List of abbreviations

A	Adenine
ACSF	Artificial cerebrospinal fluid
Allo	Allopurinol
AMC	Antimycin A
AMPA	α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid
AQP8	Aquaporin-8
ATP	Adenosinetriphosphate
BDNF	Brain-derived neurotrophic factor protein (human)
C	Cytosine
CA	Cornu ammonis
CA1	Cornu ammonis 1
CA3	Cornu ammonis 3
Ca ²⁺	Calcium ion
CaCl ₂	Calcium chloride
cAMP	Cyclic adenosine monophosphate
Cat	Catalase
CDKL5	Cyclin-dependent kinase-like 5 gene (human)
CN ⁻	Cyanide
CO ₂	Carbon dioxide
CpG	Cytosine-phosphate-guanine
cpYFP	Circularly permuted yellow fluorescent protein
CREB1	cAMP responsive element binding protein 1
CTD	C-terminal domain
cyto-roGFP1	Reduction/oxidation-sensitive green fluorescent protein 1 selectively targeting cytosol
DIV	Days <i>in vitro</i>
DG	Dentate gyrus
DMSO	Dimethyl sulfoxide
DNA	Deoxyribonucleic acid
DPI	Diphenyleneiodonium chloride
DTT	1,4-dithio-DL-threitol
e.g.	Exempli gratia

FAD	Flavin adenine dinucleotide
FCCP	Carbonyl cyanide 4-trifluoromethoxy)phenylhydrazone
FCS	Fetal calf serum
Fe ²⁺	Iron ion
<i>FOXG1</i>	Forkhead box protein G1 gene (human)
FRET	Fluorescence resonance energy transfer
GFP	Green fluorescent protein
GP	Glutathione peroxidase
GR	Glutathione reductase
GSH	Glutathione
GSSG	Glutathione disulfide
GST	Glutathione S-transferase
H ₂ O	Water
H ₂ O ₂	Hydroxyl peroxide
HBSS	Hanks' balanced salt solution
HDAC	Histone deacetylase
HEPES	4-(2-hydroxyethyl)piperazine-1-ethanesulfonic acid
HIF1 α	Hypoxia-inducible factor 1 alpha
HyPer	Hydroxyl peroxide sensor
IGF-1	Insuline-like growth factor 1
IsoPs	Prostaglandin-like-compounds
K ⁺	Potassium ion
KCl	Potassium chloride
KOH	Potassium hydroxide
LOI	Line of interest
MAP2	Microtubule associated protein 2 neuronal marker
MBD	Methyl-CpG-binding domain
MECP2	Methyl-CpG binding protein 2 protein (human)
<i>MECP2</i>	Methyl-CpG binding protein 2 encoding gene (human)
<i>Mecp2</i>	Methyl-CpG binding protein 2 encoding gene (mouse)
MeCP2	Methyl- CpG binding protein 2 protein (mouse)
MEM	Minimum essential medium
Mg ²⁺	Magnesium ion
MgCl ₂	Magnesium chloride

mGluR	Glutamate metabotropic receptor
MgSO ₄	Magnesium sulfate
mito-roGFP1	Reduction/oxidation-sensitive green fluorescent protein 1 selectively targeting mitochondria
mRNA	Messenger ribonucleic acid
N ₂	Nitrogen
Na ⁺	Sodium ion
Na ₂ SO ₃	Sodium sulfite
NaCl	Sodium chloride
NADH	Nicotinamide adenine dinucleotide
NADPH	Nicotinamide adenine dinucleotide phosphate
NaH ₂ PO ₄	Sodium phosphate
NaHCO ₃	Sodium bicarbonate
NaOH	Sodium hydroxide
NLS	Nuclear localization signal
NMDA	N-methyl-D-aspartate receptor
NO	Nitric oxide
NOX	NADPH oxidase
o/n	Overnight
O ₂	Oxygen
OH ⁻	Hydroxyl anion
ONOO ⁻	Peroxynitrite
PBS	Phosphate buffered saline
PCR	Polymerase chain reaction
PD	Postnatal day
PFA	Paraformaldehyde
Rh123	Rhodamine 123
roGFP1	Reduction/oxidation-sensitive green fluorescent protein 1
roGFP1c	Transgenic mouse line, carrying cytosolic roGFP1 specifically in neurons
ROS	Reactive oxygen species
rpm	Revolutions per minute
RT	Room temperature
rxYFP	Redox-sensitive yellow fluorescent protein

