hexadecyl-2-O-methyl-sn-glycerol	Sigma Aldrich
O-Ac-Cer	1-oleoyl-N-heptadecanoyl-D-erythro-sphingosine	Sigma Aldrich

2.11.4 Kinetics and analysis

Michaelis constant (K_M) and maximal reaction rate (v_{max}) were analysed using the reaction parameter from the Hitfinder Assay. First, the reaction conditions from the Hitfinder Assay were used and constant sample concentrations were incubated with the substrate (2mM) for various times (reaction volume scaled up to 50μL). The longest time span that showed a linear conversion rate of the substrate into product + fatty acids (detected with the NEFA-Assay) was used for the further analysis. Various substrate concentrations (0.25, 0.5, 0.75, 1, 1.25, 1.5, 1.75, 2mM) were tested for selected substrates of the Hitfinder assay. For each concentration, the fatty acid release was measured as duplicates. Assuming that PUML follows a Michaelis-Menten kinetic the quantified amounts of fatty acids / time_(constant time) released at the various substrate conditions were plotted against the concentration. The reaction rate can be described by the Michaelis-Menten equation:

$$reaction\ rate\ (v) = \frac{d[P]}{dt} = \frac{V_{max}[S]}{K_M + [S]}$$

Based on the empirical values for the reaction rate (v), V_{max} and K_M were calculated by non-linear regression using the Solver Add-in of Excel (Microsoft Office 2013) by minimizing the sum of the squared normalized errors for the measured v at the various substrate concentrations $[S]$:

$$normalized\ error^2 = \left(\frac{v_{estimated} - v_{measured}}{v_{measured}} \right)^2$$

3 Results

3.1 Body fat storage in *pummelig* mutant flies

In mammals the adipose triglyceride lipase (ATGL) is activated by α/β -hydrolase domain containing 5 (ABHD5). In the *Drosophila* fat body Brummer lipase (*DmATGL*) is crucial for storage lipid mobilization and a knock out leads to increased amounts of body fat. With the high sequence similarity of *PumI* to mammalian ABHD5 it was assumed that this activation mechanism might be evolutionary conserved. With a possible interaction it was checked if may obtain comparable phenotypes when we interfere with the genes (overexpression or knock out/down) as both genes are expressed in the fat body (Gelbart and Emmert, 2013).

3.1.1 Lipid storage is increased in *pummelig* mutants

Body fat storage of *pumI¹* flies was quantified by previous contributors to the *pumI*-project but a modulation of body fat storage could not be observed (Takacs, 2007, Rosenberg, 2012). Thus, to eliminate effects that could arise from different genetic backgrounds a genetically matched control strain was generated to the *pumI¹* mutant strain (Rosenberg, 2012). In this work, it was shown that the absence of *pumI* leads to a significant increase in the amount of storage body fat comparable to effect upon loss off *bmm* (Grönke *et al.*, 2005) in adult flies analysed by a glyceride based colorimetric assay (CCA) (see Figure 13). The combination of the *pumI¹*-allele with a deficiency-allele covering the *pumI* gene locus supports the exclusive effect of the *pumI* gene on body fat storage. Similar to a knockdown of *bmm*, body fat storage can be increased by a knockdown of *pumI* specifically in the fat body tissue (*FB-SNS>GAL4*).

Figure 13 Interference with *bmm* and *puml* can lead to changes in body fat measure by CCA assay. Adiposity in response to RNAi-mediated gene knockdown is compared with null mutants. Additionally, crosses of *puml¹* with deficiency (*Df*) lines were analysed as well as gain-of-function (*gof*) experiments. Downregulation/absence of triglyceride lipase Brummer (*BMM*) leads increased body fat storage; detected by CCA assay. A knock out (*puml¹* or *Df*) or downregulation of *puml* by RNAi leads to increased amounts of body fat. In contrast to *bmm*-gain function (*gof*), which leads to lean flies, no effect can be detected in *puml*-*gof* flies. A *puml¹* *bmm¹* double mutant reveals no additive effect on the body fat storage level of the two mutant alleles. Means of relative TAG equivalents/protein normalized to average TAG equivalents/protein values of the corresponding controls \pm SEM are shown; Mann-Whitney test, ***= $P < 0.001$; RNAi and *gof* were performed in the fat body (*FB-SNS*>*GAL4*).

A gain-of-function of *bmm* in the fat body (*FB-SNS*>*GAL4*) leads to lower body fat storage ((Grönke *et al.*, 2005), Figure 13). This cannot be observed during a gain-of-function of *puml*. A double knockout of *bmm* and *puml* has no additive effect on body fat storage and did not exceed amounts of *puml¹* flies. In addition to the CCA assay, a thin layer chromatography was performed to distinguish which neutral lipid class was changed (TAG, DAG or MAG).

Comparable to *bmm¹* flies (Grönke *et al.*, 2005) also *puml¹* flies exhibited increased amounts of Triacylglycerides (TAGs) (Figure 14). Additionally, a trend for elevated amounts of DAGs was visible but no significant. The amount of FA was slightly increased (+27%) in *bmm¹*, but the low general abundance of FAs results in a very small effect size (<1 μ g) FAs between control flies and *bmm¹*.

Figure 14 Amounts of Triacylglycerides are increased in knock out mutants of *pum1* and *bmm*. A thin layer chromatography analysis (A, B, C) identifies amount of TAGs being significantly (E, D) higher in *bmm*¹ and *pum1*¹ flies. Loaded amounts of total lipids for a single TLC lane were normalized by protein to the equivalent of one control fly per lane. Plotted are the means of average fold changes in Arbitrary units (AU; measured densitometrically using ImageJ v1.49m) for the annotated lipid classes compared to control flies \pm SEM; Student's t-test, ***= $P < 0.001$, **= $P < 0.01$, *= $P < 0.05$. In C the dotted line marks a break due to a removal of a lane on the TLC plate.

3.1.2 *pummelig* and *brummer* mutants are obese but not overweight

In addition to body fat measurements it was tested if *pum1*¹ and *bmm1*¹ flies are overweight. Indeed, both mutants were actually lighter than control flies (Figure 15). *pum1*¹ had ~15% decrease in body weight whereas the effect was less pronounced in *bmm1*¹ (-8%). This indicates that obesity in flies does not necessarily correlate with overweight in flies.

3.1.3 Body fat over-storage can be observed in *pummelig* mutant flies but not larvae

So far it could be shown that adult *pum1*¹ flies store more fat than control flies but I was interested if this phenotype can be also observed in larvae. Additional body fat measurements revealed no significant changes in L3 larvae. A first difference in total body fat storage between *pum1*¹ and controls could be observed in freshly eclosed flies that became even more pronounced in older flies (Figure 15). As the adult fat body develops within the first six days after eclosure it might be possible that the

differences in the regulation of the larval and the adult fat body might be reason that only in adult *pum1¹* flies stored more fat than control flies.

Figure 15 *pummelig* mutant flies are obese but not larvae. (A) Body weight of *pum1¹* and *bmm1¹* flies was decreased significantly compared to control flies. (B) Increased lipid storage of *pum1¹* mutants can be observed in freshly eclosed flies (one-way ANOVA $F_{1,14}=0.04$, $P=0.02$) but not in wandering L3 larval stage (one-way ANOVA $F_{1,14}=0.04$, $P=0.82$). There was no difference between freshly eclosed females or males (two-way ANOVA $F_{1,34}=0.55$, $P=0.46$).

3.2 Mean life time is decreased in *pummelig* mutant flies

Lipid overstuffing flies like fly mutants of the insulin pathway have an expanded lifespan (Partridge *et al.*, 2011). On the other hand, *bmm1¹* that have higher body fat as well have a shorter lifespan (Grönke, 2005). Compared to its genetically matched control, *pum1¹* flies had a significantly shorter mean life expectancy of ~12% (Figure 16). In the two independent experiments the difference was significant. Whereas the *pum1¹* strain had a very similar death curve and an average median lifetime of $62,6 \pm 0,9$ days, the control flies had a bigger variation $70,2 \pm 2,5$ days. Thus, a knockout of *pum1* negatively affects the life expectancy in flies.

Figure 16 Mean-life time is decreased in *pum1¹* compared to genetically matched control flies (A, B). The two repetitions show the bigger variation in median life time of the control flies (log Rank-P test; $n=240$ animals/genotype; A) $P=3.47 \cdot 10^{-8}$; B) $P=2.9 \cdot 10^{-4}$).

3.3 *Pummelig a starvation-responsive gene*

3.3.1 Expression of *pummelig* is increased under starvation

It is known that *bmm/DmATGL* is a starvation responsive gene (Grönke *et al.*, 2005) and over-expression of *bmm* leads to reduced amounts of body fat (Grönke *et al.*, 2005). As described earlier *puml¹* flies exhibit a comparable lipid over-storage phenotype to *bmm¹* flies (Figure 13). Additionally, Puml has high similarity to the activator of mammalian triacylglyceride lipase (ATGL) namely ABHD5/CGI-58 (Figure 10). Therefore, it was assumed that the core lipid mobilization module ATGL-ABHD5 could be evolutionary conserved in *Drosophila melanogaster* and that higher expression of *bmm* might be correlated with higher expression of *puml* and increased amounts of Puml.

In order to address this, *bmm* expression was modulated by starvation (for 16h) or fat-body specific overexpression (FB-SNS>GAL4) and relative RNA levels of *puml* were analysed by RT qPCR (RNA isolated from total flies). Indeed, like *bmm* (19±5.8 fold) also *puml* (Figure 17) showed a significant increase (3±1,5 fold) in RNA levels under starvation and was elevated (9,3±3 fold) while *bmm* was over-expressed in the fat body (Figure 17). In order to analyse whether protein levels of Puml were elevated as well, a starvation experiment was performed using flies with *puml::gfp* under its endogenous promotor and compared to fed flies from the same strain. After 16h flies from both groups were collected and Puml::GFP abundance was checked by Western Blot analysis using whole fly extracts. Comparable to the RNA levels, abundance of Puml::GFP was significantly increased by 4 fold during starvation (Figure 17). The data indicate an involvement of *puml* in the modulation of lipid mobilization.

Figure 17 *puml* and *bmm* RNA levels are increased under starvation. Puml::GFP protein amounts (expressed under the endogenous promotor) are elevated under starvation. (A) Starvation leads to

increased amounts of *puml* and *bmm* RNA. (B) Overexpression of *bmm* specifically in the fat body (*FB-SNS>GAL4*) enhances RNA levels of *puml* as well (shown are the average fold changes \pm SEM of the RNA levels; Mann-Whitney test; ***= $P<0.001$). (C) Detection of endogenously expressed *Puml::GFP* using α -GFP antibody during starvation shows increased protein abundance of *Puml::GFP*. Plotted are means of *Puml::GFP* signal measured densitometrically normalized to β -tubulin measured on the same western blot membrane \pm SEM, Mann-Whitney test; ***= $P<0.001$).

3.3.2 Starvation resistance is enhanced in *pummelig* mutant flies

As shown before both *bmm*¹ as well as *puml*¹ flies have increased lipid storage. Also, *bmm* and *puml* have higher expression during starvation. It is known from literature that, the lipid over-storage phenotype of *bmm*¹ flies is accompanied by a higher starvation resistance (Grönke *et al.*, 2005). Therefore, it was checked if this is also the case for *puml*¹ flies. Earlier experiments (Takacs, 2007) indicated no phenotype but the outbred *puml*¹ strain used in this work exhibits a significant increase in the median starvation time (Figure 18). Compared to control flies which had a mean survival time of 38,5 \pm 4,2 hours (average from five independent experiments) it was increased by 15% in *puml*¹ flies (44,7 \pm 3,8 hours). *bmm*¹ flies exhibited the biggest difference in mortality under food-deprivation with an increase of 56% in the mean survival time (60,1 \pm 2,5 hours). Thus, the higher body fat storage in *bmm*¹ and *puml*¹ allows for a higher survival under starvation.

Figure 18 Mortality curve of *bmm*¹, *puml*¹ and control flies under food-deprivation. Starvation resistance of *puml*¹ comparable to *bmm*¹ is significantly increased (A, B) (log Rank-P test; n=64 animals/ genotype in A, n=100 for *puml*¹ and control and n=20 for *bmm*¹ in B; $P<0.001$ in both experiments). The two independent experiments show a strong variability of the used control flies in the median survival time under starvation.

3.4 Enzymatic characterization of PumI

3.4.1 PumI is not the activator of Bmm and has no triacylglyceride hydrolase activity

The high similarity of PumI (**Figure 10**) to the mammalian paralogs ABHD4 and ABHD5 implied a possible conservation of the core lipid mobilization module formed by ATGL-ABHD5 (Lass *et al.*, 2006, Yamaguchi *et al.*, 2007) or a direct enzymatic activity like ABHD4 (Liu *et al.*, 2008). *pumI* and *bmm* are expressed at higher levels during starvation and the absence of each single one or both leads to increased body fat storage in form of TAGs. Additionally, *pumI*¹ and *bmm*¹ flies are more starvation resistant (see above). In order to show that PumI directly stimulates Bmm's a triacylglyceride hydrolase activity both proteins were recombinantly expressed and lysates from overexpressing cells were used in a triacylglyceride hydrolysis assay. Protein expression was controlled by SDS-PAGE and subsequent Commassie staining. Expression of His-tagged proteins was checked by Western Blot analysis using an antibody against the His-tag (using a HRP-coupled secondary antibody). β -Galactosidase (β -Gal.) was expressed as negative control. Whereas Bmm-GST (**Figure 19**) was expressed in *E.coli* the remaining proteins with an N-terminal His-tag (**Figure 19**, B and C) were produced by COS-7 by cells (Schweiger *et al.*, 2014).

Cell lysates (from overexpressing cells) were used for an *in vitro* lipid hydrolase assay using triolein (spiked with [9,10(N)-3H]-Triolein) emulsified with a mixture of Phosphatidylcholine/Phosphatidylcholine (PC/PI). The radioactive TAG hydrolase assays were performed by Dr. Christoph Heier (Karl Franzens University, Graz). ATGL and Bmm containing lysates exhibited a basal hydrolase activity in comparison to the control lysate containing β -Galactosidase. Neither PumI nor ABHD5 had a significant hydrolase activity on triolein. The co-incubation of ATGL with ABHD5 resulted in a stimulated hydrolase activity (+4 fold). A comparable enhanced activity could not be observed for the incubation of Bmm with PumI. Inter-species combinations of PumI, ABHD5 with Bmm or ATGL could not reveal an evolutionary conservation of the activation property of ABHD5 on ATGL for its TAG hydrolase activity. This finding

Figure 19 PumI cannot hydrolyse Triolein and does not stimulate Bmm lipase activity. Recombinant protein expression of PumI and Bmm for Triacylglyceride hydrolase assay. (A) Commassie stained SDS-PAGE. Bmm-GST (83,2KDa) expression was clearly visible in induced cells (IPTG, 1mM added at $OD_{600}=0.5-0.6$, cultivation for 3h at 22°C). (B) Commassie stained gel of His-tagged proteins size separated by SDS-PAGE and (C) Western Blot from a parallel run gel (protein detection using an α -His antibody). Expression could be detected for: β -Gal. (116KDa), PumI (50,4KDa), MmHSL (~85KDa), ABHD5 (39,1KDa) and MmATGL (55,3KDa). (D, E) Calculated hydrolase activity of the lysates with the overexpressed proteins based on the amounts of released fatty acids in the Triacylglyceride hydrolase assay. Protein expression was performed by me (Plasmids used were obtained as mentioned in the Material and Methods part), radioactive triglyceride hydrolase activity assays were performed by Dr. C. Heier (Karl Franzens University, Graz). Calculations were performed as described in chapter 2.11.1. ATGL and Bmm have basal TAG hydrolase activity (D). Co-incubation of ATGL and ABHD5 results in stimulated hydrolase activity compared to ATGL+ β -Galactosidase. Bmm activity is not enhanced by co-incubation with PumI or ABHD5 (E). Plotted are the means \pm SEM (D, E), Student's test, ***= $P<0.001$ (Statistical tests were performed using following controls; (D) β -Galactosidase lysate; (E) ATGL or Bmm + β -Galactosidase mixtures).

corresponds with additional experimental data from Catharina Ebner and Dr. Christoph Heier (Karl Franzens University, Graz, unpublished data). Therefore, PumI and Bmm seem not to directly interact in order to achieve a higher hydrolase activity on TAG.

3.4.2 Recombinant PumI has phospholipase activity

Different to ABHD5, that lost its catalytic center in its Serine-hydrolase motif by a point mutation (GxNxG), ABHD4 as well as PumI both have an active Serine-hydrolase motif. ABHD4 is directly involved in the regulation of brain N-acyl phospholipids (Lee

et al., 2015). A pilot experiment by Maria Pribasnik (Karl Franzens University, Graz) indicated a possible activity of Puml, like for ABHD4, on the N-acyl phospholipid NAPE (1,2-dioleoyl-sn-glycero-3-phosphoethanolamine-N-arachidonoyl). In order to confirm this and to find possible hydrolysis targets for Puml, a substrate screen with neutral and polar lipids was performed. For this *puml* and as a negative control β -Galactosidase were over-expressed in insect cells (Hi-5 cells).

Figure 20 A Substrate screen identifies Puml as a potent phospholipase. (A) Puml and β -Galactosidase are expressed in insect cells (Hi-5). Expression of Puml (see arrow in A) increased with longer cultivation time with a peak during the drop of cell viability to under 70%. The protein could be found in the 1000 x g pellet after cell lysis and in the supernatant used for the enzymatic assays (shown is a Commassie stained SDS-Page). (B) Hydrolase activity of Puml on NAPE, monitored by quantification of FA release from the substrate, showed an a preference for basic pH. (C) Substrate screen for Puml. Data is represented as mean fold increase in FA release from the substrates in comparison to β -Galactosidase. Puml exhibits various substrate affinities: Phosphatidic acid (PA), Phosphatidylglycerol (PG), NAPE (N-acylphosphatidylethanolamine), medium chain Phosphatidylcholine (MCPC), medium-chain Phosphatidylglycerol (MCPG), Bis(Mono-acylglycerol)-phosphate (BMP[R,R]) and Ethyl palmitate (EP). Besides a low enzymatic activity on Mono-olein, Puml shows no affinity in hydrolysis neutral lipids (e.g. TAGs [TO-C8; TO-C18:1], DAGs [DO(rac)], Retinylester (RE)). More detailed descriptions on the substrates can be found in the material and methods part. Plotted are means \pm SEM, Mann-Whitney test, *= P <0.05, **= P <0.01, ***= P <0.001.