SD	Standard deviation
Sin3A	SIN3 transcription regulator family member A
SOD	Superoxide dismutase
SOD1	Cu-Zn-SOD; cooper, zinc superoxide dismutase (cytosol)
SOD2	Mn-SOD; manganian superoxide dismutase (mitochondria)
SOD3	EC-SOD (extracellular elements)
S-S	Disulfide bridge
SypHer	Modified, pH-sensitive and redox-insensitive variant of HyPer optical sensor (Hyper C199S)
T	Tymine
tBHP	Tert-butylhydroperoxide
TRD	Transcription repression domain
TRX1	Thioredoxin isoform 1
TRX2	Thioredoxin isoform 2
Trx	Thioredoxin reductase
<i>Ugcrc1</i> (mouse)	Ubiquinol-cytochrome c reductase core protein 1 gene
UTR	Untranslated region
WT	Wildtype
XDH	Xanthine dehydrogenase
XO	Xanthine oxidase
YFP	Yellow fluorescent protein
$\cdot\text{O}_2^-$	Superoxide
$\cdot\text{OH}$	Hydroxyl radical
3`	3-phosphate-end

Summary

Rett syndrome is a neurodevelopmental disorder that primarily occurs in girls with a prevalence of 1:10.000–1:15.000 live births. The main genetic reasons of Rett syndrome are mutations in the methyl-CpG binding protein 2 (*MECP2*) gene. After a short, but normal development, a Rett child falls into developmental stagnation, which is followed by neuronal and autonomic dysfunction, and manifests as mental retardation, breathing impairment, epilepsy, loss of speech, mobility disturbances and stereotypical hand movements. Growing evidence shows that Rett syndrome is associated with mitochondrial dysfunction and oxidation stress. Mitochondria of *MeCP2*-deficient (*Mecp2*^{-/-}) mouse brain have been previously confirmed to be partly uncoupled and to show increased respiratory rates. More oxidized baseline conditions, exaggerated responses to oxidants and mitochondrial inhibition have been detected in the hippocampus of *Mecp2*^{-/-} mice. To unveil the molecular causes of this redox imbalance specifically in neurons, and to enable a quantitative live-cell imaging of sub-cellular redox dynamics, viral vectors, expressing the genetically-encoded optical redox sensor reduction/oxidation-sensitive green fluorescent protein 1 (roGFP1) in cytosol and mitochondrial matrix have been generated. For quantitation, the ratiometric responses of roGFP1s were calibrated to full oxidation and reduction in mitochondrial and cytosolic compartments. Detailed fluorescence microscopy and two photon imaging confirmed that mitochondrial and cytosolic redox baselines were more oxidized in *Mecp2*^{-/-} hippocampal neurons. Redox challenge induced by hydrogen peroxide (H₂O₂) and severe hypoxia elicited intensified oxidizing and reducing transients in *Mecp2*^{-/-} neurons, respectively. Moreover, inhibition of superoxide dismutase (SOD) caused a less intense oxidation in *Mecp2*^{-/-} cytosol and mitochondria, suggesting a decreased efficiency of this scavenging enzyme in Rett mice. Interestingly, differences among wildtype (WT) and *Mecp2*^{-/-} mice were evident especially in the more complex organotypic slices, and they occurred already at neonatal stages in mitochondria and the cytosol. Furthermore, the current work is the first study, showing a pronounced shift towards more oxidizing conditions in *Mecp2*^{-/-} neurons in response to different

neurotransmitters. Taking advantage of the recently generated transgenic mouse lines, stably expressing roGFP1 in neuronal cytosol, the redox changes could be also confirmed for hippocampal neurons of adult and symptomatic *Mecp2*^{-y} mice. Taken together, roGFP1 responds reliably to oxidation and reduction, and it allows for semi-quantitative recordings of redox changes specifically in neurons. Since mitochondria are a primary source of reactive oxygen species (ROS), and the neuronal mitochondria of *Mecp2*^{-y} hippocampus revealed a more oxidizing and more vulnerable redox balance, this supports the hypothesis that mitochondrial dysfunction underlies the oxidative burden in Rett syndrome and drives potentially disease progression. Moreover, the roGFP1 transgenic mice will extend quantitative redox imaging to all postnatal stages and more complex preparations. This will enable studying disease progression and redox conditions throughout the brain of maturing Rett and WT mice.

1. Introduction

1.1. Pathology of Rett syndrome

Rett syndrome is a progressive, postnatal and neurodevelopmental disorder which was originally described by the Austrian paediatrician Andreas Rett as an 'unusual brain atrophy syndrome' in 1966 (Rett 1966; Hagberg et al. 1983). This X-linked disorder affects predominantly girls with a prevalence of approximately 1:10.000-1:15.000 live births worldwide, and is apparently lethal in male embryos. However, individual cases of Rett syndrome in male patients were also reported (Wan et al. 1999; Clayton-Smith et al. 2000; Meloni et al. 2000; Orrico et al. 2000; Villard et al. 2000).

Four main stages constitute the typical disease progression, spanning from normal development through developmental and neuronal stagnation up to rapid regression, and final motor deterioration (Chahrour and Zoghbi 2007). Rett girls develop properly during the first 6-18 months. Hence, the first step of Rett syndrome often might be not even noticed. While fine motor functions develop, head growth and circumference starts to decelerate (Schultz et al. 1993). Along with an acquired microcephaly, general growth retardation is followed by a loss of weight and muscle hypotonia. With the onset of the rapid regression, patients start losing hand skills, developing stereotypic hand movements such as washing movements, clapping, wringing, flapping or putting hands into the mouth (Chahrour and Zoghbi 2007; Weng et al. 2011). Furthermore, motor abnormalities together with seizures, loss of speech and social interaction occur and patients fall into a stationary, and late motor deterioration stage. They also acquire additional symptoms such as scoliosis, mental retardation, autism, epilepsy, sleep disturbances and anxiety (Chahrour and Zoghbi 2007). Other characteristic features, which might associate with the disease are teeth grinding, laughing or crying at night and screaming episodes (Young et al. 2007; Weng et al. 2011).

Furthermore, although the lifespan of Rett patients is very diverse and some individuals might even reach their 60s (Hagberg et al. 2001; Hagberg 2005), life expectancy might be highly reduced due to serious breathing

complications, which is one of the hallmarks of Rett syndrome (Kerr et al. 1997; Julu et al. 2001; Acampa and Guideri 2006). The respiratory abnormalities appear in the rapid regression stage of the disease and include breath-holding, aerophagia, forced expulsion of air and saliva as well as frequent apnoeas (Chahrour and Zoghbi 2007).

Impaired regulation of normal brain development might arise from changes in various neurotransmitters and neuropeptides such as altered levels of dopamine (Zoghbi et al. 1985; Brucke et al. 1987; Zoghbi et al. 1989; Lekman et al. 1990; Percy 1992), serotonin (Segawa 1997), noradrenaline, acetylcholine (Wenk and Mobley 1996; Wenk 1997; Wenk and Hauss-Wegrzyniak 1999), nerve growth factor (Lappalainen et al. 1996; Riikonen and Vanhala 1999), endorphins, substance P (Matsuishi et al. 1997; Deguchi et al. 2000), glutamate (Hamberger et al. 1992; Lappalainen and Riikonen 1996) and other aminoacids as well as their receptor expression levels (Jellinger 2003; Acampa and Guideri 2006). Altered neurotrophin signalling together with reduced serotonin plasma and substance P levels may lead to disturbances in the autonomic nervous system. This causes cardiac autonomic nervous system alterations, sympathetic imbalance and reduced cardiac vagal tone, each of which contributes to life threatening cardiac arrhythmias. In fact, sudden death represents ~25% of mortality rate among Rett patients (Kerr et al. 1997; Julu et al. 2001; Acampa and Guideri 2006).

So far, reports have shown a reduced size of the brains of Rett patients (Armstrong 2005). Moreover, neuronal size in cortex, thalamus, basal ganglia, amygdala and hippocampus has been reported to be decreased (Bauman et al. 1995). Also, studies on cerebral cortex indicated a less complex dendritic arborisation and decreased numbers of dendritic spines. Furthermore, less afferent axons were found in Rett mice as well as in patients (Belichenko et al. 1994; Belichenko and Dahlstrom 1995; Belichenko et al. 2009).

Although obvious brain structural and functional impairments in Rett syndrome are manifesting, no clear neuronal or glial cell atrophy or degeneration as well as no gliosis, demyelization or disruption of neuronal

migration have ever been reported. Therefore, Rett syndrome is not considered as a neurodegenerative disorder (Jellinger et al. 1988; Reiss et al. 1993; Armstrong 2005).

1.2. Genetic cause of Rett syndrome

Mutations in the *MECP2* gene, encoding the methyl-CpG binding protein 2 (MECP2), are the primary cause of Rett syndrome, and they have been confirmed in more than 95% of typical cases of this disorder (Amir et al. 1999). *MECP2* is located on chromosome X in the Xq28 band position and it consists of four exons. Due to alternative splicing of exon 2 and alternative use of the polyadenylation sites in the 3' untranslated region (3'UTR), two different variants of *MECP2* transcripts can be created. It has been shown that expression of the MECP2-e1 longer transcript in brain is high especially during embryonic development, but it decreases in the postnatal period, and increases again in adulthood (Shahbazian et al. 2002; Pelka et al. 2005).

De novo mutations in *MECP2* occur in the male germline, and therefore they are transmitted from the father (Trappe et al. 2001). Mutations of *MECP2* involve transition of C to T at CpG dinucleotides (Wan et al. 1999; Trappe et al. 2001), and include missense, nonsense and frameshift mutations as well as entire exons' deletions (Christodoulou et al. 2003; Archer et al. 2006). Although Rett syndrome is a sporadic disorder, arising from spontaneous sperm mutations, ~1% of reported cases support a genetic basis for the disease and a damaged copy of *MECP2* from one inheritance of generation to the next (Zoghbi 1988; Schanen et al. 1997).

However, also atypical forms of Rett syndrome exist. They arise from mutations in the cyclin-dependent kinase-like 5 (*CDKL5*) gene (Tao et al. 2004; Weaving et al. 2004; Weaving et al. 2005; Archer et al. 2006). Moreover, congenital variants of Rett syndrome are caused by mutations in the forkhead box protein G1 (*FOXG1*) gene (Ariani et al. 2008).