High FA release in comparison to control (β -Galactosidase expressed) lysates could be observed for (**Figure 20**): Phosphatidic acid (PA), Phosphatidylglycerine (PG), NAPE (N-acylphosphatidylethanolamine), MCPC, MCPC and BMP(R,R). Besides Ethyl palmitate and a low affinity for Monoolein, neutral lipids were no preferred hydrolysis targets for PumI. Therefore, PumI does not contribute to the hydrolysis of storage fat. PumI showed a high activity in neutral to basic pH. (**Figure 20**). Curve-fitted data from substrate saturation measurements revealed a K_M of $\sim 0.78\text{mM}$ for Phosphatidic acid (PA) and $\sim 0.11\text{mM}$ for Phosphatidylglycerol (PG) showing a preference for the latter one. Interestingly, v_{max} values for PA were ~ 2.5 fold higher than PG. This indicates that the TAG over-storage might be caused by a different mechanism than just a lower mobilization of storage lipids in *pumI*¹ flies.

3.5 Energy storage of *pummelig* mutant flies under fed and stress conditions

3.5.1 Glycerolipid consumption under starvation is higher in *pummelig* mutants compared to control flies

As shown before *pumI*¹ flies have an increased starvation resistance and store more TAGs than control flies. However, a direct hydrolytic activity on lipids (TAGs and DAGs) could not be detected. Perhaps, this is caused by a lower mobilization rate of storage lipid. In order to test if lipid mobilization was impaired in *pumI*¹ flies a starvation assay was performed. Compared to *bmm*¹, the general capability to mobilize storage lipids was not impaired in *pumI*¹ during starvation (**Figure 21**).

Figure 21 *pumI*¹ flies mobilize lipids faster during starvation than control flies. Plotted are means of TAG \pm SEM. Both, *pumI*¹ and *bmm*¹ exhibit increased body fat storage at starvation start (six days after eclosion; one-way ANOVA $F_{(2,8)}=19.03$, $P=9.09 \times 10^{-4}$). During starvation, all tested flies could mobilize

storage lipids (two-way ANOVA, genotype and starvation time as fixed effects, $F_{(2,31)}=72.41$, $P=4.23 \times 10^{-14}$). *bmm*¹ showed a slower TAG mobilization during the first 24h of starvation and a substantial amount of TAGs remained immobilized in dead flies. *pum*¹ mobilized around half of the storage lipids (much more than control flies) within the first 24h of starvation. Lipid utilization became less in the following time of starvation and a significant amount of lipids remained in dead flies compared to control flies (one-way ANOVA, $F_{(2,14)}=5.40$, $P=0.01$; Fisher's LSD $P<0.05$). Control flies exhibited a similar pattern of reduced lipid mobilization with prolonging starvation but nearly used up all stored lipids.

Indeed, *pum*¹ flies used up ~30% more lipids during the first 24h of starvation compared to control flies. Besides a significantly higher amount of un-mobilized lipids found in post-mortem flies, in total *pum*¹ utilized on average ~60% more lipids than control flies during starvation time. Thus, *pum*¹ is not crucial for lipid utilization in general. Nevertheless, it is possible that a subset of lipids is not mobilized in *pum*¹ flies.

Figure 22 Locomotor activity and metabolic rate of *pum*¹ are similar to control flies during starvation.

(A) For each fly line, the individual locomotor activity levels of individual flies ($n=64$) were measured in 5-minute bins. In order to generate a group profile, the sum of activity was plotted for each genotype. (B) Box plot for the total number of beam-passes during starvation time per animal; Center lines show the median, box limits indicate 25th and 75th percentiles as determined by OriginPro software; whiskers extend 1.5 times the interquartile range from the 25th and 75th percentiles; $n=63$ for each genotype. Average of total beam-passes during starvation was significantly higher in *bmm*¹ flies (Mann-Whitney test; $***=P<0.001$). (C) Metabolic rate is represented as box plot (generated as described shortly before). Metabolic rate was

lower in starved (16 hours under starvation) cohorts (one cohort= 3 animals; checked at zeitgeber +8h) but no difference between *puml¹* and control flies could be detected (Mann-Whitney test).

3.5.2 Total locomotor activity is not increased in *pummelig* mutant flies under starvation.

In order to identify the cause for the increased lipid consumption in *puml¹* flies, locomotor activity from starving flies was monitored in the *Drosophila* activity monitoring system (Trikinetics). Single flies were kept in glass tubes and motion was quantified by counting passes through an infrared light beam. There was no difference in the activity between *puml¹* and control flies during starvation (Figure 22). Activity peaks were similar between all tested genotypes. Total starvation activity (Figure 22) was significantly higher in *bmm¹* compared to *puml¹* and control flies. Since median survival time under starvation (**Figure 18**) is increased in *bmm¹* flies, allowing for a higher total activity, average total accumulated activity during starvation was increased in *bmm¹* flies. However, higher lipid utilization of *puml¹* flies, especially in the first twenty-four hours, was not correlated with higher activity during starvation.

3.5.3 Metabolic rate is not changed in *pummelig* mutant flies

Modulation of lipid storage in *puml¹* is different compared to control flies. During ad libitum feeding *puml¹* have increased body fat storage. Under fasting conditions these lipids are utilized faster than in control flies but locomotor activity is not changed. A possible reason for the higher lipid consumption might be a different regulation of metabolic rate in *puml¹*. In order to address this, a metabolic rate assay was performed using fed and fasted (16h under starvation) flies. Metabolic rate was significantly reduced under starvation compared to *ad libitum* fed flies (**Figure 22**). However, no difference in metabolic rate between *puml¹* and control flies was detected for fed as well as for fasted flies (**Figure 22**).

3.5.4 Glycogen storage is decreased in *pummelig* mutant flies

As shown before *puml¹* had higher lipid storage under fed conditions but faster utilization of this energy storage. *puml¹* flies did not have a higher activity under starvation and metabolic rates of were not different under feeding condition or during nutrient deprivation. As only the oxygen consumption was monitored for the

metabolic activity and no data for CO₂ was acquired, the oxidative quotient could not be used to identify which energy source is mainly used by the fly. Therefore, a more detailed time course experiment was performed to monitor energy stores during the first 24h of starvation. Besides neutral lipids also protein content and glycogen stores were analysed (Figure 23). The amount of protein did not change significantly during the first 24h of starvation, whereas lipids were utilized faster in *pum1¹* flies. Interestingly, glycogen stores in *pum1¹* were decreased by ~42% compared to control flies (Student's test, $P=7,51 \cdot 10^{-4}$) in fed flies. Glycogen stores depleted simultaneously with the lipids in *pum1¹* and control flies (Figure 23). Due to the lower amount of glycogen in *pum1¹* they were used up much faster leaving up lipids as the main energy source. Therefore, higher lipid mobilization of *pum1¹* is mainly caused by lower availability of carbohydrates under nutrient deprivation.

Figure 23 Less glycogen is stored in *pum1¹* flies. Plotted are mean values for Protein (triangle; green), Triacylglycerides (dots; blue) and Glycogen (rectangle, red) \pm SEM during starvation. *pum1¹* flies (B) store increased amounts of TAG and have lower Glycogen stores (control flies (A) store ~42% more Glycogen). Protein amounts were not changed significantly during the initial 24h of starvation. Glycogen stores in *pum1¹* flies (B) were completely utilized during the observation time leaving lipids as the remaining major energy source.

3.5.5 Desiccation resistance is impaired in *pummelig* mutant flies

It is known that glycogen vastly contributes to desiccation resistance in *Drosophila melanogaster* (Marron et al., 2003). Therefore, it was tested if the reduced glycogen storage has a negative impact on the mean survival time under these conditions. In correlation with lower Glycogen storage in *pum1¹* also mean survival time under desiccation was significantly decreased (-17% see Figure 24).

Figure 24 Desiccation resistance is decreased in *puml¹* flies ($n=128$ animals per genotype; Log Rank test; $P=5.41 \times 10^{-6}$).

Taken together, it was assumed that the TAG over-storage phenotype in *puml¹* flies was caused by an impaired mobilization of lipids. Interestingly, conversely to the high TAG storage, Glycogen stores in *puml¹* flies were significantly lower in *puml¹* indicating that the storage type of energy in *puml¹* was changed. In general storage lipid mobilization was not impaired in *puml¹* flies and metabolic rate was indifferent from control flies (under fed conditions and during starvation). However, *puml¹* utilized always more lipids during starvation than control flies indicating that lipids might be the preferred substrate for energy generation. The substrate screen identified Puml as an active phospholipase but how this effects lipid storage needs to be unravelled.

3.6 *pummelig* mutant flies are normophagic

As shown earlier lipid mobilization is actually higher *puml¹* flies but body fat storage is increased. Additionally, metabolic rate is similar to control flies. A possible increase in food intake and the resulting increased caloric loading could explain the increased body fat. Therefore, it was tested if *puml¹* flies are hyperphagic. In order to address this question, individual food intake was measured using the CAFÉ system (as recently described (Baumbach *et al.*, 2014a)).

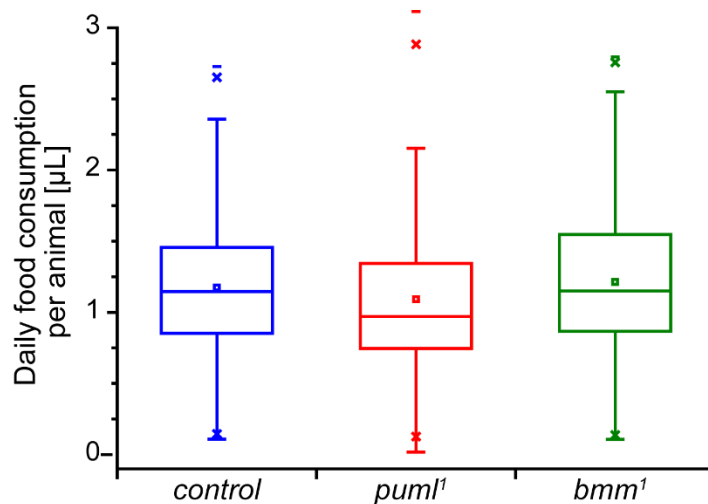

Figure 25 *pum1*¹ and *bmm1*¹ flies are not hyperphagic (one-way ANOVA, $F_{(2,407)}=1.92$, $P=0.14$). Box plot of the daily food consumption (5% Yeast extract + 5% sucrose) of the tested genotypes (followed from six days after eclosure for six days). Center lines show the median, box limits indicate 25th and 75th percentiles as determined by OriginPro software; whiskers extend 1.5 times the interquartile range from the 25th and 75th percentiles; $n \geq 136$ for each genotype.

*bmm1*¹ were checked additionally as these flies are also obese and to see if there is a comparable mechanism in these flies. Food intake varied from day to day but average food intake over six days was not significantly changed in the observed genotypes (**Figure 25**). However increased body fat storage of *pum1*¹ flies compared to control flies was persistent in the CAFÉ system. Thus, an altered feeding behaviour does not seem to be the cause for the observed changes in the TAG storage.

3.7 Lipogenesis is increased in *pummelig* mutant flies

With a comparable food intake and the knowledge that *pum1*¹ have lower glycogen storage I assumed that *pum1* may acts as a metabolic modulator changing the preference for an energy storage towards in lipids (on the cost of carbohydrates) in *pum1*¹ flies through an unknown mechanism. In mice it could be shown that the absence of ABHD5 promoted the metabolic switch of cells towards aerobic glycolysis (Ou *et al.*, 2014). In order to monitor if lipogenesis, *pum1*¹ flies were transferred on a diet with a radioactive tracer (uniformly ¹⁴C-labeled glucose) for 24h (pulse flies) and radioactivity was measured in lipid extracts from total flies (in principle as described in (Katewa *et al.*, 2012)).

Figure 26 Rate of de novo lipid synthesis is increased in *pum1* flies. Plotted are means of dpm (disintegrations per minute) \pm SEM (Student's test; n=5) measured in neutral lipid (A, B) and phospholipid fractions (C, D) from 20 flies after 24h on diet supplemented with ^{14}C glucose and a second measurement after additional 60h on non ^{14}C glucose diet. Rate of de novo lipid synthesis is significantly increased in *pum1* generating more lipids with ^{14}C incorporated lipids within 24h (A) on this diet. The difference in amounts of labelled neutral lipids is maintained during the chase phase indicating no utilization of the generated lipids (B). Amounts of synthesized phospholipids were similar after 24h feeding on ^{14}C diet (C). Significant differences could be detected after continuous time on non-labelled diet (D).

Lipids were fractionated into neutral and phospholipids and analysed separately. Both genotypes exhibited *de novo* lipid synthesis (measured by decay of incorporated ^{14}C into lipids from the fed ^{14}C glucose) under the experimental conditions and food regime. Measured radioactivity in the neutral lipids fraction was significantly higher in *pum1* compared to control flies. The amounts of labelled phospholipids were similar between the tested genotypes. Therefore, *pum1* flies appear to generate more storage lipids although food intake is not increased. Even though flies were kept on regular diet for additional 60h (without ^{14}C glucose; Chase flies), amounts of labelled neutral lipids were increased in both genotypes compared to flies collected directly after the 24h pulse. This indicates that *de novo* lipid synthesis from ingested ^{14}C glucose continued after the feeding phase that might be driven by stored ^{14}C glucose supplemented food in the crop. Utilization/turnover of the labelled lipids cannot be addressed by the used experimental approach. It is possible that utilization of lipids is not occurring and not clear if the maximal incorporation of ^{14}C glucose is or has been reached in the tested +60h samples. At least phospholipid levels in control flies were stable in at both time points arguing in favour of higher lipogenesis rates in *pum1*.

Taken together *pum1* lipid over-storage phenotype in adult flies is rather the result of a preference to store energy as neutral lipids than carbohydrates. Reduced

glycogen storage, unchanged metabolic rate in *puml¹* and increased lipogenesis support this model. Future experiments should also address the incorporation of ¹⁴C glucose into glycogen in order to get a better insight into the channelling of the fed glucose into the different energy stores.

3.8 Localization of Pum1 and lipid storage phenotypes in *pummelig* mutant flies

3.8.1 Pum1 is a member of the lipid droplet proteome

Various studies identified Pum1 as a lipid droplet (LD) resident. It was found on embryonic LDs (Cermelli *et al.*, 2006). Previous work (in our lab) on Pum1 by Anna Takács using a C-terminal labelled Pum1::mCherry fusion protein (expressed by using the target system and expression under endogenous promotor) showed a LD association in larval fat body and free floating adipocytes (Takacs, 2007). Jonathan Rosenberg (a former bachelor student in the lab) located the same C-terminal tagged protein constructs on LDs in larval wing discs, the proventriculus and on LDs in Malpighian tubules in larvae and adult flies (Rosenberg, 2012). More recently, a different C-terminal labelled (mCherry) construct was expressed in the *Drosophila melanogaster* S2-cell line that localized on LDs in these cells (Krahmer *et al.*, 2013) as well.

First, the localization of Pum1::mCherry on LDs was verified in the adult fat body.

Localization of Pum1::mCherry was comparable to the published lipid droplet resident Brummer (Grönke *et al.*, 2005) that showed a uniform and dot-like distribution on LDs in the adult fat body. Pum1::mCherry fusion protein in accordance with previous findings for Pum1 localization (described above) could be found on LDs in adult fat body cells as well. Most of the Pum1::mCherry exhibited a uniform/ring-like distribution on LDs but a portion showed accumulations in close proximity to LDs or distant from lipid-dye stained structures.

Figure 27 *Pum1::mCherry and Bmm::EGFP are localized to lipid droplets in adult fat body tissue (C, F). Bmm::EGFP (Lipids stained with LIPID TOX) exhibits homogeneous and dot-like localization (A-C; Box in B). Pum1::mCherry localized on also on lipid droplets and showed a uniform/ring-like localization (D-F) as well as local accumulations on the LDs surface or in very close proximity to it (E in the Box, arrow). Additionally, accumulations not overlapping with neutral lipid staining (Bodipy493/503) could be seen for Pum1::mCherry (see Box in F).*

3.8.2 *pummelig* mutant flies exhibit ectopic lipid storage in Malpighian tubules

In order to find out where Pum1::mCherry accumulates besides lipid droplets I switched to a more accessible cell biology system in the fly. Prior work on *puml* function concentrated on finding a biological phenotype in the *puml*¹. Whereas increased total body fat storage was shown in this work for the first time a screening for possible lipid accumulation phenotypes in *puml*¹ was performed by Jonathan Rosenberg. Based on the expression data for *pummelig* (*CG1882*) obtained from the FlyAtlas project (Chintapalli *et al.*, 2013) various tissues were screened. The strongest change in lipid storage (followed by Oil Red O staining) of *puml*¹ correlated with the highest expression of *puml* in Malpighian tubules (Rosenberg, 2012), the renal organs of the fly. A comparable over-storage of lipids could also be observed in *bmm*¹ (Rosenberg, 2012) using Oil Red O to stain for lipids.

During this work the over-storage phenotype in Malpighian tubules could be confirmed for both *puml*¹ and *bmm*¹ (**Figure 28**) using Oil Red O staining, fluorescent

lipophilic dyes (e.g. Bodipy493/503) and electron microscopy (sample preparation and image acquisition were performed by Dr. Dietmar Riedel (MPI-bpc)). Compared to *puml* that has a very high expression in Malpighian tubules, *bmm* expression is only moderately in this tissue and compared to other *bmm* expressing tissues quite low. Nevertheless, increased lipid storage in Malpighian tubules of *bmm*¹ flies exceeds the levels of *puml*¹ flies. An electron microscopic analysis could confirm the particles as lipid droplets and no obvious changes (besides more lipid droplets) in cellular morphology of Malpighian tubules could be observed in both mutants (*puml*¹ and *bmm*¹).

3.8.2.1 *pummelig* expression in *pummelig* mutant flies can rescue the lipid over-storage phenotype

As shown before in this work, an overexpression of *puml* had no effect on body fat storage in the fly. In order to see if it is functional and capable of reversing/prohibiting the lipid over-storage phenotype it was expressed in *puml*¹. A ubiquitous (Act5c>GAL4) and tissue specific expression in the fat body (FB-SNS>GAL4) and Malpighian tubules (UO>GAL4) in *puml*¹ flies resulted in a significant reduction in body fat storage in adult flies (**Figure 29**).