1.3. MeCP2 protein – structure, function and expression

MeCP2 is a 53 kDa protein and it is a member of the methyl-CpG binding protein family (Hendrich and Bird 1998). It consists of three main domains: methyl-CpG binding domain (MBD), transcriptional repression domain (TRD) with two nuclear localization signals (NLSs), and C-terminal domain (CTD) (Figure 1).

Figure 1. MeCP2 structure.

The MeCP2 protein consists of three main domains, and two of them are especially important for MeCP2 function: methyl-CpG binding domain and transcriptional repression domain, which includes two nuclear localization signals. Third domain of MeCP2 is the C-terminal domain.

The MBD domain binds specifically to methylated CpG dinucleotides, allowing therefore for MeCP2-chromatine interactions and chromatine modulations. However, the presence of adjacent A/T base pairs for efficient MeCP2-DNA binding is mandatory (Klose et al. 2005). Yet, an equally efficient methylation-independent form of MeCP2-DNA binding was also identified (Galvao and Thomas 2005). The TRD domain consists of residues that were originally thought to be required only for transcriptional repression (Nan et al. 1997). The hypothesis of transcriptional silencing (Figure 2 A) is based on the binding of SIN3 transcription regulator family member A (Sin3A) to MeCP2 protein, which recruits histone deacetylases (HDACs) and mediates post-transcriptional modifications of histone tails (Chahrour et al. 2008).

On the other hand, MeCP2 acts also as a transcriptional activator (Figure 2 B), and by microarray analysis it was found to activate the majority (~85%) of genes in the hypothalamus (Chahrour et al. 2008). Also, mass spectrometry analysis revealed that the cAMP responsive element binding protein 1 (CREB1) is the major co-activator, which binds to MeCP2 protein and thus,

allows for a successful transcription of target genes (Chahrour et al. 2008). The CTD domain of MeCP2 is not yet completely known. Nevertheless, data on mice lacking the CTD domain show that CTD is necessary for proper MeCP2 function and facilitates the MeCP2-DNA binding processes (Shahbazian et al. 2002).

Figure 2. MeCP2 acts as a transcriptional repressor and activator.

A) The TRD domain of MeCP2 binds to the Sin3A co-repressor and recruits HDAC, causing transcriptional repression of MeCP2 target genes.

B) Due to interaction of MeCP2 with co-activators such as CREB1, successful transcription of MeCP2 target genes may take place.

From Chahrour M, Jung SY, Shaw C, Zhou X, Wong ST, Qin J, Zoghbi HY. MeCP2, a key contributor to neurological disease, activates and represses transcription. *Science* 2008; May 30; 320(5880):1224-9. Reprinted with permission from AAAS.

MeCP2 is a nuclear and multifunctional protein. Apart from its role in transcriptional repression and activation as well as chromatin modulation, it modulates neuronal development and neuronal differentiation. Studies on MeCP2 expression have confirmed a changing pattern of MeCP2 protein levels. MeCP2 expression is low during embryogenesis and increases during neuronal maturation at the postnatal stage, finally reaching its peak in mature neurons (Shahbazian et al. 2002; Balmer et al. 2003; Cohen et al. 2003; Kishi and Macklis 2004; Mullaney et al. 2004). Thus, it has been suggested that MeCP2 is involved in modulation of general activity and/or plasticity of mature neurons (Chahrour and Zoghbi 2007). Furthermore, MeCP2 was reported to modulate RNA splicing (Young et al. 2005).

1.4. Animal models of Rett syndrome

Over the years, various mouse models of Rett syndrome have been developed and they include *Mecp2* knockout, *Mecp2* mutant and *MECP2* knock-in mice.

The 'Bird strain' *Mecp2*^{tm1.1Bird}, which was used in this study, represents a *Mecp2*-deficient mouse model. Its *Mecp2* gene lacks exons 3 and 4 and therefore, it remains completely dysfunctional with no expression (Guy et al. 2001). Mouse strain *Mecp2*^{tm1Tam}, which was generated by removal of the coding sequence of the MBD domain of MeCP2, constitutes another *Mecp2*-null mouse (Pelka et al. 2006). The *Mecp2*-null male mice develop hindlimb clasping and reduced spontaneous movements, growth arrest, uncoordinated gait, irregular breathing and increased mortality (Guy et al. 2001). These mice die around postnatal day (PD) 50. Moreover, studies on brain sections from cerebral cortex, cerebellum and hippocampus showed smaller size and increased density of neuronal cell bodies and nuclei (Chen et al. 2001; Fischer et al. 2009). The *Mecp2*-null females represent only the minimal initial phenotype. They regularly take care of their offspring, live more than a year and develop clinical features only with a marked delay (Guy et al. 2001).

The group of *Mecp2* mutant mouse models are mice that express only a truncated MeCP2 protein, cell-type-specific *Mecp2* deletions and mutations or reduced levels of *Mecp2* (Calfa et al. 2011). The *MECP2* knock-in mice carry human *MECP2* mutations associated with Rett syndrome and hence, they represent a cohort of experimental animal models mimicking the specific mutations of Rett syndrome in humans (Lawson-Yuen et al. 2007; Jentarra et al. 2010; Wegener et al. 2014). So far, all of the developed mouse models of Rett syndrome reveal behavioural symptoms and clinical features that are associated with the disease (Ricceri et al. 2008; Tao et al. 2009). Yet, they clearly differ in the severity of symptoms and the time course at which they appear.

Interestingly, a novel *Mecp2* knockout rat model of Rett syndrome has recently become available, and very first studies on neuronal behavioural processing of communication in Rett syndrome have been performed (Engineer et al. 2015). However, it should be mentioned that none of the various rodent models fully corresponds to the complex clinical conditions of the human disorder.

1.5. Breathing impairment and mitochondriopathy in Rett syndrome

It is commonly known, that Rett syndrome is associated with severe and life-threatening breathing irregularities, causing a sudden death (Kerr et al. 1997; Julu et al. 2001; Acampa and Guideri 2006). Also, the *Mecp2*^{tm1.1Bird}-null mouse model (Guy et al. 2001) for Rett syndrome shows such respiratory disruptions. After PD 20 these *Mecp2*-deficient mice develop erratic breathing characterized by alternating fast and slow breathing frequencies as well as long-lasting apnoeas, resulting in drops of arterial oxygen saturation defined as intermittent systemic hypoxia (Julu et al. 2001; Viemari et al. 2005; Ogier and Katz 2008; Stettner et al. 2008; Katz et al. 2009).

Recent data suggest an enhanced hypoxia susceptibility of neuronal networks of hippocampus and brainstem in *Mecp2*-null mice. As possible underlying mechanisms, contributing to this increased hypoxia susceptibility, disruption of K⁺ channel function as well as an imbalance in Ca²⁺ homeostasis were proposed (Fischer et al. 2009; Mironov et al. 2009; Kron and Müller 2010; Kron et al. 2011). Also, since mitochondria are actively involved in the Ca²⁺ uptake and Ca²⁺ release pathways (Duchen 2000; Brookes et al. 2004), it is tempting to take a closer look at these organelles.

Indeed, various signs of mitochondrial pathology have been found in tissue samples from Rett patients and mouse models. A case report on the frontal lobe biopsy tissue of a Rett individual at age 3 showed impaired mitochondrial morphology, which became evident due to numerous large and spherical mitochondria, low-density structure of mitochondrial matrix, few rudimentary

cristae and abundant ribosomal content. Moreover, electron microscopy studies on brain post-mortem tissue from the same 15 years old patient showed granular matrix inclusions and disorganized membranous material (Cornford et al. 1994). Basing on muscle biopsy material, also mitochondrial distention, vacuolisation as well as irregular cristae were uncovered by other studies (Ruch et al. 1989; Eeg-Olofsson et al. 1990).

Apart from morphological studies, strong evidence of mitochondrial enzyme impairment has been also reported (Coker and Melnyk 1991; Gibson et al. 2010). Enzyme assays performed on muscle biopsy material revealed lower levels of cytochrome *c* oxidase and succinate cytochrome *c* reductase in three Rett girls (Coker and Melnyk 1991). Furthermore, the cytochrome *c* oxidase subunit 1 was downregulated in the frontal cortex of *Mecp2*-deficient mice (Gibson et al. 2010).

Mitochondrial impairment has been confirmed also on the gene level. Gene expression profiles, which were performed on the peripheral blood lymphomonocytes from Rett patients by using microarray assays, suggest misregulation of 482 genes, out of which 146 genes are involved in mitochondrial function, ubiquitination, proteosome degradation, mitochondrial organisation, ATP-synthesis, chromatin modulation and RNA processing (Pecorelli et al. 2013). Moreover, expression analyses performed on Rett mice identified an overexpression of the ubiquinol-cytochrome *c* reductase core protein 1 (*Uqcrc1*), which encodes for a complex III subunit of the mitochondrial respiratory chain, and whose promoter interacts with MeCP2 (Kriaucionis et al. 2006). Along with these findings, a potential uncoupling and 30% more intensified respiration rates of isolated brain mitochondria were identified. However, due to various tissue processing and mRNA extraction protocols, microarray studies might lead to differing results and quite variable gene expression patterns. Moreover, it should be mentioned, that a change on the gene level does not always correspond to a downstream modulation of protein activity (Li et al. 2013).

Evidence for altered mitochondrial function as well as oxidative changes has been also reported by our group. An increased FAD/NADH autofluorescence ratio in both neonatal and adult Rett mice was detected, confirming more intensively respiring mitochondria (Großer et al. 2012; Müller and Can 2014). Based on blood analyses on human patients, a reduced activity of the scavenging enzyme SOD (Sierra et al. 2001) and decreased levels of vitamin E were identified, which also plays an important role in the cellular scavenging system (Formichi et al. 1998).