The ubiquitous expression of the *puml* resulted in a reduced body fat and reduced nearly absent lipid droplets in Malpighian tubules (**Figure 29**). When expressing the construct in Malpighian tubules specifically the effect on the body fat storage was much smaller but still significant and lipid over-storage phenotype of *puml*¹ in the Malpighian tubules was reverted. A fat body specific expression on the other side had a strong effect on body fat but lipid over-storage phenotype in Malpighian tubules was not affected. Therefore, the used UAS-*puml* construct is functional and capable of reverting the lipid-over-storage.

Figure 28 Lipid storage is drastically increased in Malpighian tubules of *puml¹* and *bmm¹* flies. Upper Row shows an Oil Red O staining in fixed Malpighian tubules from six day old adult flies. Mid row displays electron microscope pictures (high pressure freezing; sample preparation and image acquisition was performed by Dr. Dietmar Riedel; MPI-bpc). Fluorescence microscope pictures using DAPI for nucleic staining, Bodipy493/503 for lipids and Cellmask™ for plasma membrane staining are shown in the lower row.

Lipid storage in general appears to be a native property of Malpighian tubules (see **Figure 28**) and *puml* and *bmm* are involved in the modulation of this energy source. Also the fact, that a fat body specific expression of *puml* in *puml¹* flies does not change ectopic lipid storage in Malpighian tubules drastically indicates that lipid storage in Malpighian tubules is not directly coupled to lipid storage in the fat body.

Figure 29 Overexpression of *Pum1* rescues lipid over-storage phenotype in Malpighian tubules from *pum1*¹ flies. Plotted are average fold changes of body fat (\pm SEM) of *pum1*¹ flies and under the ubiquitous (*Act5c>GAL4*) or tissue-specific expression (*FB-SNS>GAL4* [fat body] and *UO>GAL4* [Malpighian tubules]) of *pum1* compared to control flies and the genetic match of the experiment. Body fat is significantly lower during the expression of *pum1* in *pum1*¹ flies. A ubiquitous (C) and Malpighian tubule (E) specific expression both reduce lipid storage in Malpighian tubules. A fat body specific expression leads to decreased body fat storage (A) but does not affect lipid stores in Malpighian tubules (D). Pictured are representative images from Malpighian tubules (mid-segment) stained with DAPI (for nucleic acids) and Bodipy(493/503) for lipids. (Student's test; **= $P < 0.01$, ***= $P < 0.001$). The dashed red line represents the fold change in body fat of *pum1*¹ flies compared to control flies (blue dashed line; represents body fat storage of genetically matched control to *pum1*¹ flies).

3.8.3 Pummelig::mCherry fusion protein is localized on peroxisomes

As shown before Malpighian tubules can store lipids and *bmm*¹ and *pum1*¹ flies exhibit elevated lipid storage in this tissue. An overexpression of *pum1* in Malpighian tubules can reverse this phenotype. Therefore, I chose this biological cell system to investigate the localization of Pum1::mCherry further as it was not only found on lipid droplets but also showed additional accumulations in the cytoplasm.

For *Arabidopsis thaliana* ABHD4/5 (*At4g24160*) it is known that it can localize to LDs (James *et al.*, 2010) and interacts with PXA1 and can be found on or in association with Peroxisomes (Park *et al.*, 2013, Park *et al.*, 2014). Therefore, I checked if non-lipid associated Pum1::mCherry signal could be a localization on Peroxisomes. Indeed,

a co-localization could be observed with endogenously expressed Pum1::mCherry in flies (**Figure 30**) with a ubiquitously expressed peroxisome targeted EYFP (Act5c>eYFP-Pts1; UAS-eYFP::Pts1 was a kind gift from Dr. J. Faust (Faust *et al.*, 2014).

Figure 30 Pum1::mCherry is localized on lipid droplets and peroxisomes. Pum1::mCherry (expressed by the endogenous promotor) and eYFP::Pts1 (ubiquitously expressed: Act5c>GAL4) localization was analysed in *pum1¹* genomic background. ~62% of eYFP::Pts1 signal overlapped (A) with Pum1::mCherry (C) indicating a peroxisomal (B) abundance of Pum1::mCherry. Less than 10% of the total Pum1::mCherry signal exhibited a co-localization with eYFP::Pts1. The majority of Pum1::mCherry showed a ring-like distribution (potentially lipid droplets) and accumulations that neither were ring-like or co-localized with eYFP::Pts1 (F). Image A, B, C and F show ureter of an adult fly.

The majority (~92%) of Pum1::mCherry signal exhibits a circular pattern (potentially around lipid droplets) or roundish accumulations. The remaining ~8% of the Pum1::mCherry signal overlaps with ~62% of eYFP::Pts1 signal. With eYFP::Pts1 representing the peroxisomes it can be claimed that over half of the peroxisomes is populated with Pum1::mCherry but the majority of the protein is not on peroxisomes. Interestingly, a peroxisomal targeting signal (Pts1) that consists of a C-terminal *SKL-motif* (Faust *et al.*, 2012) is not conserved in Pum1 though this localization may requires an interaction partner.

3.9 Lipid over-storage in Malpighian tubules of *pummelig* mutant flies does not impair osmotic resistance

Malpighian tubules perform various tasks in *Drosophila melanogaster* e.g. osmoregulation (Berridge and Oschman, 1969, Wessing and Eichelberg, 1969) and are important for immune response (McGettigan *et al.*, 2005). More recently, it was shown that *bmm* and *puml* are upregulated under osmotic stress (Stergiopoulos *et al.*, 2009). As lipid storage was altered in *puml*¹ Malpighian tubules it was assumed that biological functions of this tissue might be impaired. Therefore, *puml*¹ flies were subjected to diet containing high amounts of sodium chloride (**Figure 31**)

Figure 31 Osmotic stress resistance of *puml*¹ flies is not impaired. Six-day old flies were transferred to either one of the following dietary regimes: normal food, starvation or food with 4% NaCl added ($n=120$ flies per tested diet). Flies survived longer on salted food compared to starved flies (log Rank test, $P<0.001$) and starved *puml*¹ flies showed higher mean survival time than control flies (log Rank test, $P<0.001$). Under osmotic stress (salty diet) no significant difference in the mean survival time could be observed between the two tested genotypes.

Compared to flies under starvation mean survival time on high salt diet was significantly increased. Although there is a significant difference in mean survival time between *puml*¹ and control flies this difference cannot be observed under osmotic stress (Fig. X). So the increased lipid storage in Malpighian tubules of *puml*¹ has no drastic negative effect on the osmoregulatory capacity of flies lacking *puml*.

3.9.1 Lipid droplet distribution is altered in *pummelig* mutant flies

As introduced before, body fat is increased in *puml*¹ and lipid storage is elevated in Malpighian tubules that can be rescued by tissue-specific expression of *puml*-cDNA. Microscopic analysis of lipid storage using fluorescent lipophilic dyes indicated a difference in the lipid droplet size distribution between *puml*¹, *bmm*¹ and control

flies. Due to the limited biological dimensions of Malpighian tubules, this tissue was used to analyse the lipid droplet size between these genotypes (**Figure 32**).

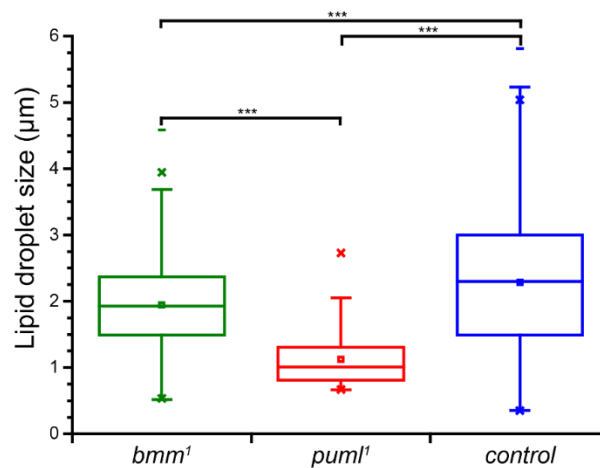

Figure 32 Average lipid droplet size (diameter) is reduced in Malpighian tubules of *puml*¹ flies. Box plot of lipid droplet size quantified from confocal pictures of fluorescently stained lipid droplets in Malpighian tubules. Center lines show the median, box limits indicate 25th and 75th percentiles as determined by OriginPro software; whiskers extend 1.5 times the interquartile range from the 25th and 75th percentiles (Mann-Whitney test; $n_{lipid\ droplets}$ analysed per genotype: *bmm*¹=1206, *puml*¹=1715 and control=306).

Lipid storage is quite low in Malpighian tubules of control flies (**Figure 32**) reflected by the low number of individual lipid droplets that were used for the size distribution (diameter of lipid droplets was calculated from the total area from a maximum intensity projection of an acquired 3D-confocal image stack). Though, the quantified lipid droplets on average had the largest diameter compared to *bmm*¹ and *puml*¹. As described earlier both mutants had a much higher lipid storage in Malpighian tubules but average lipid droplet (LD) sizes were significantly smaller. A possible explanation might be an alternated phospholipid metabolism in *puml*¹ and *bmm*¹ flies that finally effects also the phospholipid composition of the LDs and therefore shaping their size.

3.9.2 Long-chain fatty acids and poly-unsaturated fatty acids are elevated in *pummelig* mutant flies

Lipid stores are elevated in *puml*¹. The major neutral lipid class contributing to this are TAGs (**Figure 14**). During starvation lipids are mobilized in general but on average a significantly higher amount of lipids remain in dead animals (**Figure 21**). Additionally, lipid droplet size distribution in Malpighian tubules is changed in *puml*¹.

AtABHD4/5 null mutants (plants) exhibit similar to *puml¹* ectopic lipid storage in leaves (James *et al.*, 2010). The major elevated neutral lipid class were TAGs and content of poly-unsaturated fatty acids (PUFAs) esterified in the neutral lipids were elevated (James *et al.*, 2010) and a shift towards longer fatty acid sidechains of neutral lipids could be seen. Additionally, it had been shown that *AtABHD4/5* interacts with the peroxisomal ABC-transporter 1 (PXA1) (Park *et al.*, 2013). A single *PXA1* mutant and a *AtABHD4/5, PXA1* double mutant exhibited the same phenotype on TAGs as the single *AtABHD4/5* mutant.

As shown before *Puml* is localized on lipid droplets and *Puml::mCherry* can be found on peroxisomes as well. Also, a portion of neutral lipids remains immobilized during starvation to death in *puml¹*. Therefore, I hypothesized a comparable phenotype of changed TAG composition. In order to identify changes, the lipidome was analysed using mass-spectrometry. Malpighian tubules were explanted from adult *puml¹* and control flies on standard diet (density controlled). Lipid extraction and mass spectrometry were performed by Vinzenz Hofferek (pilot experiment; 5 independent extractions from each 10 MT pairs; MPIMP-golm; average standard deviation of Mol % TAG species=0,15% for both genotypes) and independently by Dr. Thomas Eichmann (University of Graz; 3 independent extractions from each 100 MT pairs; average standard deviation of Mol % TAG species=0,50%).

The main TAG species in control flies are: 46:1, 48:0, 48:1, 50:1, 52:0 and 52:1. In *puml¹* flies: 48:2, 50:1, 50:2, 52:2, 52:3 (**Figure 33, Figure 34**). As no total hydrolysis was performed, ratios for the single free fatty acids were not acquired and the individual composition of each TAG species can only be predicted with an amount of uncertainty. Based on the desaturation grade found in the most common lipids and their size (first number represents total number of carbon atoms found in the sidechains of the glycerolipids; second number indicated the number of C=C-bonds [desaturation grade]) it is very likely that oleic acid (C18:1) and linoleic acid (C18:2) represent the major fatty acids contributing to these TAG species.

Compared to *puml¹* the most abundant TAG species had a shorter length in control flies (**Figure 33, Figure 34**). In correlation with a higher relative abundance of long

chain fatty acids (LCFA) also the relative abundance of TAGs with a higher desaturation grade was increased in *puml*¹. Both experimental approaches confirmed a higher abundance of TAGs (in absolute amounts) in Malpighian tubules of *puml*¹ and complement the data from microscopic analyses and TLC results of lipid extracts deriving from total flies.

The current lipidomics data also strengthens the idea of Puml being involved in the peroxisomal directed β -oxidation of long chain fatty acids (LCFAs: C13 - C21). Comparable to *AtABHD4/5* mutants we have increased abundance of PUFAs and LCFAs in *puml*¹. A similar phenotype can also be observed in human patients of the Zellweger syndrome (Suzuki *et al.*, 1996).

Figure 33 LCFA-TAGs and abundance of PUFAs are elevated in Malpighian tubules of *pum1^Δ* flies. Plotted are the means of Mol % \pm SEM (n=4 independent extractions) per molecular TAG species (upper numbers represent number of C=C bonds in the fatty acid side chain; lower number the total number of carbon atoms from the esterified FAs; data from control flies are shown in blue; *pum1^Δ* data depicted in red). (A, B) Lipid extraction, mass spectrometry and lipid annotation performed by Vinzenz Hofferek (MPIMP-golm). (C, D) Lipid extraction, mass spectrometry and lipid annotation performed by Dr. Thomas Eichmann (University Graz). Long chain fatty acids (LCFAs) [50, 52] were elevated in *pum1^Δ* compared to control flies in both experiments. Additionally, more poly-unsaturated fatty acids (PUFAs) could be detected in *pum1^Δ* [48:2, 48:3, 50:3, 50:4, 50:5, 50:2, 50:3, 50:4, 50:5, 52:2, 52:3, 52:4, 52:5].

The Zellweger syndrome is characterized by a general loss of peroxisomal functions (Jones *et al.*, 1992). This includes the impaired degradation of mono- and poly-unsaturated fatty acids (Christensen *et al.*, 1986, Wanders *et al.*, 1987).

Taken together, *in vitro* assays revealed no esterase activity for Pum1 on neutral lipids. In *pum1^Δ* flies body fat is increased and TAGs mostly contribute to this phenotype (Figure 14). Multiple lipidomics analyses confirmed increased TAG storage and revealed PUFAs and LCFAs being more abundant in *pum1^Δ*. This is very like caused by an involvement of Pum1 in the peroxisome targeted lipid degradation that at least seems to be decreased in *pum1^Δ* and would explain the dual localization on LDs and peroxisomes.

Additionally, Pum1 is a potent phospholipase and shows some affinity for PA, PG or BMP(R,R) suggesting a modulating role on the phospholipid monolayer of lipid droplets. This may also provide some explanation why the lipid droplet size distribution is changed in *pum1^Δ* as well.

Figure 34 Heat map of TAG species distribution shows increased abundance of PUFAs and shift towards longer fatty acid sidechains in Malpighian tubules from *pum1¹* flies. Lipid extraction, mass spectrometry and Lipid annotation done by Vinzenz Hofferek (MPIMP-golm; Pilot experiment; represented are data from 5 discrete extractions from 10 Malpighian tubules [MTs] pairs) and Dr. Thomas Eichmann (University Graz; represented are data from 3 independent extractions from each 100 MT pairs; data with n.a-coloring were not annotated).

Looking at the organismal level absence of *pum1¹* is not crucial as homozygous *null mutants* are viable. On the other hand, carbohydrate stores (glycogen) and lipid stores are modulated differently in *pum1¹*. Whereas food intake is not impaired in

puml¹, ingested food is preferentially stored in form of TAGs to the account of carbohydrates. This may contribute to the findings that *puml¹* have a higher starvation resistance but are more susceptible to desiccation.

Lipid mobilization in general is not impaired in *puml¹* and a direct enzymatic activity on neutral lipids could not be detected. Therefore, the biological role of *puml* seems to be more indirect in assisting lipolysis, directing fatty acids and acting more like a metabolic switch at the junction between carbohydrate and lipid metabolism in *Drosophila melanogaster*. This would also characterize the core lipid mobilization module of ABHD5-ATGL more as a specialization during evolution providing an additional level of control and enhanced efficiency of lipid mobilization in higher organisms rather than an evolutionary conserved theme.

4 Discussion

4.1 Localization, interactions and structure of Pummelig

High throughput expression pattern data for *puml* shows that different isoforms are expressed throughout all developmental stages (Gelbart and Emmert, 2013). Whereas they differ in total length, they can be separated into two groups that share the core α/β -hydrolase domain. The main difference is variable length of their N-termini. Experiments from Anna Takacs (Takacs, 2007) indicated differences in the localization of mCherry-tagged overexpression of the long (Puml-PA) and the shorter (Puml-PB) protein. Both tagged proteins exhibited a dot-like pattern in the cytoplasm. Whereas Puml-PA::mCherry additionally localized on lipid droplets the shorter version (Puml-PB::mCherry) did not. This might indicate that the longer N-terminus is needed for the LD association. Indeed, recent findings for ABHD5 showed that the N-terminal region is crucial for LD binding (Gruber *et al.*, 2010). Another study revealed that a small Tryptophan-rich arm mediates the interaction with the phospholipid monolayer (Boeszoermyeni *et al.*, 2015). Interestingly, a more detailed analysis of the Puml isoforms (Figure 11) showed, that the longer N-terminus contained multiple phenylalanine (F^{52,53}) and tryptophan (W^{55,57,61}) residues implying a comparable lipid-anchor motif in Puml. This might explain the different localization pattern of the Puml::mCherry isoforms as only Puml-PA::mCherry with the long N-terminus can be found on lipid droplets.

Puml shares the α/β -hydrolase domain with ABHD4 and 5, but in contrast to ABHD5 the catalytic center (GxSxG motif) is active in Puml. Additionally, enzymatic experiments revealed that Puml does not stimulate the lipase activity of Brummer on triglycerides indicating that the lipid mobilization core module ABHD5-ATGL is not evolutionary conserved. As the α/β -hydrolase domain contains two active catalytic sites (GxSxG and HxxxD) Puml may modulate lipid metabolism in a different way. Perhaps, part of the function of puml depends on its localization as the different isoforms (tagged mCherry constructs) appear to have different localization patterns. By this Puml may have a different function on lipid droplets than on peroxisomes.