Other evidence for a functional impairment of mitochondria in Rett syndrome includes variations in mitochondrial ATP production and energy disturbances. Indeed, Saywell and colleagues showed decreased ATP levels in Rett mice, which was detected by using magnetic resonance imaging (Saywell et al. 2006). Our group could, however, not confirm these observations as no significant changes in ATP levels between adult hippocampus of *Mecp2*-null and the respective WT tissue have been observed (Fischer et al. 2009). Interestingly, increased cellular ATP levels and more intensified ATP turnover have been recently reported for neonatal *Mecp2*-deficient hippocampus by using the ATP-specific genetically-encoded sensor Ateam 1.03 (Toloe et al. 2014).

1.6. Reactive oxygen species

Mitochondria are considered to be one of the most important and major generators of superoxide ($\cdot\text{O}_2^-$) (Loschen et al. 1971; Boveris et al. 1972). Approximately 2-5% of electrons escape during the electron transit within the respiratory chain from complex I to complex IV and bind to molecular oxygen, forming thereby $\cdot\text{O}_2^-$ and contributing to the secondary production of other reactive oxygen species (ROS) such as hydroxyl radicals ($\cdot\text{OH}$) at complexes I and II (Boveris and Chance 1973).

Superoxide anions are highly unstable and reactive molecules. They rapidly convert into the somewhat less reactive H_2O_2 . The H_2O_2 might form $\cdot\text{OH}$ and hydroxyl anions (OH^-) in the presence of iron (Fe^{2+}) due to electron

acceptance from a transition metal in a Fenton reaction. Furthermore, it can generate peroxynitrite (ONOO^-) in a reaction with nitric oxide (NO) (Dean et al. 1997; Lipton and Nicotera 1998) (Figure 3).

Figure 3. ROS generation and cellular scavenging systems

A) The respiratory chain complexes I and III generate $\cdot\text{O}_2^-$ due to the electron (\bar{e}) flow in mitochondria.

B) The superoxide dismutase (SOD); catalase (Cat), thioredoxin reductase (Trx); glutathione peroxidase (GP), glutathione reductase (GR) and glutathione S-transferase (GST) constitute the main components of the cellular anti-oxidant defence. GSH represents monomeric glutathione, and GSSG represents the oxidized glutathione disulfide. NO, nitric oxide; ONOO^- , peroxynitrite.

Generation of ROS within mitochondria is constant and low levels of ROS play an important role in cellular physiology. ROS were proven to participate in various cellular signalling pathways, e.g. the control of the vascular tone in the brain (Demchenko et al. 2002). Furthermore, they take part in host defence and cellular proliferation, and they are also involved in aging and cell apoptosis processes (Sinha et al.; Harman 2003; Kroncke 2003; Nathan 2003; Finkel 2011; Sinha et al. 2013).

However, any imbalance in ROS production due to mitochondrial dysfunction, e.g. enhanced mitochondrial activity, respiratory chain inhibition or disruption in the cellular ROS neutralization systems, leads to oxidative stress, and may therefore seriously threaten cell viability or cell function (Sies 1991; Halliwell and Cross 1994). Due to oxidation challenge, highly activated ROS constitute stress signals, causing DNA damage, protein nitrosylation, lipid peroxidation and alterations in DNA methylation level, and finally changes in gene expression (Weitzman et al. 1994) (Figure 4). Yet, the severity of cellular changes due to ROS interference depends on the exact type of ROS. Whereas H_2O_2 seems to be less harmful, $\text{O}_2^{\cdot-}$, $\cdot\text{OH}$ and ONOO^- are considered to be very aggressive in their reactivity (Halliwell and Gutteridge 1984; Lipton 1999; Chan 2001; Foster et al. 2006).

To prevent intensified ROS accumulation, cells developed various enzymatic defence systems, e.g. catalase (Cat), superoxide dismutases (SOD1, SOD2, SOD3), glutathione peroxidase (GP), glutathione S-transferases (GST), glutathione reductase (GR), peroxiredoxins (Prxs), glutaredoxin and two thioredoxin isoforms (TRX1 and TRX2). Also, non-enzymatic scavengers take part in the cell endogenous protection against ROS, e.g. glutathione disulfide (GSH) thioredoxin, α -tocopherol (vitamin E), ascorbic acid (vitamin C), beta carotene, uric acid and melatonin (Sinha et al.; Milton and Sweeney 2011; Sinha et al. 2013) (Figure 3).

Figure 4. ROS as a potential source of cellular damage

A) Healthy mitochondria generate only low levels of ROS and downstream reactive nitrogen species (RNS). Redox balance is guaranteed due to properly functioning cellular scavenging systems.

B) Impairment of mitochondria or less efficient scavenging capabilities may, however, give rise to abnormally intensified generation of ROS. This unequivocally culminates in aberrant redox conditions and oxidative stress, and therefore, it may cause profound cellular damage.

This research was originally published in Portland Press Limited. Müller M, Can K. Aberrant redox homoeostasis and mitochondrial dysfunction in Rett syndrome. 2014 Aug; 42(4):959-64, Biochemical Society Transactions.