As ABHD5 orthologues in *Arabidopsis thaliana* (James *et al.*, 2010), *Saccharomyces cerevisiae* (Ghosh *et al.*, 2008a) and *C. elegans* (Xie and Roy, 2015) are also known to modulate lipid metabolism and have active catalytic sites its absence in ABHD5 might be a relatively new evolutionary adaption. Also, a forward-mutation (A155S) to reconstitute the active GxSxG-motif in ABHD5 does not resemble the lipolytic activity (Wang *et al.*, 2011). This indicates that perhaps additional structural changes may occurred in ABHD5 leading to a diversion from the ancestral mechanism through which ABHD5 regulates lipid metabolism. On the other hand, the biological function of ABHD5 does not rely exclusively on the interaction with ATGL as ATGL knock out mice do not exhibit lipid accumulations in the skin [ichthyosis] (Lefevre *et al.*, 2001). Additionally, ABHD5 knock out mice exhibit severe defects in skin permeability, ectopic lipid storage, hepatic steatosis and decreased acyl-ceramide production leading to early death after birth (Radner *et al.*, 2010). This indicates that ABHD5 has an ATGL independent function with an up to now unknown mechanism.

It is known, that ABHD5 interacts with PLIN1, PLIN2, PLIN5, ATGL and FABP (Yamaguchi *et al.*, 2004, Lass *et al.*, 2006, Granneman *et al.*, 2009, Hofer *et al.*, 2015). For this interaction the C-terminus was identified to mediate this protein-protein interactions (PPI). A single point mutation (E262K) eliminates the interaction with PLIN1 and PLIN2 (Yamaguchi *et al.*, 2004, Yamaguchi *et al.*, 2007). The region of the first and second α -helix loop is important for the binding do FABP (Hofer *et al.*, 2015).

The overexpression of Pum1-PA::mCherry in *Drosophila* free floating adipocytes from freshly hatched *plin1¹* flies leads to reversion of the giant lipid droplet phenotype of *plin1¹* (Takacs, 2007) indicating that Plin1 is not crucial for LD binding of Pum1 but does not exclude a possible interaction. However, the reduced lipid storage in six-day old flies expressing Pum1::mCherry in the fat body of *plin1¹* flies (Takacs, 2007) suggests at least a possible negative effect on a lipolytic function of Pum1 that may rely on the interaction of Plin1 and Pum1.

On the other hand, Pum1 was found on embryonic lipid droplets (Cermelli *et al.*, 2006) a developmental stage where Plin2 is predominantly expressed compared to Plin1 (Gelbart and Emmert, 2013). As Plin2 is more abundant on LDs in *plin1¹* larvae (Sahu-

Osen, 2015), implying a redundant role of Plin2 to Plin1, Puml may interact with this member of the perilipin family. However, *plin1¹ plin2¹* double knockout flies exhibit very low body fat storage after hatching that partially recovers to the levels of *plin2¹* flies, which still have a ~40% reduced body fat storage than control flies, indicating that these flies might be lipolytically more active like *bmm-gof* flies that are also store less body fat (**Figure 13**).

puml-gof flies showed no decrease in body fat storage, which is congruent with data from mice overexpressing ABHD5 (Caviglia *et al.*, 2011), also (**Figure 13**). On the other hand, upon *puml-gof* in *puml¹* flies the over-storage phenotype could be reverted to normal levels. This argues rather in favour of *puml* modulating lipid storage indirectly and not by actively participating in neutral lipid breakdown.

Interestingly, whereas the expression of *puml* in *puml¹* flies reverted the body fat over-storage this could not be achieved by the expression of Puml-PA::mCherry. Although Puml-PA::mCherry localizes on lipid droplets and peroxisomes, preliminary data shows that body fat storage and ectopic lipid storage in Malpighian tubules remained unchanged [**Figure 35**].

Figure 35 A genomic rescue of *puml* with *Puml::mCherry* does not reduce the amount of body fat to control flies and does not improve ectopic lipid storage. Lipids (stained by Bodipy493/503) can be still found in malpighian tubules (A, E [magnified box from A]) with expressed *Puml::mCherry* (B, F [magnified box from B]). DAPI was used to stain nuclei (C) and the merged channels (D) show a localization of *Puml::mCherry* on lipid droplets. A magnified picture shows the ring-like pattern (F) of *Puml::mCherry* that match with stained lipid droplets (E). Body fat storage (G) was still increased in the genomic rescue flies (average fold change in $\mu\text{g TAG equivalent/mg protein} \pm \text{SEM}$; Mann-Whitney test, $***=P<0.001$).

As the C-terminal localization signal for peroxisomes (SKL-motif) is absent in Pum1, this supports the theory of a needed interaction partner for the localization to peroxisomes, which remains to be identified but this possible interaction is not prohibited by the C-terminal mCherry-tag. However, the modulation of lipid storage seems to be impaired in the fusion protein. This might be due to structural inaccessibility caused by the mCherry-tag shielding a binding site for other proteins or possible phosphorylation sites. An *in silico* analysis predicted 27 potential phosphorylation sites that were enriched at the C-terminal end of Pum1 (**Figure 11**). As phosphorylation partially modulates the function of ABHD5, that is a phosphorylation target of PKA (Ser239) (Sahu-Osen *et al.*, 2015), this post-translational protein modification might be impaired in Pum1-PA::mCherry limiting its full biological function. However, the PKA consensus-sequence: RKYS²³⁹S²⁴⁰ is only partial conserved in Pum1 (RKFQS) this activation behaviour might be not evolutionary conserved. On the other hand, this phosphorylation site is also not conserved in ABHD4 (**Figure 10**) supporting a different mechanism by which *pum1* is modulating lipid storage.

Thus the identification of possible binding partners is of high importance to elucidate the biological function of *pum1* in lipid metabolism. For this, it might be crucial to obtain a functional antibody to detect endogenous Pum1 as N-terminal tags might interfere with the lipid droplet localization and C-terminal tags may prohibit, needed post-translational modifications or impair protein-protein interactions with Pum1 directly. Also, an antibody could be used to verify the localization of Pum1::mCherry. An approach (in this work) that covered the generation of several monoclonal antibodies against different peptides from Pum1 did not produce a useable antibody to detect endogenous Pum1 (data not shown).

4.2 Enzymatic activity of Pum1

Based on the similarity to ABHD5 it was assumed that Pum1 may activates Bmm lipase. However, *in vitro* assays provided no evidence for Pum1 stimulating the TAG hydrolysis activity of Bmm. On the contrary, comparable to the mammalian ABHD4 or orthologues in plants (James *et al.*, 2010), yeast (Ghosh *et al.*, 2008b) or nematodes

(Ashrafi *et al.*, 2003) also Pum1 modulates lipid storage and has an active catalytic center (GxSxG-motif) (**Figure 10**). Therefore, a substrate screen was performed to find potential targets for Pum1. The Substrate screen identified Pum1 as an active phospholipase (PA, PG, BMP[R,R], NAPE) with a very weak affinity for MAG, that works preferentially in physiological to basic pH. This hydrolase activity measured by the quantification of the released non-esterified fatty acids (NEFAs) was determined by the activity of both catalytic sites as preliminary data for each single knock out showed a total loss of activity (**Figure 36**).

Figure 36 Preliminary data shows that a point mutations in each single catalytic site of Pum1 results in a total loss of enzymatic activity for the tested substrates of the screen. Pum1 wildtype and point-mutants were expressed in insect cells for this screening. Shown are the fold changes in FA release normalized to the β -Galactosidase (negative control). A fold change of 2 was used as a lower threshold. The qualitative measurement reveals that the point mutations Pum1-PA:S190N and Pum1-PA:D371A both abolish the enzymatic activity of wildtype Pum1-PA.

Knowing possible targets for Pum1 raised the question what biological relevance these potential activities might have. A possible explanation for the increased body fat storage of *pum1¹* flies was a possible impairment of the lipolytic capability but the time course experiment revealed that the neutral lipid mobilization actually occurred faster in *pum1¹* flies.

Endocannabinoid signaling is known to influence energy metabolism (Panakova *et al.*, 2005) and exists in *Drosophila* (Tortoriello *et al.*, 2013, Khaliullina *et al.*, 2015). As it is known that ABHD4 is involved in the generation of N-acylethanolamines (NAEs) from N-acylphosphatidylethanolamines (NAPEs) it might be possible that Pum1 serves a similar function in the fly hydrolysing NAE precursors. However, data in *pum1¹* larvae exhibited no drastic changes in NAE levels. Besides a small significant reduction in

NAE C18:2 by ~40% ($P < 0.05$) no changes could be seen for NAE C16:0, C18:0 and C18:1 (data from a pilot experiment, personal communication from Tomasz Buhl; Eaton lab; MPI-CBG: Dresden). However, these experiments were performed in *puml*¹ larvae and only for the four most abundant NAEs were analysed. Therefore, it might be possible that *Puml* has a specificity for other NAEs.

Taken together, *Puml* is not necessary for the generation of the most abundant NAEs in larvae; however, NAE levels were not analysed in adults. Thus, it cannot be excluded that *Puml* may be involved in NAE synthesis in adult flies. Nevertheless, this should be investigated further as NAEs are involved in various biological processes in mammals like food intake, immune- and inflammatory response as well as energy metabolism (Heier *et al.*, 2016).

Bis(monoglycero)phosphate (BMP[R,R], sn-(3-oleoyl-2-hydroxy)-glycerol-1-phospho-sn-1'-(3'-oleoyl-2'-hydroxy)-glycerol (ammonium salt) is a known substrate of mammalian ABHD6 (Pribasnig *et al.*, 2015) an enzyme that can act as a MAG lipase and is affiliated with endocannabinoid signalling. More specifically BMP is enriched in late endosomes/ lysosomes where it is crucial for lipid sorting and the formation of intraluminal vesicles (Pribasnig *et al.*, 2015). With an overlap in the substrate specificity (MAG, BMP(R,R)) *Puml* may serve a similar role in *Drosophila* in directing lipid catabolism. To show a possible association lysosomes/endosomes additional localization studies with *Puml* are needed. Since *Puml* localizes partially to peroxisomes and majorly to LDs these organelles might represent an additional resting site.

Interestingly, the affinity for BMP(S,s) was very low, indicating a strong steric preference for its stereoisomer. Besides this *Puml* also exhibits hydrolase activity for the structural isomer of BMP: Phosphatidylglycerol (PG) with long (C18) and medium (C12) fatty acid sidechains (**Figure 20**). Also *Puml* can hydrolase Phosphatidic acid (PA). However, PA and PG do not represent the most abundant phospholipid species in *Drosophila*. The most abundant phospholipids in yeast and mammals are Phosphatidylcholine (PC) with 50-60% followed by Phosphatidylethanolamine (PE) (20-30%) whereas in fruit flies it is switched (PE 50-60% followed by PC 20-25%)

(Tauchi-Sato *et al.*, 2002, Bartz *et al.*, 2007, Carvalho *et al.*, 2012, Guan *et al.*, 2013). This is of interest as Puml is localized on LDs and *puml¹* flies have decreased LD size in malpighian tubules. Therefore, Puml might be involved in the regulation of the phospholipid monolayer finally defining the physiochemical parameters of LDs and by this defining its size and maybe accessibility by proteins. However, modulation of PC but not PE is highly critical for LD size (Krahmer *et al.*, 2011). This might be supported by the fact that RNAi mediated knockdown of CG1882 in S2-cells revealed no lipid droplet phenotype (Guo *et al.*, 2008) but it could be possible that this LD size phenotype is restricted to the adult stage. Of course, in order to show a changed phospholipid composition on LDs a lipidomics analysis should be performed on purified LDs from adult *puml¹* flies.

Taken together, Puml exhibits phospholipase activity and several potential targets could be identified in a substrate screen. However, it is not clear if Puml actually hydrolyses these substrates *in vivo* and how this missing activity contributes finally to increased storage of TAGs.

4.3 Lipogenesis in *pummelig* mutants

As shown in this work *puml¹* adult flies have increased body fat storage and exhibit ectopic lipid storage as well. One possible explanation was that this was caused by an impaired capability to mobilize storage lipids like in *bmm¹*. However, this is very unlikely as *puml¹* flies could mobilize their storage lipids.

Another theory was that the increased TAG storage might be caused by increased lipogenesis in *puml¹* flies. Indeed, lipogenesis was increased in *puml¹* flies (**Figure 21**). More interestingly, this was not due to an increased food intake but more likely a redirection from ingested glucose into storage lipids as glycogen stores were decreased in *puml¹* (**Figure 23**).

Especially the significant differences in phospholipids after the chase periods might be interesting as they may indicate an imbalance in the phospholipid metabolism of *puml¹* as well.

However, the experiments performed on lipogenesis do not allow to draw conclusions about the turnover of lipids. Probably, this should be addressed in the future as neutral lipid storage disease (NLS) in mammals is characterized by an abnormal glycerolipid metabolism (Igal and Coleman, 1996) and a higher synthesis and turnover of phospholipids. Though, *puml¹* flies may serve as an animal model system for NLS to find therapeutics to treat this disease.

Additional experiments should also focus on the actual nutrient resorption from the food using labelled substrates as *puml¹* flies may consume comparable amounts of food but utilize them more efficiently than control flies and therefore have a higher caloric loading from the food. As endocannabinoids are known to interfere with the microbiome in the gut of mice (Muccioli *et al.*, 2010) maybe a possible impairment in this signaling in *puml¹* shapes it towards a direction that allows a more efficient nutrient resorption also in flies.

A possible involvement of *puml* for lipogenesis on the other side so far remains puzzling. A possible reason for the increased generation of TAGs may can be explained with the PA hydrolase activity of Puml as PA is a precursor for various phospholipids and DAG (Igal and Coleman, 1996) that is needed for the generation of TAGs. As it is known in other organisms that high levels of PA (Toschi *et al.*, 2009, Brown *et al.*, 2010) promote the generation of TAGs, may locally increased amounts of PA in *puml¹* might be directed into TAGs as well. Whether PA levels are elevated in *puml¹* is not known and should be addressed in the future. Interestingly, it has been shown that specific PA species (C18:0 and C18:1) and PGs are elevated in ABHD5 knock down mice (Brown *et al.*, 2010). However, the mechanism of PA generation in mice based on the Lyso-phosphatidic acid acyl-transferase (LPAAT) activity of ABHD5 (2012a). LPAAT activity was first described in 2010 (Montero-Moran *et al.*, 2010) but rejected in 2014 (McMahon *et al.*, 2014a). Therefore, it remains open how PA levels in ABHD knock down mice were changed.

As PA stabilizes dTOR (Foster and Toschi, 2009, Toschi *et al.*, 2009) which is known to regulate energy homeostasis by negatively modulating the expression of *bmm* and *dilp2* and *dilp5* lower basal lipolytic activity may contributes to the increased amount

of storage lipids found in *puml*¹. It is also known for PA to negatively regulate AMPK a critical cellular energy sensor (Hardie, 2011, Mukhopadhyay *et al.*, 2015) that modulates also autophagy, mitochondrial biosynthesis and β -oxidation. Therefore, increased amounts of PA in *puml*¹ flies could lead to a lower activity of AMPK. Subsequently, the negative regulation of Acetyl-CoA-carboxylase (ACC) by AMPK would be absent that would finally enhance the generation of Malonyl-CoA from Acetyl-CoA in the cells. As high amounts Malonyl-CoA is an intermediate substrate for lipid synthesis and inhibits CPT1, the rate limiting enzyme for the transport of long chain fatty acids (LCFAs) into mitochondria, beta-oxidation would be negatively regulated also on another level. This would also provide an explanation for the increased amounts of LCFAs and very long chain fatty acids (VLCFAs) found in *puml*¹ flies.

Taken together the PA hydrolase activity of Puml might be important for the regulation lipogenesis by lowering the concentration of this intermediate substrate that is used for the synthesis of TAGs and by this avoiding high amounts of PA that could lead to an increased TOR signaling and lower AMPK signaling in *puml*¹. By this, *puml* would provide an additional mechanism antagonistic to insulin signaling establishing a negative feedback loop to balance lipogenesis and lipolysis in the cells.

Interestingly, many tumours exhibit suppressed AMPK- and increased TOR signalling, which enables cancer cells to avoid mitochondrial ATP generation and shift the metabolism towards cytosolic glycolysis (Warburg effect) (Jones *et al.*, 2005, Faubert *et al.*, 2013). As ABHD5 has been described as an anti-cancer gene (Ou *et al.*, 2014) maybe this principle mechanism is evolutionary conserved. A knockdown of ABHD5 but not ATGL lead to decreased phosphorylated AMPK levels, increased amounts of pAKT and lower amounts of p53 in mammalian cells (SW620 and HCT116 cells) (Ou *et al.*, 2014). This lead in ABHD5 knock down cells to a higher glucose disposal (Brown *et al.*, 2007) and lower fat utilization that was accompanied by a higher fat storage in these cells as well. However, Ou *et al.* (Ou *et al.*, 2014) could not provide a direct mechanism by which ABHD5 absence was contributing to the cellular alterations but postulated an ATGL independent function of ABHD5. In agreement with the finding that p53 was involved in mediating the metabolic shift in mammalian cells towards

glycolysis a conserved mechanism could be identified in flies (Barrio *et al.*, 2014). Dp53 is regulated by dTOR via miR-305 and insulin signaling. Under feeding conditions high nutrient availability leads to the upregulation of miR-305 and increased insulin signaling that inhibits generation of p53 and fosters p53 degradation. Through this pathway, dTOR activity is enhanced by a positive feedback loop. As high dTOR signaling leads to decreased cAMP generation PKA stimulated lipolysis is decreased. Additionally, high levels of activated PKB/Akt lead to a greater inhibition of Glycogensynthase by phosphorylation through GSK3 α and thereby decreased glycogen storage in mammals. This mechanism is conserved in flies where GSK-3 (shaggy) is negatively regulated during insulin-like signaling and limits glycogen synthesis (Papadopoulou *et al.*, 2004). As *puml*¹ flies have decreased glycogen storage maybe cells experience a state of hyper-activated insulin-like signaling that leads to inhibition of glycogen synthesis and simultaneously to increased TOR signaling resulting in decreased lipolysis under basal conditions and enhanced lipogenesis (Figure 37).

In order to be able to adapt to constantly changing environmental conditions also the energy storage and mobilization needs to be regulated very precisely. The underlying mechanisms are highly complex and involve several extracellular to and intracellular signals in the fat body. Therefore, the proposed indirect mechanism by which *puml* could modulate lipid metabolism might work on regulatory level at the cellular level rather than actively participate in the hydrolysis of storage lipids. The current model can explain the decreased glycogen levels and increased TAG storage observed in *puml*¹ flies.

Figure 37 Current model of *puml* regulating lipid storage in flies. Signalling pathways and their connection were depicted based on literature data (black). Regulation during energy expenditure/starvation are shown in black. Red labelling indicates possible effects of *puml* deficiency in adult flies under fed conditions.

The protective role of obesity against the harmful effects of a high sugar diet has been addressed recently (Musselman *et al.*, 2011). The study showed that the metabolic fate of glucose was reprogrammed in flies under a high sugar diet (HSD) regime and in lean flies. Based on the finding that a high sugar diet leads to increased blood sugar and systemic insulin resistance in developing larvae and adult flies (Musselman *et al.*, 2011) they followed the carbon flux using a stable isotope tracer (^{13}C -glucose). Indeed, storage fat synthesis from dietary glucose was lower in larvae raised on HSD and TAG species shifted towards shorter esterified fatty acids and contained more unsaturated fatty acids (Musselman *et al.*, 2013). Conversely, larvae on HSD exhibited increased amounts of NEFAs. Consistent with this finding lipogenic genes like *Mio* (CG18362) and *desat1* (CG5887) and β -oxidation genes (*e.g.* *DmCPT1* or *ACS*) were upregulated under HSD. In order to generate lean fat body tissue they performed a knockdown of *mio* which encodes a protein homologues to carbohydrate-responsive transcription factor (ChREBP) in mammals (Postic *et al.*, 2007). Consistently, a knock

down of *Mio* (*cg-GAL4*) caused a decreased expression of fatty acid synthase (FAS), lipid storage modulators like *bmm*, *plin1* or *plin2* and genes involved in insulin signaling (*chico*, *Tor*, *Akt*, *S6K*, *PDK*, *PI3K*). This led to decreased storage lipid mobilization and insulin resistance in *cg-Gal4>mio-RNAi* wandering larvae on a HSD. Interestingly, expression of several lipases but not *bmm* were upregulated, as well as *whd* (*DmCPT1*) and genes involved in Ketone metabolism. As a result, carbon flux was channelled towards generation of NEFAs through ketones and improved β -oxidation in *mio* knock down larvae on a HSD.

Surprisingly, *puml* was upregulated in *cg-Gal4>Mio-RNAi* wandering larvae on HSD (Musselman *et al.*, 2013) indicating a different function for this protein in modulating lipid metabolism. Consistent with the current working model (**Figure 37**) *puml* might be repressed by *mio*. This regulation would lead to a decreased expression of *puml* during increased carbohydrate load of fat body cells mimicking the effects of *puml*¹ flies leading to increased generation of storage lipids and increasing insulin sensitivity of the fat body. On the other hand, the upregulation of *puml* in *mio* knock down larvae challenged by a caloric overload of sugar (HSD) would improve AMPK signaling leading to increased mitochondrial biosynthesis and decreased inhibition of *DmCPT1* by Malonyl-CoA (AMPK inhibits ACC) but would not improve the insulin insensitivity observed in larvae with a *mio* knock down in the fat body on a HSD.

4.4 Lipolysis

NLSD is characterized by the imbalanced phospholipid metabolism, increased TAG storage but normal lipolysis rate (Igal and Coleman, 1996). Igal and colleagues favoured a mechanism by which generated DAG during lipolysis was majorly utilized for re-synthesis of TAGs. As shown before *puml*¹ share some characteristics with NLSD patients like increased storage of TAGs, also ectopically and lower glycogen storage. Therefore, one theory of the increased body fat storage was based on the increased lipogenesis in *puml*¹ flies that could be shown in this work. However, the second possibility was an impairment in the storage lipid mobilization in *puml*¹ flies.

Apparently, lipid mobilization in *pum1¹* flies was not lower but actually higher during nutrient deprivation. Metabolic rate measurements revealed no differences between *pum1¹* and control flies (**Figure 22**) but as oxygen consumption was quantified and not exhaled carbon dioxide no assumptions for the major catabolic substrate can be made from the respiratory quotient. Though, Glycogen and lipids are mobilized simultaneously in the flies until glycogen stores were completely depleted (**Figure 23**). Probably additional respirometric measurements should be performed on *pum1¹* flies to identify the main carbon source for energy synthesis under fed conditions and during starvation. Though, increased TAG storage in *pum1¹* seems to be the main cause for the increased starvation resistance compared to control flies.

One possible reason of the increased lipolysis during starvation might be reduced Glycogen storage in *pum1¹* flies. It had also been described that high amounts of non-esterified fatty acids (NEFAs) can impair glucose utilization leading to the so called Randle effect (Randle *et al.*, 1963, Ussher and Lopaschuk, 2009). So far it has not been shown whether basal lipolytic activity in *pum1¹* is changed as well as it would provide an additional explanation why glucose metabolism is changed in *pum1¹* flies. So far, TLC data (**Figure 14**) provided no evidence for increased amounts of FAs in *pum1¹* flies.

NEFAs are detected by HNF4 (*Drosophila* ortholog to mammalian PPAR α) that leads to increased expression of peroxisomal and mitochondrial genes and therefore allowing a higher fatty acid oxidation (Palanker *et al.*, 2009). Therefore, also basal lipolysis might be increased in *pum1¹* flies leading to higher availability of NEFAs that could be sensed by HNF4.

This could lead to an increased capability of lipid catabolism that might be not used due to an increased re-synthesis of TAGs in *pum1¹* and missing activation of hydrolysed fatty acids by *pudgy* (*Drosophila* Acetyl-CoA synthetase [ACS]). As *pudgy¹* flies have increased fat storage, decreased Glycogen stores, exhibit lower *dilp* (*dilp2* and 5) expression and are hyperglycemic this might be an explanation for the higher lipolysis during starvation (Xu *et al.*, 2012). As *pudgy* is a transcription target from dFoxo and therefore underlying gene suppression by insulin-like signalling may provide an additional argument for the elevated TAG storage in *pum1¹* flies.

Also *pudgy*¹ flies exhibited an increase of many but not all TAG species with a preference for longer acyl-chains and higher unsaturation grade a phenotype that has some similarity with *puml*¹ flies were LDs in Malpighian tubules accumulated TAGs with longer side-chains and had a higher abundance of PUFAs.

However, besides increased lipid mobilization in *puml*¹ a significant amount remained un-mobilized in *puml*¹. Whether these lipids are mobilization resistant or remained due to the general higher abundance storage lipids in *puml*¹ flies and the possibility that lipids alone are not the only limiting factor during starvation remains to be answered. A starvation experiment with the corresponding analysis of lipid content in early dying animals and the best 5-10% of survivors of starvation might provide a better insight if some lipids cannot be utilized in *puml*¹. With the localization of Puml on peroxisomes it is very likely that these “mobilization resistant” lipids then would have LCFAs or VLCFAs esterified to the glycerol and might have a higher unsaturation grade due to the delimited metabolism through peroxisomes.

4.5 Global fat storage role of *puml*

In summary, *puml*¹ flies have increased body fat storage in the form of TAGs and lower Glycogen stores. This is rather caused by increased lipogenesis than inhibited storage lipid mobilization. As *pudgy*¹ flies exhibit a similar phenotype this protein might be potential binding partner for Puml [*pudgy* is localized on mitochondria (Xu *et al.*, 2012)]. However, hyperthrealemia observable in *pudgy*¹ should be also addressed in *puml*¹. On the other hand, conversely to *puml*¹ flies, *pudgy*¹ flies are long lived and have a slightly reduced body size a phenotype associated with decreased insulin signaling (Xu *et al.*, 2012). However, the tight transcriptional regulation of *Pudgy* might explain the effect that a *puml-gof* does not lead to decreased body fat storage.

In general, the lipid routing might be impaired in *puml*¹ flies. Lipidomics analysis from malpighian tubules revealed an enrichment in PUFAs and LCFAs and VLCFAs. As these enriched lipids are degraded via the peroxisomes this pathway is at least mitigated in *puml*¹ flies. It remains to be shown if there actually are TAG species in *puml*¹ that are mobilization resistant. Aside with the observation that Puml::mCherry is also

associated with peroxisomes at least supports the model of *puml* in aiding in the channelling/sorting of lipids. Interestingly, a ABHD5 knock down in hepatocytes exhibits a similar phenotype with hepatic steatosis (lipid accumulation in the liver) accompanied with an accumulation of PUFAs and VLCFAs. At the same time the ABHD5 knock down prevented high fat diet induced obesity in these mice and improved the global glucose tolerance and increased insulin sensitivity (Lord *et al.*, 2012). However, the cellular mechanism by how these changes derive might be different between vertebrates and flies. Interestingly, at the same time ABHD5 knock out adipose tissue had decreased lipogenesis and lysates exhibited lower *in vitro* Triglyceride hydrolase activity. This very likely is caused by the absence of ABHD5 stimulating function of ATGL in this tissue. Furthermore, ABHD5 knock down data from mice show clear tissue specific difference by how ABHD5 acts as liver and fat storage tissue. Therefore, the different physiology in insects is accompanied by a different molecular mechanism that finally results in similar cellular changes in the absence of *puml*¹.

In this context the importance of a proper peroxisomal lipid metabolism should be emphasized. Peroxisome biogenesis disorders (PBDs) are highly complex multi-organ dysfunction orders that exhibit a wide range of defects. The *Zellweger syndrome* is one of four groups of PBDs that is caused by mutations in the two peroxin (*pex*) genes *PEX3* and *PEX16*. A *Drosophila* model for *Zellweger* disease was generated by the disruption of *pex3* and *pex16* gene (Nakayama *et al.*, 2011). Various phenotypes could be observed in *pex3* mutants such as larval lethality, shortened longevity, locomotion defects and abnormal lipid metabolism (Nakayama *et al.*, 2011, Faust *et al.*, 2014). Additionally, homozygous *pex16* mutant male flies were sterile (Nakayama *et al.*, 2011).

Whereas fecundity of male flies was not impaired (Rosenberg, 2012), *puml*¹ flies shared other characteristics of *Zellwegers* disease. Longevity of *puml*¹ flies was significantly decreased (**Figure 16**) and lipid metabolism was altered. Mutually, *puml*¹ as well as *pex16*¹ and *pex10*¹ flies (Faust *et al.*, 2014) accumulate VLCFAs.

PBDs patients feature various neurological defects among them motor dysfunctions (Steinberg *et al.*, 2006). Along with this *pex16¹* flies showed locomotion deficits in climbing (Nakayama *et al.*, 2011). Similarly, preliminary data indicate lower startle induced climbing activity in *puml¹* as well (**Figure 38**). A possible reason for neurological defects may be an impaired sphingolipid-production. Sphingolipids are crucial for a proper neuronal signal transmission and peroxisomes are the nascent site for this lipid. Thus, sphingolipid generation should be addressed in *puml¹* flies in the future as it might be impaired in *puml¹* flies. Complementary to this *puml¹* flies should be screened for other neurological disorders. By this *puml¹* would provide an additional suitable invertebrate system to study neurological defects associated with a disturbed lipid metabolism.

Figure 38 Preliminary results indicate that startle induced climbing activity is decreased in *puml¹* flies and a knock down of predicted peroxisomal β -oxidation genes can lead to increased body fat storage. A climbing index was calculated for *puml¹* and control flies. Startle induced climbing activity was significantly decreased in *puml¹* flies (A). A fat body specific (FB-SNS>GAL4) knock down of different candidates for peroxisome located β -oxidation and peroxisome biogenesis (*Pex16*) was performed. *Pex16*-RNAi as well as *CG17597*-RNAi (coding for protein with predicted β -ketothiolase activity) caused a significant increase in body fat storage of adult flies (B). The climbing index (A) is shown as a Box plot from individual climbing indices from eight different fly cohorts (20 flies per cohort). Center lines show the median, box limits indicate 25th and 75th percentiles as determined by OriginPro software; whiskers extend 1.5 times the interquartile range from the 25th and 75th percentiles; $n \geq 136$ for each genotype (A). Averages of protein normalized TAG amounts \pm SEM are shown for the body fat measurements (Mann-Whitney test, ***= $P < 0.001$; **= $P < 0.01$).

As shown in this work *Puml* resides on lipid droplets and peroxisomes (**Figure 30**) mutants that induce PBDs support the involvement of *Puml* in channelling lipids towards the peroxisomal pathway in a supportive manner. Indeed, preliminary data from RNAi mediated knock downs of selected genes predicted to be involved in peroxisomal β -oxidation (Faust *et al.*, 2012) provided some evidence, that an

impairment of this metabolic pathway can be already sufficient to increase body fat storage (**Figure 38**). So far only one candidate could be confirmed to actually change body fat storage, but candidates predicted by Faust and colleagues (Faust *et al.*, 2012) were assigned based on similarity to known vertebrate genes. Therefore, redundancies are possible as well as different functions of the annotated candidate genes that are largely uncharacterized so far. However, the actual localization of these genes remain to be addressed as well in order to assign the effects of a knock down exclusively to peroxisomes.

Interestingly, peroxisome proliferator-activated receptor alpha (PPAR- α) target gene expression was decreased in ATGL knock out mice (Haemmerle *et al.*, 2011). PPAR- α requires its coactivator PGC-1 α or PGC-1 β , the heterodimerization with retinoic X receptors and cognate lipid ligands for its function as a transcriptional activator. Transcription targets genes are important for fatty acid transport, oxidative phosphorylation, ketogenesis and gluconeogenesis (Lefevre *et al.*, 2001, Sharma and Staels, 2007). Besides augmented adipose tissue mass ATGL deficient mice exhibit decreased expression of genes responsible for oxidative phosphorylation, ectopic lipid storage in multiple tissues and suffer from severe skeletal- and cardiomyopathies (Huijsman *et al.*, 2009). These phenotypes can be retrieved in human patients of NLSA. It was therefore assumed that ATGL was needed to produce crucial mediators in order to generate lipid ligands that activate PPARs. Consistent with lowered PPAR- α activation in ATGL knock out mice, cardiac mitochondrial respiration was impaired. Triglyceride storage was elevated and glycogen was increased in cardiomyocytes. Additionally, although the overall structure of mitochondria was not affected and cristae appeared normal, mitochondria in ATGL knock out mice were significantly enlarged (Haemmerle *et al.*, 2011). Interestingly, preliminary data shows also an increased size of mitochondria in malpighian tubules of *bmm*¹ and *puml*¹ flies (**Figure 39**).

Figure 39 Preliminary data indicates that Mitochondria in Malpighian tubules from *puml¹* and *bmm¹* flies are enlarged. Box plot of mitochondrial diameter quantified in electron microscope pictures (Sample processing and image acquisition were performed by Dietmar Riedel) of Malpighian tubules. Center lines show the median, box limits indicate 25th and 75th percentiles as determined by OriginPro software; whiskers extend 1.5 times the interquartile range from the 25th and 75th percentiles (Mann-Whitney test; $n_{mitochondria}$ analysed per genotype: $bmm^1=291$, $puml^1=123$ and control=96).

Drosophila hepatocyte nuclear factor 4 (*Hnf4*) acts ortholog to PPAR in mammals and regulates the expression of nuclear and mitochondrial genes needed for an efficient oxidative phosphorylation (Palanker *et al.*, 2009, Barry and Thummel, 2016). *Hnf4* mutant flies are hyperglycaemic, glucose intolerant, have impaired glucose-stimulated insulin secretion and extremely short lived. Of course, metabolic defects can be observed already in *Hnf4* deficient larvae (Palanker *et al.*, 2009) the effects become highly pathological in adults (Barry and Thummel, 2016). Interestingly, expression of *Hnf4* is vastly increased at the onset of adulthood (Barry and Thummel, 2016) that may explain the more pronounced metabolic defects and indicates the importance of *Hnf4* for adult energy homeostasis. As the size of mitochondria is altered it might be possible that *bmm¹* and *puml¹* flies produce less lipid mediators for a proper *Hnf4* function leading to a reduced expression of oxidative phosphorylation genes. Whether *bmm¹* and/or *puml¹* flies have reduced mitochondrial respiration needs to be investigated further. However, an overexpression of *bmm* in the fat body is known to protect flies from HFD induced ectopic lipid storage in cardiomyocytes (Birse *et al.*, 2010). Therefore, a positive feedback loop for the lipid mobilization and energy production may be conserved in

flies as well. In this model Bmm and/or Pum1 not only mobilize lipids but may provide additionally lipid mediators for Hnf4 activation that finally leads to improved oxidative capacity in the fly. As *Hnf4* is highly expressed in the midgut, oenocytes, the fat body and in malpighian tubules (Gelbart and Emmert, 2013) this might be the reason why we can observe elevated body fat and ectopic lipid storage in malpighian tubules of *bmm*¹ and *pum1*¹.

Besides TAG species with even numbers of esterified fatty acids the pilot experiment measured also TAG species with odd C-atom numbers in the esterified fatty acids (**Figure 32, Figure 33**). These odd TAG species are actually common in *Drosophila* (personal communication from Vincenz Hofferek [MPImp-golm] and Dr. Ralf Pflanz[MPI-BPC]) but most lipidomics studies do not annotate these lipids. The origin of odd-numbered fatty sidechains needs to be clarified but it is very likely that they are synthesized from C3-bodies and might derive from bacteria and might be just ingested by the flies. Besides this, the odd TAG species may contain branched fatty acids from fatty acid-hydroxy fatty acids (FAHFAs), a recently identified class of lipids that can act as signaling molecules modulating insulin sensitivity of cells (Yore *et al.*, 2014). So far, the existence of FAHFAs (with odd and even numbers of C-atoms) need to be confirmed in flies but from their general structure they might be also potential targets for Pum1 and conceivably this recently identified lipid signaling might be evolutionary conserved between invertebrates and mammals as well. Interestingly, peroxisomes are required for a processing of branched lipids (Vanhoe *et al.*, 1993, Seedorf *et al.*, 1994) indicating the importance of this organelle for lipid metabolism. In addition, FAHFAs would provide another connection between lipid metabolism and insulin signaling.