1.7. Oxidative stress in Rett syndrome and oxidative stress markers

Cellular alterations elicited by ROS have been confirmed in various neurodevelopmental and neurodegenerative disorders (Fernández-Checa et al. 2010). For example, oxidative damage was proven to play a substantial role in the development of Alzheimer's disease, Parkinson's disease, Huntington's disease or Amyotrophic lateral sclerosis (Zhang et al. 1999; Rahman et al. 2012). Oxidative stress can provoke neuronal cell dysfunction and/or neuronal death and therefore, it might drive disease progression. Hence, studies on the detailed effects mediated by ROS constitute a central focus of research over the last years.

Also for Rett syndrome, extended studies have confirmed an involvement of oxidative stress. Already in 1987, reduced levels of ascorbic acid and

glutathione were found in post-mortem brain tissue of Rett patients (Sofić et al. 1987). Furthermore, lipid peroxidation and significantly elevated plasma protein carbonyl levels as well as increased hypoxia-induced oxidative stress were demonstrated in patients with typical Rett syndrome (De Felice et al. 2009). Furthermore, studies on Rett patients clearly indicated mutations in target genes of MeCP2 such as the brain-derived neurotrophic factor (BDNF) and CREB (De Felice et al. 2009). These genes were proven to be involved not only in neuronal protection against hypoxia, but also in ROS scavenging (Lee et al. 2009; Pereira et al. 2009). In addition, recent data pointed out an important role of the insulin-like growth factor 1 (IGF-1). It mediates neuroprotection against oxidative stress under control conditions (Heck et al. 1999), and it has been also shown to partially reverse some of the Rett syndrome-like symptoms by e.g. improved spine density, synaptic potential restoration and cortical plasticity stabilization (Tropea et al. 2009). Moreover, further evidence of a direct connection between MeCP2 and oxidative stress was reported by the group of Valinluck as the affinity properties of the MBD domain of MeCP2 were found to be inhibited by oxidative damage (Valinluck et al. 2004). Accordingly, such ROS-mediated changes might therefore culminate in epigenetic DNA damage and disrupt chromatin organization.

Further investigations of parameters, which might be involved in functional neuronal disruptions in Rett syndrome, revealed changes in the antioxidant defence responses. For example, SOD activity was found to be significantly decreased in erythrocytes of Rett patients (Sierra et al. 2001). Following these studies, other data showed critically increased levels of malondialdehyde – a marker for content lipid peroxidation – also in Rett individuals. This could possibly lead to peroxidative damage of cellular membranes, and finally in consequence to progression of dementia, impaired motor function, changes in behaviour and seizure incidence (Ross 2000; Sudha et al. 2001). Nevertheless, there are numerous and currently available oxidative stress markers that are specific for pro-oxidant factors, lipid peroxidation and protein oxidation as well as for mitochondrial impairment, enzyme activity and gene expression (De Felice et al. 2012). Among this large group of biomarkers, isoprostanes (IsoPs) – the prostaglandin-like

compounds – represent a reliable class of bioproducts of oxidative imbalance (Kadiiska et al. 2005). They originate from the peroxidation of polyunsaturated fatty acid precursors and fulfil a diversity of biological functions. For example, they take part in inflammatory responses and act as pain mediators or neuromodulators (Jahn et al. 2008; Milne et al. 2011). Additionally, reduced vitamin E concentrations were identified in Rett patients' serum, suggesting less efficient antioxidant capacity in Rett syndrome (Formichi et al. 1998).

1.8. Imaging of reactive oxygen species – outline of redox sensors

Over the years, various dyes and ROS/redox sensors for imaging of ROS formation and/or oxidative stress detection became available. Compounds such as dichlorodihydrofluorescein (LeBel et al. 1992) dihydroethidium (Gallop et al. 1984) and Amplex Red (Mohanty et al. 1997) accumulate in the cytosol after entering a cell and become fluorescent once being oxidized due to cellular ROS production.

To evaluate and detect ROS/redox changes directly in mitochondria, other synthetic dyes targeting the mitochondrial matrix were generated, namely dihydrorhodamine (Dugan et al. 1995), RedoxSensor Red CC-1 Stain (Chen and Gee 2000), MitoSOXRed (Robinson et al. 2006), and the MitoTracker probes, e.g. MitoTracker Red CM-H₂XROS, MitoTracker Orange CM-H₂TMROS (Esposti et al. 1999). Due to very intense fluorescence of these synthetic dyes, mitochondrial morphology as well as tracking of mitochondrial particles and mitochondrial content might be also assessed within a single cell (de la Monte et al. 2000; Stamer et al. 2002). All of these redox indicators become intensively fluorescent only upon oxidation. But this conversion is irreversible. Moreover, any sensitivity of these dyes to reducing conditions is lacking. Thus, quantifiable evaluation of cellular ROS levels and/or redox changes is not achievable. Although these ROS dyes are relatively easy to handle and sufficient cell loading occurs within minutes, other disadvantages such as fast photo-bleaching, auto-oxidation, and/or accumulation in other

compartments restrict a reliable functional analysis of ROS levels and their changes within a cell.