4.6 A new insight in lipid storage control in *Drosophila*

In flies, a complex regulatory network permanently monitors metabolic pathways and adapts the synthesis and mobilization of energy stores to the current metabolic state in order to maintain energy homeostasis. With their high volumetric energy density neutral lipids represent the major energy store in flies. At the same time these versatile molecules cannot only be used for oxidative phosphorylation (after β -

oxidation) but also serve as precursors for glyco- or phospholipids, are used for post-translational protein modifications or even act directly as signaling molecules (Berg *et al.*, 2007). As an imbalance in lipid generation, storage and turnover can have deleterious effects on the organismal health, high efforts have been taken to identify the underlying mechanisms and players of lipid metabolism. In this context *Drosophila melanogaster* provides a powerful model system for basic and applied research.

In this work I extended the commonly accepted model for lipid storage modulation in adult flies (**Figure 37**). The current model provides an explanation for the observed lipid storage phenotypes and carbon flux in *puml¹* flies.

According to the proposed model Puml would act on LDs by modulating lipogenesis and possibly during lipolysis. Additionally, Puml would aid in the channelling of lipids to peroxisome and possibly may modulates maturation of late endosomes/lysosomes.

The important feature to perform these actions might be combinatorial. By modulating PA levels Puml would regulate AMPK and TOR signaling in flies. With a downregulation or absence of *puml* expression PA levels may locally increase and inactivate AMPK leading to decreased Bmm mediated lipolysis and increased lipogenesis due to increased insulin signaling in flies. However, during time of energy expenditure or nutrient deprivation this mechanism could be overwritten. Based on the assumption that PA derives mostly from DAG, that is generated continuously by basal TAG hydrolysis on lipid droplets and is normally re-esterified und basal conditions, starvation leads to post-translational modifications of various lipid storage modulators and changes their localization. By the activation and translocation of *DmHsl* the DAG pool would be rapidly decreased and would diminish PA amounts. This would improve AMPK signaling and lower the insulin/TOR cascade leading to increased expression of lipolytic, peroxisomal and mitochondrial genes. At the same time AMPK activation would inhibit ACC leading to higher activity of CPT1 improving the lipid shuttling into mitochondria for oxidative phosphorylation. By this

mechanism lipid utilization for energy production would not be impaired in *puml¹* and at the same time would explain why *puml¹* show increased lipid storage.

Of course, the very important piece in this puzzle (PA amounts) needs to be investigated. Probably an extended lipidomics approach is needed to detect possible changes as the concentration differences are more likely expected in a very low molar range than in changed amounts of μg that would be detectable on a TLC using whole fly extracts. Indeed, ABHD5 knock out mice actually exhibit increased PA levels indicating that, besides its ATGL stimulating character, ABDH5 may possess a so far unknown function for regulating PA and may the current working model can be applied to humans as well. Thus, the ATGL activating function of ABHD5 embodies an acquired evolutionary adaptation to rapidly boost TAG hydrolysis, while at the same time providing a two factor control system to tightly adapt neutral storage lipid mobilization.

The current working model provides an idea why *AKHR¹* flies mobilized lipids during starvation (Grönke *et al.*, 2007). Of course the primary signaling cascade induced by AKH binding would be impaired. At the time the insulin signaling would decrease leading to less inhibition of dFoxo and subsequently increased expression of lipolytic genes like *pudgy* or *bmm* (Xu *et al.*, 2012). With a positive feedback loop by Hnf4 lipolysis would be enhanced without AKHR signaling. Due to the involvement of insulin signaling, expressional changes and protein translation this would provide cause for the delay (Grönke *et al.*, 2007) in enhanced lipolytic activity in *AKHR¹* flies and why lipolysis does not occur in *AKHR¹ bmm¹* double mutant flies. With a possible activation of Bmm by phosphorylation the increased lipolytic activity would majorly be driven by the higher amounts of Bmm in *AKHR¹* flies. The basal expression in normal flies would provide a basic pool of Bmm protein that is responsive for fast adaptations to lipid mobilization needs via AKHR signaling before transcriptional and translational processes enhances lipolysis and energy production. However, *bmm* deficient flies are still capable to mobilize lipids. Although, the lipolytic activity is less enhanced in *bmm¹* flies it is dependent on Plin1 (Grönke *et al.*, 2007) indicating that maybe *DmHsl* or so far unknown lipases contribute to this activity. Yet, changes in

mitochondria size of *bmm*¹ flies implicate that respiratory capacity might be lower due to impaired Hnf4 signaling lowering the oxidative capacity of these flies.

Taken together, to consolidate the current working model additional should be performed. A critical factor are the PA levels that represent the signaling molecule that links lipid- and carbohydrate metabolism. It should be addressed with high priority in *puml*¹ flies. Also, the proposed inactivation of AMPK but stabilized Akt and TOR should be shown in *puml*¹ flies. This could be done by immunohistochemistry of these proteins directly or quantification of gene expression from transcriptional targets of the respective pathways. Postulated high amounts of Akt in *puml*¹ flies should provide a higher phosphorylation (and thereby inactivation) of GSK3 (*shaggy*) and subsequently Glycogensynthase (explains low Glycogen storage due to decreased synthesis), dFoxo and Dp53. The stabilized Tor as well as increased phosphorylation of S6K and PI3K would provide an evidence for the increased insulin sensitivity of *puml*¹ flies. In this context it would be also interesting how blood sugar levels in *puml*¹ flies are.

Consistently with the increased lipogenesis detected in *puml*¹, it should be checked if genes like *fas* and *mdy* are upregulated and *pudgy* and *bmm* are downregulated under feeding conditions. As lipid mobilization in *puml*¹ flies is elevated under starvation it should be checked if glycolytic genes like pyruvate kinase or hexokinase c are downregulated. Whether basal lipolysis is increased as well has not been addressed in *puml*¹ flies so far. Hence, it would provide an explanation for the observed higher labelling of phospholipids in the radioactive glucose feeding assay as a results of increased PL synthesis and turnover.

As *puml* was upregulated in *mio* flies on a high sugar diet it would be interesting to see if *puml* is a direct target of *mio*. A *mio*-gof should suppress *puml* expression and should lead to increased lipid storage accompanied with lower glycogen storage.

A last point should be the analysis of the oxidative capacity of *bmm*¹ and *puml*¹ flies. The enlarged mitochondria provide some evidence for an impairment but this should correlate with decreased expression of mitochondrial genes like cytochrome c-oxidase (COX), pyruvate dehydrogenase (PDH) or succinate dehydrogenase (SDH).

With the possible participation of *bmm* and *puml* in Hnf4 signaling, additional adult tissues in adult flies of the respective mutants should be screened for elevated lipid storage *e.g.* oenocytes or cardiac muscles.

In conclusion *puml* modulates carbon flux in *Drosophila melanogaster* but is not crucial for survival. Certain characteristics of the proposed mechanism by how *puml* mediates metabolic regulation might be conserved between mammalian ABHD5 (lipid over-storage, ectopic lipid storage). However, *puml* seems to perform additional functions in flies that are not shared with ABHD5 (no activation of Bmm by Puml) but partially with its mammalian paralog ABHD4 (*e.g.* phospholipase activity).

Combined, the identified set of characteristics of Puml may represent the ancestral function of this protein family. Evolutionary adaptations and gene duplication generated the two paralogs ABHD4 and ABHD5 that retained parts of their original functions but might be regulated differently nowadays (changed intracellular localization or different tissue expression profiles) or acquired new functions (ATGL activation by ABHD5) due to changed organismal demands on energy homeostasis. Therefore, *puml*¹ flies may serve as an animal model for neutral lipid storage disease to find therapeutics to treat this human disease.

5 Supplement 1

5.1 Characterization of *DmHsl* (CG11055)

Lipid storage and mobilization is a well-orchestrated process that can be performed by most if not all cells. In mammals, a specific set of proteins has been identified that play a key role in the mobilization of storage lipids. Among them are: Adipocyte triglyceride lipase (ATGL) (Zimmermann *et al.*, 2004) with its activator ABHD5/CGI-58 (Lass *et al.*, 2006), hormone-sensitive lipase (HSL) (Haemmerle *et al.*, 2002a) and Perilipins (Greenberg *et al.*, 1991). For mammalian ATGL and Perilipin1 homologues can be found in *Drosophila melanogaster* namely Brummer lipase (Grönke *et al.*, 2005) and Perilipin1/Lsd-1 (Beller *et al.*, 2010).

As presented in the current work a sequence-related protein can be found for ABHD5 in flies, that has been named Pummelig (Puml/CG1882), but the mechanism by how Puml is modulating lipid storage seems not be evolutionary conserved.

Mammalian hormone-sensitive lipase has been studied for over half a century now and was long considered to be the sole key lipase for induced lipolysis in adipose tissue. Only a decade ago ATGL was identified as the important lipase in the first step of triacylglyceride (TAG) mobilization (Zimmermann *et al.*, 2004) that also underlies an additional level of regulation. For an optimal TAG hydrolase activity, ATGL relies on its activator ABHD5 (Lass *et al.*, 2006, Granneman *et al.*, 2007) that competes with the ATGL inhibitor GOS2 (Cerk *et al.*, 2014). Additionally, ABHD5 serves as a platform to recruit fatty acid binding protein (FABP) creating a sort of lipid mobilization complex. Further on ABHD5 is localized on lipid droplets under basal conditions and requires Perilipin1 as a binding partner (Granneman *et al.*, 2007, Granneman *et al.*, 2009).

Upon a lipolytic stimulus, *e.g.* by β -adrenergic signalling, PKA phosphorylates PLIN1 (pPLIN1) (Tansey *et al.*, 2001, Tansey *et al.*, 2004) and HSL (pHSL) (Huttunen *et al.*, 1970). This leads to the release of ABHD5 from pPLIN1 that now can interact with the pHSL which in turn translocates from the cytoplasm onto the lipid droplet (Sztalryd *et al.*, 2003). The released ABHD5 competes with the ATGL inhibitor GOS2. With the protein interaction of ATGL-ABHD5 (Lass *et al.*, 2006, Granneman *et al.*, 2007) this

complex localizes onto LD surface again and lipolysis starts. In a three-step process the first fatty acid (FA) from TAGs is cleaved off by ATGL. Subsequently, the DAG is hydrolysed by HSL and in the last MAG is cleaved by MAGL into FA and the glycerol backbone.

In *Drosophila* two perilipins can be found that have distinct roles in lipid metabolism. A study of the lipid droplet proteome revealed that LDs from *Dmplin1*, *Dmplin2* single- and *Dmplin1,Dmplin2* double-mutants are populated differently by proteins (Sahu-Osen, 2015) indicating the modulating role of perilipins by controlling access of proteins to LDs.

Dmplin1 mutant flies have increased lipid storage with a giant lipid droplet phenotype, are hyperphagic but lipolysis in general is not impaired (Beller *et al.*, 2010). Body fat storage of *Dmplin2* mutants, on the other hand, is decreased and overexpression leads to obesity (Grönke *et al.*, 2003).

As mentioned before a complete breakdown of glycerolipids into fatty acids and the glycerol backbone is a three step process. *Brummer* has been described as an important TAG lipase (Grönke *et al.*, 2005). *bmm* mutants have increased body fat storage, increased starvation resistance (Grönke *et al.*, 2005). Whereas, a single knockout of *bmm* is still capable to mobilize storage lipids a double knockout of *bmm* and *Dmplin1* cannot mobilize storage lipids at all (Beller *et al.*, 2010). In mammals HSL had been identified as the main DAG lipase in adipose tissue (Fredrikson *et al.*, 1986, Haemmerle *et al.*, 2002a).

In order to see if the core lipid mobilization module in mammals is evolutionary conserved in the fly a search for a HSL homolog was performed and *DmHsl* (CG11055) was identified as the sole member of the HSL-family in *Drosophila*. To study the function of *DmHsl* a knockout mutant was generated and initially characterized by Sebastian Grönke (Grönke, 2005). Comparable to *HSL*^{-/-} knockout mice (Haemmerle *et al.*, 2002a) total body fat was not increased in *DmHsl*¹ flies and starvation resistance was not changed compared to control flies (Grönke, 2005). *DmHsl* is expressed during all developmental stages of *Drosophila melanogaster* with a strong enrichment in early embryonic stages (0-3h) indicating a maternal contribution

(Grönke, 2005, Bi *et al.*, 2012, Gelbart and Emmert, 2013). In larvae, comparable to *bmm*, *DmHsl* expression is increased during starvation (Bi *et al.*, 2012). A mutant independently generated and characterized by (Bi *et al.*, 2012) exhibited increased lipid storage (+30%) and lipid mobilization deficits during starvation in larvae.

An important characteristic of mammalian HSL function is its translocation from the cytoplasm to LDs that requires pPLIN1 on LDs (Sztalryd *et al.*, 2003). However, known phosphorylation sites in mammalian HSL are only poorly conserved in the fly (Grönke, 2005). Several studies identified *DmHsl* as a lipid droplet resident (Cermelli *et al.*, 2006, Krahmer *et al.*, 2013). A *in vivo* approach, using a fat body specific overexpression of *DmHsl::eGFP* showed in larvae that *DmHsl::eGFP* was majorly localized in the cytoplasm under fed conditions (Bi *et al.*, 2012). In addition, abundance of *DmHsl::eGFP* on LDs was higher during nutrient deprivation (Bi *et al.*, 2012). While *DmHsl::eGFP* still showed a LD localization in *plin2¹* larvae it was nearly absent on LDs in *plin1¹* larvae indicating a conserved role of *DmPlin1* in sequestering *DmHsl::eGFP* onto the LD surface (Bi *et al.*, 2012).

Studies on *DmHsl* concentrated mainly on larval stages and the data indicate a conserved function to mammalian HSL (Grönke, 2005, Bi *et al.*, 2012). Therefore, *DmHsl* was analysed further to characterize its function in adult flies and identify a possible biological phenotype in *DmHsl¹* flies.

5.2 Body fat storage is not altered in *DmHsl¹* flies

The *DmHsl¹* fly stock was generated by an imprecise P-element excision and has been initially characterized by Sebastian Grönke in 2005. Body fat measurements revealed no changes in *DmHsl¹* flies in comparison to a generated control and average mean survival times under starvation did not exceed controls (Grönke, 2005).

In order to avoid the detection of false-positive phenotypes deriving from inbreeding effects of the *DmHsl¹* strain and having a proper genetically matched control the *DmHsl¹* strain was backcrossed for ten generations into a *w¹¹¹⁸* background and a homozygous *DmHsl¹* stock was established again.

Figure 40 Body fat storage is unchanged in *DmHsl¹* flies. An *DmHsl-RNAi* in the fat body (*FB-SNS>GAL4*) showed the same phenotype. A fat-body targeted (*FB-SNS>GAL4*) or ubiquitous (*Act5c>GAL4*) overexpression of GFP-tagged and non-tagged *DmHsl* lead to reduced body fat storage but the effect was highly variable. Plotted are means of relative TAG equivalents/protein normalized to average TAG equivalents/protein values of the corresponding controls \pm SEM; Mann-Whitney test; **= $P < 0.01$; *= $P < 0.05$).

A reanalysis of body fat content in backcrossed *DmHsl¹* flies verified the results from S. Grönke. The overexpression of *DmHsl* and *DmHsl::GFP* always showed a trend towards lower body fat but the effect was highly variable (Figure 40).

5.3 Diacylglycerols are not elevated in *DmHsl¹* flies

Consistent with data from mice total amounts of glycerolipids are unchanged in adult *DmHsl¹* flies (Figure 40). However, in accordance with the high Diacylglycerolhydrolase activity of *MmHSL* (Fredrikson *et al.*, 1986), DAGs levels are elevated in *HSL knock out* mice (Haemmerle *et al.*, 2002a). Therefore, a TLC analysis was performed in order to separate and quantify the different neutral lipid classes in *DmHsl¹* flies. In comparison to control flies no neutral lipid class (TAG, DAG, MAG, FA) was changed in lipid extractions from total *DmHsl¹* compared to control flies (Figure 41). Lipids are transported mainly as DAGs in the hemolymph of flies (Fernando-Warnakulasuriya and Wells, 1988, Pennington and Wells, 2002). Therefore, it might be possible that DAG accumulations only can be observed in lipid degrading tissues and overall relative amounts might be low in total fly lipid extracts. In order to answer this question, TLC analyses were performed from lipid extractions deriving from

muscle enriched samples (Thorax) and lipid storing tissues like fat body and intestine (Abdomen sample).

Figure 41 Neutral lipid classes are unchanged in *DmHsl¹* flies. (A, B) TLC analysis from *DmHsl¹* and control flies. (C, D, E) TLC analysis of *DmHsl¹* and controls using lipid extractions from thorax (muscle tissue) and abdomen (enriched in fat body and intestinal tissue). (B, D, E) Plotted are the means of average fold changes in Arbitrary units (AU; measured densitometrically using ImageJ v1.49m) for the annotated lipid classes compared to control flies \pm SEM; Student's *t*-test. Dotted lines (A, C) mark a break due to a removal of a lane on the TLC plate. Cholesterol formate (CF) was used in C as an internal control for extraction yield. Measured AUs in D,E and were normalized for CF and then compared between the samples.

Also in the muscle enriched tissue samples no differences could be detected between *DmHsl¹* flies and controls. Differences could be seen between the various tissue samples as DAG species appeared much more prominent in abdomen sample in general (Figure 41).

Taken together, besides an identical substrate spectrum of *DmHsl* compared to *MmHSL*, DAGs are not elevated in *DmHsl¹* indicating a redundant mechanism of DAG hydrolysis in *Drosophila melanogaster*.

5.4 *DmHsl::EGFP* abundance on LDs is higher during starvation in larvae and adults

An important characteristic of *MmHSL* is its translocation from the cytoplasm onto lipid droplets upon phosphorylation by PKA and the interaction of phosphorylated

PLIN1 in adipose tissue (Sztalryd and Kraemer, 1994, Lass *et al.*, 2006). Overexpressed *DmHsl::EGFP* shows a comparable behaviour in larval fat body cells and is more abundant on LDs during starvation (Bi *et al.*, 2012). Bi *et al.* (Bi *et al.*, 2012) also postulated that *DmPlin1* is needed for a proper localization of *DmHsl::GFP* on LDs during starvation in larvae. As the studies on *DmHsl* concentrated on the larval stage I was interested if localization behaviour is the same in adult flies. Comparable to larvae (**Figure 42**) higher abundance of *DmHsl::GFP* (expressed in the fat body tissue [FB-SNS>GAL4]) on LDs could be observed in adults as well (**Figure 43**). Whereas *DmHsl::GFP* was omnipresent on small lipid droplets (<8 μ m) the abundance was most strikingly increased on large LDs (>10 μ m) during nutrient deprivation (**Figure 45**).

Figure 42 *Hsl::GFP* localizes on lipid droplets in larval fat body. Upper row shows lipid storage in fed animals (Lipids were stained by LipidTOX) and LD localization of fat body expressed (FB-SNS>GAL4) *Hsl::GFP* (ring-like pattern in D). Ring-like localization on LDs become more evident (E) during starvation (early L3 larvae were starved for 6h).

Figure 43 *Hsl::GFP* localization on lipid droplets also occurs in adult fat body tissue. Ring-like localization of fat body (*FB-SNS>GAL4*) expressed *DmHsl::GFP* on LDs is clearly visible under starvation. Additionally, *Hsl::GFP* signal appears to be more prominent on large LDs during starvation whereas it is mostly found on small LDs during feeding periods.

5.5 Lipid mobilization in *DmHsl¹* flies is not impaired

The independently generated *DmHsl^{b24}* mutant (Bi *et al.*, 2012) showed impaired lipid mobilization in larvae. With a comparable localization pattern of *DmHsl::GFP* under fed and starvation conditions a similar behaviour was expected in *DmHsl¹* adult flies. For this, starved flies were starved and body fat was measured by CCA assay (**Figure 44**). However, *DmHsl¹* flies could mobilize their lipids assuming a possible redundancy of *DmHsl* function.

Figure 44 *DmHsl¹* flies can mobilize lipids. Average fold change of TAG equivalents / mg protein in fed and starved control and *DmHsl¹* flies \pm SEM. Student's test revealed no significant differences between the two genotypes.

5.6 *DmPlin1* is crucial for localization of *DmHsl::GFP* on large LDs (>10 μ m) but not small

Figure 45 *Hsl::GFP* expressed in *plin1*¹ larvae and flies localizes on lipid droplets under fed and fasting conditions in larvae (A-I) and adults (J-O). Note, that giant lipid droplet phenotype is not changed (F, J, M) drastically upon *Hsl::GFP* expression (FB-SNS>GAL4). Even during fasting conditions bigger lipid droplets (>10 μ m) seem to be spared from *Hsl::GFP* localization (I, O).

In order to see if the HSL sequestering role of PLIN1 is conserved in flies *DmHsl::GFP* was expressed in the fat body (FB-SNS>GAL4) in *plin1¹* flies. Comparable to data from Bi *et al.* (2012) *DmHsl::GFP* could be found on LDs in general in larvae (**Figure 45**). The same was the case in the adult fat body (**Figure 45**). In *plin1¹* larvae as well as in adult *plin1¹* flies large LDs (>10µm) were spared from *DmHsl::GFP* signal. The large LD phenotype of *plin1¹* was persistent in larvae and adults expressing *DmHsl::GFP*. Whether the avoidance of *DmHsl::GFP* populating large LDs was due to the lack of its interaction partner PLIN1 or an indirect effect like the size and therefore the curvature of the LD itself remains to be answered.

5.7 Fecundity in *DmHsl¹* flies is not impaired

DmHsl::GFP abundance on LDs is increased under starvation. Also, *DmHsl* has a comparable substrate spectrum to *MmHSL* (personal communication by Dr. C. Heier) but no increase in DAGs in *DmHsl* deficient flies. It was therefore assumed that *DmHsl* function is not exclusively limited to hydrolyse primarily DAGs in storage lipid mobilization. Expression data (Gelbart and Emmert, 2013) and *in situ* hybridisations (Bi *et al.*, 2012) indicated a strong maternal contribution of *DmHsl*-RNA in embryos. Therefore, fecundity of *DmHsl¹* was analysed in order to address a possible function of *DmHsl* during embryogenesis indicating an important function of *DmHsl* during embryogenesis.

Figure 46 Fecundity is not impaired in *DmHsl¹* flies. *DmHsl¹* (+) and *DmHsl¹* (-) flies were used. Homozygous stocks were compared to crosses of female *DmHsl¹* and males from controls and vice versa to address a possible gender dependent phenotype of *DmHsl* deficiency. Total numbers of viable progeny did not vary significantly in the tested conditions (A). Lower survival rate of egg → larvae were compensated by higher egg deposition (B). Survival rates of larval stages and during metamorphosis are nearly 100% for all tested conditions (SEM, student test, *=P<0.05, n>550 / combination).

Total numbers of viable progeny were comparable between crosses of *DmHsl¹*, controls and heterogenic combinations crossing *DmHsl¹* virgins with male control flies

and *vice versa* (Figure 46). Survival from egg to larval stages were relatively low but similar between the tested conditions. Only control crosses appeared to have higher survival rates. As total numbers of progeny per female were equal the disadvantage of the lower survival rate was compensated by higher egg deposition rates. Survival rates for the later development were at nearly 100% in all tested conditions. A significant effect on fecundity in *DmHsl* deficient flies could not be detected. Of course an involvement of *DmHsl* cannot be excluded due to possible redundancies for its function.

5.8 Discussion

Taken together total body fat storage is not changed in *DmHsl¹* flies compared to control flies. A detailed analysis of different neutral lipid species by thin layer chromatography and lipidomics revealed no increase in total DAG species as observed in *HSL^{-/-}* mice (Haemmerle *et al.*, 2002a). However, the substrate spectra of *DmHsl* and mouse HSL in *in vitro* assays are identical (personal communication from Dr. Christoph Heier and Dr. Robert Zimmermann [University Graz]) covering hydrolytic activities on: TAGs, DAGs (Fredrikson *et al.*, 1986) (highest activity), MAGs (Fredrikson *et al.*, 1981) and Cholesterol esters (Contreras *et al.*, 1998). This would argue in favor of an evolutionary conserved function in *DmHsl* in flies. However, fly physiology differs from mammals as the main transport form of lipids in *Drosophila* are DAGs bound to lipoproteins (Palm *et al.*, 2012). Therefore, it might be possible that there is a general redundancy of direct DAG lipolysis or a more flexible metabolism that allows a different processing of DAGs e.g conversion into a phospholipid and subsequent hydrolysis by specific phospholipases.

Shortly before I started my work on *DmHsl* the original *DmHsl¹ flies* (+ *DmHsl^{revertant}* and *Act5c>GAL4 UAS-DmHsl*) were sent (prepared by Iris Bickmeyer and Dr. Ronald Kühnlein) for a lipidomics analysis performed by the Lipidomics facility from Medical University Graz (used were 2x50 six-day-old flies, from seeding 150 embryos / midsize vial; from two independent density seedings). The analysis from the annotated lipid data revealed a significantly higher total TAG storage of control flies (*DmHsl^{revertant}*) compared to the *DmHsl¹* and a ubiquitous (*Act5c>GAL4*) overexpression of *Hsl* (Figure

47). Total amounts of DAGs per fly were also highest in control flies and no significant differences could be observed between *Hsl* overexpressing or deficient flies (Figure 47). Nevertheless, the % of DAGs from total TAGs indicated a significant increase in % of DAGs of total lipids in *DmHsl¹* and *gof-DmHsl* flies (Figure 47). No differences could be detected between the mutant and overexpression flies indicating that there is no significant increase DAG species in *DmHsl¹* flies. The observed differences are rather a result of a sub-optimal matched control for the *DmHsl¹* stock as TAG amounts in backcrossed flies did not differ between *DmHsl¹* and controls (Figure 47). A TLC analysis (performed by Iris Bickmeyer) of flies used for the lipidomics analysis revealed differences in TAG storage but not in DAGs (data not shown).

Figure 47 Preliminary results indicate that *DmHsl¹* flies do not accumulate diacylglycerol. A lipidomic analysis performed by the Lipidomics facility of the Medical University Graz using non-backcrossed *DmHsl¹* flies (6d males, prepared by Iris Bickmeyer and Dr. Ronald Kühnlein) showed a small but significant increase in %DAGs from total detected TAGs (C). Absolute amounts of TAGs and DAGs were significantly higher in control flies compared to *DmHsl¹* but flies ubiquitously over expressing *DmHsl* (*Act5c>GAL4*) showed comparable total amounts. A strong accumulation of DAGs cannot be seen (consistent with TLC data). Plotted are the means of average lipid amounts of all detected TAG and DAG species detected per male flies (A,B) and calculated % of DAGs (C) of total TAGs (\pm SEM; Student's *t*-test, $*=P<0.05$).

As fed flies were used for the TLC experiment as well as for the Lipidomics analysis (non-backcrossed *DmHsl¹* stock was analyzed) a possible effect of DAG accumulations might be too mild in order to be detected. On the other hand, lipid mobilization in *DmHsl¹* flies was indifferent from control flies. The TLC analysis from abdomen and thorax samples exhibited a different lipid species profile with a strong enrichment in a lipid with a comparable running behavior as DAGs on the TLC plate. Though a difference between *DmHsl¹* and control flies could not be detected. Conversely, an

overexpression of *DmHsl::egfp* exhibits a trend towards decreased body fat indicating a involvement in lipolysis of *DmHsl*.

Comparable to studies in larvae (Bi *et al.*, 2012) overexpressed *DmHsl::egfp* also showed in adult fat body tissue increased abundance on LDs under starvation. A general absence of overexpressed *DmHsl::GFP* on LDs in starved *plin1¹* flies could not be seen but large lipid droplets were omitted. Whether this is caused by the absence of Plin1 directly, due to a missing interaction partner for *DmHsl* or an indirect effect caused by changed physicochemical properties of large LDs remains to be answered. Though overexpressed *DmHsl::egfp* was used for *in vivo* localization studies in larvae (Bi *et al.*, 2012) and adults, *DmHsl* could also be found on embryonic LDs (Cermelli *et al.*, 2006) and on induced LDs in S2 cells (Krahmer *et al.*, 2013). Apart from that *DmHsl* was not found on LDs in fed larvae (Beller *et al.*, 2006, Sahu-Osen, 2015). As embryogenesis represents a starvation state and the larval stage a feeding state a conserved mechanism of *DmHsl* localizing to lipid droplets under catabolic conditions might explain the finding and absence in the different lipid droplet proteomic studies.

The high maternal mRNA contribution of *DmHsl* as well as the detection of *DmHsl* on embryonic LDs implied a possible impairment in fertility of *DmHsl¹* flies. *DmHsl¹* flies showed no noticeable difference during general stock keeping compared to control flies. Consistently, a fecundity assay revealed no changes between control and *DmHsl¹* flies. Although male *HSL^{-/-}* mice were sterile due to gonadal hypotrophy and oligospermia (Osuga *et al.*, 2000), *DmHsl¹* male flies generated similar numbers of offspring with *DmHsl¹* and control females. However, fecundity was analyzed under laboratory terms providing ideal conditions for propagation. Therefore, a *DmHsl* deficiency might only be detrimental under wildtype living conditions. Also, the data indicates again a possible redundancy of *DmHsl* function as, despite the maternal *DmHsl* mRNA contribution, a *DmHsl* deficiency does not affect survival rate of embryos significantly.

When comparing the two available *DmHsl* deficient fly stocks (*DmHsl¹* and *DmHsl^{b24}*) possible differences should be addressed. Of course studies on *DmHsl^{b24}* mutants were restricted to larvae but these mutants showed TAG mobilization defects as well

as increased body fat storage in L3 larvae (Bi *et al.*, 2012). Both effects could not be detected in *DmHsl¹* adults. Therefore, the *DmHsl¹* data should be verified with *DmHsl^{b24}* flies and a proper genetically matched control for this strain.

In summary, *DmHsl¹* flies are homozygous viable and show no obvious alterations in lipid storage and mobilization which might be compensated by so far undetected proteins. Interestingly, no homolog for hormone-sensitive lipase homolog can be found in birds suggesting also an alternative way to mobilize DAGs.

6 Supplement 2

6.1 Characterization of *Cyp1* (CG9916)

The structure of lipid droplets can be divided into a core, consisting mostly of neutral lipids like TAGs or Cholesterol esters, and phospholipid monolayer into which proteins are embedded that control the access to the core. LD-associated proteins in *Drosophila melanogaster* like Brummer lipase (Zimmermann *et al.*, 2004, Grönke *et al.*, 2005) or perilipins (Greenberg *et al.*, 1991, Beller *et al.*, 2010) have clear orthologues in humans.

Perilipins represent the most abundant protein species on LDs. Whereas, in humans five different perilipins can be found flies only have two perilipins. Additionally, the partial redundancy of perilipins in humans makes it difficult to characterize these proteins. Therefore, perilipins can be studied easier in flies.

A *Dmplin1* mutant (referred to as *plin1¹*) exhibits increased body fat storage in adults but not in larvae and adult flies are hyperphagic (Beller *et al.*, 2010). Lipid droplet size distribution of *plin1¹* is changed compared to control flies and LDs with diameters larger than 30µm (called giant LDs) can be found. Interestingly, giant LDs appear already during larval stage, persist and become predominant in adults (Beller *et al.*, 2010). A loss of *Dmplin2* (referred to as *plin2¹*), on the other hand, leads to reduced body fat storage, whereas an overexpression has a diametric effect (Grönke *et al.*, 2003, Teixeira *et al.*, 2003). The lipid storage of *plin1¹,plin2¹* (double mutant) flies is also decreased compared to control flies with the preference to towards bigger LDs (Beller *et al.*, 2010).

Based on the hypothesis that perilipins modulate the abundance of proteins on LDs and that the *plin1¹* giant LD phenotype is the cause or consequence of an altered proteome, the proteome of LDs isolated from *plin1¹*, *plin2¹*, control flies and *plin1¹,plin2¹* was analysed by Dr. Anita Sahu-Osen (former member of the Birner-Grünberger, lab Medical University, Graz) in cooperation with our lab (Kühnlein group, MPI-bpc, Göttingen).

Anita Sahu could identify 71 proteins in LD isolates from *plin1¹ larval fat body* (Sahu-Osen, 2015). Abundance was increased for 3 proteins and 11 proteins were found less compared to control larvae.

The predicted Peptidyl-prolyl cis-trans isomerase (P25007), known as cyclophilin 1 (referred to as Cyp1 ; CG9916), exhibited the strongest up-regulation with a 20-fold increase in *plin1¹* compared to control flies. As Cyp1 abundance was not altered in *plin2¹* and *plin1¹,plin2¹* it was hypothesized that Cyp1 is involved in lipid droplet size regulation.

6.2 Cyp1::eGFP can be associated with LDs

In order to confirm the high abundance of Cyp1 in *plin1¹* a Cyp1::eGFP construct (generated by Dr. Anita Sahu and Dr. Ronald Kühnlein) was expressed in the larval fat body (FB-SNS>GAL4) of *plin1¹* flies. A fraction of Cyp1::eGFP is loosely associated with lipid droplets in a dot-like pattern (**Figure 48**). Most of the overexpressed protein is located in the cytoplasm, often accumulates and generates clusters distant to lipid droplets (**Figure 48**). Additionally, Cyp1::eGFP produces ring-like structures with no overlap of lipid droplet staining.

Figure 48 *Cyp1::eGFP is loosely associated with lipid droplets.* *Cyp1::eGFP* is expressed in larval fat body (*FB-SNS>GAL4*) of *plin1¹* larvae. A fraction of the protein is associated in a dot-like pattern (white arrow, C and magnified E, F). The major portion of *Cyp1::eGFP* generates aggregates (yellow arrow) or is localized in ring-like structures with no overlap with the LD staining (stained by LipidTOX™ Deep Red).

6.3 Average lipid droplet size is decreased in *Cyp1¹* flies

In order to characterize the biological function of *Cyp1* a mutant was used (called *Cyp1¹*). A fly stock with a EP-insertion in the ORF of *Cyp1* was available (Bloomington *Drosophila* Stock Center), backcrossed and homozygous stock was established by Ronald Kühnlein. An analysis from Anita Sahu-Osen already indicated a decrease in the average lipid droplet size during fat body targeted *Cyp1-RNAi* (Figure 49) that could be confirmed in *Cyp1¹* fly fat body tissue (Figure 49).

Figure 49 Average lipid droplet size (diameter) is reduced in *Cyp1*¹ and fat body targeted *Cyp1*-RNAi. Box plot of lipid droplet size quantified from confocal pictures of fluorescently stained lipid droplets in larval fat body cells. Center lines show the median, box limits indicate 25th and 75th percentiles as determined by OriginPro software; whiskers extend 1.5 times the interquartile range from the 25th and 75th percentiles (Mann-Whitney test; ***= $P < 0.001$; $n_{\text{lipid droplets}}$ analysed per genotype >8000).

6.4 Body fat storage in *Cyp1*¹ flies is not changed

In order to see if the smaller average LD size also affects fat storage a CCA assay was performed. Smaller LD size had no effect on global lipid storage of *Cyp1*¹ L3 larvae.

Figure 50 Body fat storage is unchanged in *Cyp1*¹ larvae (one-way ANOVA, $F_{(1,14)}=1.29$, $P=0.27$, Fisher LSD $P=0.27$). Box plot of $\mu\text{g TAG equivalent / mg protein}$ measured with CCA assay. Center lines show the median, box limits indicate 25th and 75th percentiles as determined by OriginPro software; whiskers extend 1.5 times the interquartile range from the 25th and 75th percentiles.

6.5 *Cyp1::eGFP* expression in larvae reverts small LD phenotype

As shown in **Figure 48** *Cyp1::eGFP* is loosely connected to LDs. Average LD size is reduced in *Cyp1*¹ larval fat body cells. Therefore, it was tested if an overexpression of *Cyp1::eGFP* in the fat body of *Cyp1*¹ flies can reverse this phenotype.

Figure 51 *Cyp1::eGFP* expression in *Cyp1*¹ larvae shows a dot-like distribution in close distance to lipid droplets (see white box) and non-lipid associated aggregates (arrow in C).

Indeed, expression of *Cyp1::eGFP* in the fat body (*Lpp*>GAL4) leads to a similar localization pattern (**Figure 51**) as shown in *plin1*¹ (**Figure 48**) but upon release of LDs from the cells by mechanical cell disruption much less LDs were associated with *Cyp1::eGFP*. This correlates with the quantitative proteomics data from Dr. Anita Sahu where *Cyp1* abundance was only elevated in *plin1*¹ mutants. Additionally, LD size quantification revealed a reversion of the reduced average LD size in *Cyp1*¹ towards bigger LD size (**Figure 52**).

Figure 52 Expression of *Cyp1::GFP* in *Cyp1*¹ larvae (*Lpp*>*GAL4*) rescues small lipid droplet phenotype. Box plot of lipid droplet size quantified from confocal pictures of fluorescently stained lipid droplets in larval fat body cells. Center lines show the median, box limits indicate 25th and 75th percentiles as determined by OriginPro software; whiskers extend 1.5 times the interquartile range from the 25th and 75th percentiles (Mann-Whitney test; ***=*P*<0.001; *n*_{lipid droplets} analysed per genotype >6000).

6.6 *Cyp1::eGFP* overexpression in larval fat body does not enhance giant LD phenotype of *plin1*¹ larvae

A deficiency of *Cyp1* leads to decreased average LD size and can be rescued by the expression of *Cyp1::GFP*. Therefore, it can be assumed that *Cyp1* is directly involved in LD size regulation and that the *Cyp1::GFP* construct is functional. Increased protein abundance of *Cyp1* correlates with the giant LD phenotype of *plin1*¹. Therefore, it was tested if the overexpression of *Cyp1::eGFP* in the fat body (*FB-SNS*>*GAL4*) in *plin1*¹ can enhance the giant LD phenotype.

Figure 53 Overexpression of *Cyp1::eGFP* in *plin1*¹ larvae does not enhance *plin1*¹ giant LD phenotype. Box plot of lipid droplet size quantified from confocal pictures of fluorescently stained lipid droplets in larval fat body cells. Center lines show the median, box limits indicate 25th and 75th percentiles as determined by OriginPro software; whiskers extend 1.5 times the interquartile range from the 25th and 75th percentiles (Mann-Whitney test; ***=*P*<0.001; *n*_{lipid droplets} analysed per genotype >1700).

Cyp1::eGFP could be found loosely associated with LDs (**Figure 48**) though endogenous Cyp1 is also expressed. Compared to control crosses, the average lipid droplet size in the fat body of larvae overexpressing *Cyp1::eGFP* did not show bigger LDs nor was the average LD size significantly increased (**Figure 53**).

6.7 Cyp1 contributes to lipid droplet size and storage lipid partitioning in *plin1¹* larvae

Overexpression of Cyp1::eGFP did not enhance the giant LD phenotype. In order to designate the contribution of Cyp1 to the *plin1¹* giant LD phenotype a double knock out mutant (*Cyp1¹,plin1¹*) was generated (by Dr. Ronald Kühnlein) and LD size was analysed in larval fat bodies (**Figure 54**).

Figure 54 A double knockout of *Cyp1¹,plin1¹* in larvae does not prevent the giant lipid droplet phenotype of *plin1¹* larvae. (A) Box plot of lipid droplet size quantified from confocal pictures of fluorescently stained lipid droplets in larval fat body cells. Center lines show the median, box limits indicate 25th and 75th percentiles as determined by OriginPro software; whiskers extend 1.5 times the interquartile range from the 25th and 75th percentiles (Mann-Whitney test; ***= $P < 0.001$, **= $P < 0.01$, *= $P < 0.05$; $n_{lipid\ droplets}$ analysed per genotype >1700). (B) Lipid storage partitioning reveals % of amount of lipids stored in lipid droplets of the different sized bins: <5, 5-10, 10-15, 15-20, 20-25, 25-30, >30µm.

The giant LD phenotype of *plin1¹* flies is characterized by the occurrence of LDs with more than 25µm in diameter (**Figure 54**). This does not mean that smaller LD sizes cannot be found anymore but that in general there is a shift towards larger LDs (**Figure 54**). Average LD size in *Cyp1¹* is significantly reduced (**Figure 54**) and increased in *plin1¹*. A double knock out (*Cyp1¹,plin1¹*) shows an intermediate phenotype between controls and *plin1¹*. Giant LDs can still be observed in *Cyp1,plin1¹* but total numbers of these LDs is less than in *plin1¹*. Additionally, the distribution of total lipid storage in lipid droplets larger than 20µm in diameter shifts from 75% to roughly 50% in *Cyp1¹,plin1¹* double mutants.

6.8 Discussion

In summary, Cyp1 is important for LD size modulation. A deficiency in Cyp1 directly leads to smaller LD size that can be rescued by the expression of *Cyp1::eGFP*. In a double knockout of *Cyp1¹,plin1¹* the absence of Cyp1 is not sufficient to prohibit the formation of larger LDs but reduces the severity of this phenotype. As an overexpression of *Cyp1::eGFP* does not enhance the LD size phenotype of *plin1¹*, it is very likely that Cyp1 alone is not the limiting factor for the size regulation but still plays an important role. Up to now it is not known through which mechanism Cyp1 modulates LD size. Cyclophilins exhibit a peptidyl-prolyl cis-trans isomerase (PPIase) activity that accelerates protein folding and provides them a chaperone-like function (Lodish and Kong, 1991, Stamnes *et al.*, 1991, Steinmann *et al.*, 1991, Kruse *et al.*, 1995). Therefore, Cyp1 might help proteins necessary for lipid synthesis into LDs (Wilfling *et al.*, 2013), directing fusions of LDs or shuttling of lipids between LDs or other cell organelles (*e.g.* ER) to get the right shape or stabilize complexes in order to perform these functions and finally leading to lipid droplet growth. In this context it is possible that Cyp1 is required for correct Plin1 folding to ensure a proper localization on LDs as Plin1 abundance correlates tightly with the available LD surface (Beller *et al.*, 2010).

The abundance of Cyp1 in lipid droplet isolations from *plin1¹* larval fat body cells is increased but Cyp1 was in principle detected in *plin2¹* and control flies as well, indicating a general involvement of Cyp1 in LD growth that exceeds a somehow minimal defined size as the absence of Cyp1 does not inhibit LD generation. Also the results underline the importance of Plin1 regulating access of proteins to LDs and therefore modulating the size and lipolytic accessibility of storage lipids. Part of the function of Plin1 might be limiting the maximal LD size as the possible effects from having large LDs are not completely understood. Lipid mobilization in general is not impaired in *plin1¹* and the body fat reduction during *bmm* overexpression is more pronounced than in *plin1⁺* flies (Beller *et al.*, 2010) overexpressing *bmm* but possible additional side effects have not been addressed so far.

Cyclophilins are evolutionary conserved between flies and humans and a BLAST search identifies *HsCypA* (Similarity: 84% and Identity: 75%) and *HsCypD* (79% / 67%) as potential functional homologs for *DmCyp1*. Both CypA and CypD are described to promote LD growth in their absence (by *e.g.* RNAi) in sg-1b replicon cells (express Hepatitis C virus proteins). A similar effect can be achieved via the inhibition of Cyclophilins with Cyclosporin A [NIM811] (Anderson *et al.*, 2011). However, the mechanism by which CypA and CypD modulate LD size is not known. Studies in adult *CypD*^{-/-} mice identified CypD to be important for the control of oxidative phosphorylation and the control of the mitochondrial permeability transition pore. CypD absence protected mitochondria from Ca²⁺ stress (Gainutdinov *et al.*, 2015) but also altered the metabolism of mice. *CypD*^{-/-} mice exhibited a higher metabolic rate with increased utilization of lipids (lower fat mass) and elevated body temperature. Additionally, *CypD*^{-/-} mice were protected from diet induced obesity (Devalaraja-Narashimha *et al.*, 2011, Taddeo *et al.*, 2014) but older animals developed: insulin resistance, hyperglycaemia and glucose intolerance (Devalaraja-Narashimha *et al.*, 2011). Therefore, cyclophilins are a promising group of largely uncharacterized proteins involved in metabolism.

DmCyp1 is the first cyclophilin in *Drosophila* that has been characterized with the previous (Sahu-Osen, 2015) and current work modulating LD size in larvae. Whereas, body fat storage in *Cyp1*¹ is not altered in larvae it remains to be addressed if this is also the case in adult flies. As only a portion of Cyp1::eGFP is loosely attached to LDs its exact localizations should be addressed in order to identify the underlying mechanism by which Cyp1 regulates LD size and to identify possible other biological processes it may modulates: *e.g.* metabolic rate, glycogen storage or glycolysis. Potential sites of residence are mitochondria that are often in close distance to LDs or the endoplasmic reticulum that has been described as a potential site for *de novo* lipid droplet synthesis (Zanghellini *et al.*, 2010, Krahmer *et al.*, 2011, Pol *et al.*, 2014, Wilfling *et al.*, 2014).

8 Selbständigkeitserklärung

Bestätigung zur eigenständigen Anfertigung der wissenschaftlichen Arbeit:
Hiermit bestätige ich die folgende Dissertation mit dem Titel:

“Function of the α/β -hydrolase fold family proteins Pummelig (CG1882) and hormone-sensitive lipase in the *Drosophila melanogaster* lipid metabolism “

selbstständig und ohne unerlaubte Hilfe/Hilfsmittel angefertigt zu haben.

.....
(Philip Hehlert, Ort, Datum)

9 Promovierenden-Erklärung

der Georg-August-Universität Göttingen
Name: Hehlert, Philip
Anschrift: Arndtstr. 1, 37075, Göttingen, Niedersachsen, Deutschland

Ich beabsichtige, eine Dissertation zum Thema

**Function of the α/β -hydrolase fold family proteins Pummelig (CG1882)
and Hormone-sensitive lipase
in the *Drosophila melanogaster* lipid metabolism**

an der Georg-August-Universität Göttingen anzufertigen. Dabei werde ich von Herrn

Prof.....Ernst Wimmer..... betreut.

Ich gebe folgende Erklärung ab:

1. Die Gelegenheit zum vorliegenden Promotionsvorhaben ist mir nicht kommerziell vermittelt worden. Insbesondere habe ich keine Organisation eingeschaltet, die gegen Entgelt Betreuerinnen und Betreuer für die Anfertigung von Dissertationen sucht oder die mir obliegenden Pflichten hinsichtlich der Prüfungsleistungen für mich ganz oder teilweise erledigt.

2. Hilfe Dritter wurde bis jetzt und wird auch künftig nur in wissenschaftlich vertretbarem und prüfungsrechtlich zulässigem Ausmaß in Anspruch genommen. Insbesondere werden alle Teile der Dissertation selbst angefertigt; unzulässige fremde Hilfe habe ich dazu weder unentgeltlich noch entgeltlich entgegengenommen und werde dies auch zukünftig so halten.

3. Die Richtlinien zur Sicherung der guten wissenschaftlichen Praxis an der Universität Göttingen werden von mir beachtet.

4. Eine entsprechende Promotion wurde an keiner anderen Hochschule im In- oder Ausland beantragt; die eingereichte Dissertation oder Teile von ihr wurden nicht für ein anderes Promotionsvorhaben verwendet.

Mir ist bekannt, dass unrichtige Angaben die Zulassung zur Promotion ausschließen bzw. später zum Verfahrensabbruch oder zur Rücknahme des erlangten Grades führen.

Göttingen, den

.....

Conference Contribution

German Fly Metabolism Meeting, 2015, University of Bonn; Oral presentation, Title: “Role of the α/β-hydrolase fold family protein Pummelig in lipid metabolism”

Education and working experience

- Since 06.2012 Doctoral Thesis, in the research group “Molecular Physiology” of Dr. Ronald Kühnlein in the Department “Molecular Development” at the “Max-Planck-Institute für biophysikalische Chemie”, Göttingen, Enrolled at the “Georg-August-Universität Göttingen, GGNB-Program: Genes and Development
- 03.05.2012 Acquisition of Master of Science degree of Biotechnology at LUAS
- degree: Master of Science
grade: 1,8 (good)
- 23.02.2011-03.05.2012 Master thesis at the research group: Molecular Physiology (MPI-BPC; Dr. Ronald Kühnlein) | topic: „Dynamics in Lipid Metabolism: a CARS Approach”
- grade: 1,4

01.03.2012- Matriculated at Lausitz University of Applied Science (LUAS); Senftenberg,
Master program: Biotechnology

18.02.2010 Acquisition of Bachelor of Science degree of Biotechnology at LUAS

degree: Bachelor of Science
grade: 2,2 (good)

01.08.2009-01.02.2010 Bachelor thesis at the junior research group: Real-time-PCR“ (Prof. Christian Schröder, Dr. Peter Schierack) | topic: „ Molecular analysis of the AC16 cell line generated from human adult ventricular cardiomyocytes

grade: 1,6

01.08.2008-01.03.2009 Practical term at MPI-CBG Dresden in the research group „Animal Models of Regeneration“ (Elly Tanaka) | topic: „Screening for genes specific for regeneration in *Ambystoma mexicanum*“

grade: 1,7

Since 01.03.2008 Tutor for younger students
2006 matriculated at LUAS

studies: B.Sc. Biotechnologie

2005-2006 Conscript to Bundeswehr; Luftwaffensicherungssoldat
1998-2005 Max-Planck Gymnasium Berlin-Mitte

degree: Baccalaureate
grade: 2,5

1996-1998 9th Primary school Berlin Mitte

1992-1996 2nd Primary school Berlin Mitte

Extracurricular education

2005-2006 Graduated training's course for „Stationsausbilder“ in the Bundeswehr

08.2005 Drivers licence class B

11.2005 Participated at: Simulation of the European Parliament (SIMEP) for the 2nd time

11.2004 Participated at: Simulation of the European Parliament (SIMEP)

11.2004 Attended a practical course at *Gläsernes Labor* Berlin

Grants and Stipends

- PhD Stipend from Max-Planck society (2012-2016)
- GGNB Travel Grant 2013

Language skills:

German - mother tongue
Englisch - very good reading, writing and verbal skills
Latein - Latinum

Computing literacy

- Organization and administration of Data-Storage system of the Research Group “Molecular Physiology”
- Windows and MacUser, limited experience with Linux
- Advanced knowledge in Word-, PowerPoint- and Excel
- Extended skills in Adobe Photoshop, Illustrator, Lightroom, InDesign
- Computer technics (Installation & Repairs)
- Basics in bioinformatics and primer design
- Use of OriginPro

Additional activities

- Student representative GGNB program Genes and Development (2014-2015)
- Student representative in Fachbereichsrat Bio- Chemie- und Verfahrenstechnik at LUAS
- Class representative in the 4th and 6th in primary school
- Engaged commitment in the public relations for the Max Plank Gymnasium

Interests

- Biology and medicine
- Volleyball (Active player in the “Mixed League Niedersachsen Süd” playing for “TSV Roringen”, cycling (Attendee of “Tour de Energy” and “Berlin Velothon”)
- Digital Photography (Canon, Fuji and Leica)
- Computer and technology
- Movies and cinema

Practical courses and laboratory skills

Practical courses during studies

inorganic chemistry
organic chemistry
physical chemistry
physics
microbiology
bioprocess engineering
biochemistry
technical microbiology
gene technology

Project work: Immunohistochemical detection of proliferation markers Ki-67 and MCM6 in genetically modified high proliferating and normal chondrocytes under different oxygen-levels

Lab course: „ Metabolic Analysis and Engineering “

Lab course: “Enzyme Technology”

Lab course: “Purification and Characterisation of Proteins”

Lab course: “Microbes as Macromolecule Factories”

Lab course: “Molecular biology: Principles, methods and applications”

Microbiology

- aseptic working under the flame and Laminar Air Flow
- Cultivation of different bacterial and fungal strands
- Isolation of pure fungal cultures from unsterile habitat samples
- Counting cells with THOMA-chamber
- Antibiotic sensitivity tests
- Cell preparation; Filtration, Centrifugation, French Press, working with liquid nitrogen
- Transforming bacteria, generation of chemo- und electro competent *E-coli*

Biochemistry

- SDS-Page
- Western-Blot
- FPLC und HPLC (His-tag und GST-tag purification)
- Bradford-Assay, BCA-Assay
- Coupled colorimetric assay (Glycerol measurement for fat determination)
- Thin layer chromatography
- Enzyme activity test via spectroscopy
- Triglyceride hydrolase assay + various neutral- and phospholipids
- Lipid extraction from *Drosophila* samples
- Lipid fractionation by solid phase extraction (SPE)
- Thin layer chromatography

Cell culture

- Passaging cells, Freezing, Thawing
- Cell-line used:
 - AC16, human chondrocytes, mouse fibroblasts, *Drosophila* S2 and Kc-167, COS-7, SF-9, Hi5

- Transfection of eukaryotic cells:
 - Electroporation, hiPerfect Transfection Reagent Qiagen, siPORT™ Amin Transfection Agent (Ambion), Nanofectin (PAA), Chen&Okayama (Calcium phosphate), X-treme Gene
- FACS (PI-staining)
- Antibody-staining after Fixation
- 2D and 3D-cultivation of highly proliferating chondrocytes and AC16 cells
- lacZ-assay, BrdU-staining, GFP-assay
- Fixation of living tissue from *Ambystoma mexicanum* and preparation of tissue sections with paraffin
- *Cryosectioning*
- siRNA knockdown of large T-Antigen in AC16 cells (first approaches on this cell line)
- Protein expression in COS-7 cells
- Protein expression in Sf-9 and Hi5 cells using Baculo-virus Expression system

Molecular biology

- PCR, RT PCR, qPCR, PCR with UDG-digestion, Primer design
- Agarose Gel-electrophoresis; Denaturing gradient gel electrophoresis (DGGE)
- Generation of RNA-Fragments for *in situ* hybridization, *in vitro* Transcription of RNA
- Generation of siRNA using Silencer® *siRNA* Cocktail Kit (RNase III)
- Mini-, Midi- und Maxi-Prep, Bacmid-Prep
- Restriction digestion, Blunt End reaction, de- und phosphorylation of DNA, DNA-Ligation
- Gate-way-cloning
- Gibson-Assembly cloning
- Genotyping of *Drosophila melanogaster*
- Experience with Micro beads using coupled DNA-Probes; hybridization assay

Microscopy

- LeicaSP2, Leica SP5, Leica SP5 HMS CARS, Leica GSDIM (Hands-on course)
- Zeiss LSM710
- Zeiss Axiophot Z1

Experience with animal systems:

- *Ambystoma mexicanum*
 - Basic animal keeping, surgical limb removal for regenerative time course studies
- *Drosophila melanogaster*
 - Basic fly husbandry
 - Basic genetic combinatorial skills
 - Application of Target-system