Yet, the genetically-encoded optical redox indicators are more reliable as they react to both oxidation and reduction, allowing therefore for a quantitative assessment of cellular ROS/redox changes. Moreover, they overcome most of the problems associated with photobleaching and cell movements, and they can be designed to target a specific type of cells, defined cellular compartments or even particular parts of protein (Gutscher et al. 2008). These optical sensors derive from the green and yellow fluorescent proteins (YFP, GFP). Redox-sensitive properties of these indicators are achieved by specific structural modification of the native YFP and GFP – redox-sensitive yellow fluorescent protein (rxYFP) and reduction/oxidation-sensitive green fluorescent protein (roGFP) (Ostergaard et al. 2001; Hanson et al. 2004). Mainly, it is the insertion of reactive cysteines within the fluorescent proteins, which generate a functional switch between the oxidized and reduced forms of the protein. The fluorescent hydroxyl peroxide (HyPer) sensor (Belousov et al. 2006) together with the fluorescence resonance energy transfer (FRET) constructs such as CFP-HSP33-YFP (Guzy et al. 2005), CFP-RL5-YFP (Kolossoff et al. 2008) and Redoxfluor (Cerulean –Yap1-Citrine)(Yano et al. 2010) are also members of the group of genetically-encoded optical probes. Nevertheless, especially the optical sensor roGFP1 is used for quantitative and dynamic redox imaging by our group. Since roGFP1 responds reversibly to oxidation/reduction due to the functional thiol switch, and reacts similarly to other redox-sensitive proteins, it may give detailed information on the other redox-modulated endogenous proteins. So far, our group confirmed reliable responses of roGFP1 in both murine and rat hippocampal neurons in a variety of oxidizing and reducing conditions. Moreover, in terms of response reliability, data from our laboratory ruled out any significant effects of intracellular pH or Cl⁻ changes on roGFP1 (Funke et al. 2011; Großer et al. 2012). Further details about roGFP1 and HyPer sensors are given in the following Materials and Methods section.

2. Aims of this Thesis

Although the literature is constantly growing with new findings on mitochondrial impairment, those mechanisms leading to MeCP2 dysfunction and Rett syndrome progression are still lacking detailed explanation. A variety of open questions, regarding a direct connection between oxidative stress and Rett syndrome as well as the molecular causes of oxidative imbalance, and the very reasons for damaged mitochondria still need to be answered.

The aim of this thesis was to analyze redox changes in *Mecp2*^{-/-} mice specifically in primary cultured hippocampal neurons as well as in organotypic hippocampal slices. The hippocampal formation is an established model for metabolic insults, neurodegeneration, mitochondrial and cellular signalling dysfunction, and it has been proven to respond more sensitively than other tissues to oxidative challenge (Wilde et al. 1997; Wang et al. 2007). Since the mitochondrial matrix constitutes the primary cellular source of ROS, and since ROS might be further released from mitochondria into the cytosol within a cell (Brand 2010), evaluation of redox changes in both mitochondrial and cytosolic compartments was considered to be mandatory.

Therefore, the main objectives of the current thesis were:

1. First of all, in order to analyse sub-cellular redox changes within neurons, a suitable and reliable redox indicator had to be chosen.
2. To investigate mitochondrial and cellular redox changes specifically in hippocampal neurons, viral vectors carrying the respective cytosolic and mitochondrial optical redox-sensor roGFP1 were established to optimize expression levels and the selectivity of redox sensor expression.
3. Detailed calibration of the selected redox sensor roGFP1 was performed to enable quantitative recordings of redox balance.

4. Redox responses were assessed upon control and stress conditions, e.g. hypoxia, oxidative challenge, blockade of the scavenging enzyme SOD, mitochondrial respiration inhibition and application of various neurotransmitters to define altered responses in *Mecp2*^{-/-} neurons.
5. To analyse further sub-cellular changes of *Mecp2*^{-/-} and WT neurons, local neuronal stimulation was performed, using both pressure drug ejection and extracellular electrical stimulation.
6. To decipher potential candidate processes, underlying the detected redox alterations in *Mecp2*^{-/-}, contribution of signalling pathways such as Ca²⁺ influx, role of mitochondria, involvement of NADPH oxidase and xanthine oxidase as well as an activation of G-proteins were analyzed.
7. To extend quantitative redox imaging to adult *Mecp2*^{-/-} mice, the cross-breeding of the recently generated transgenic roGFP1c mice with *Mecp2*^{+/-} mice has been started to be able to correlate redox imbalance with disease progression of Rett syndrome.

3. Materials and Methods

All experiments were conducted in accordance to German national regulations. The tissue isolation and the *in vitro* experiments were approved by the office for animal welfare of the Universitätsmedizin Göttingen “Anoxie und neuronale Netzwerke (T13-08)”.

3.1. Solutions and pharmacological compounds

Usually, chemicals obtained from Sigma-Aldrich were used, in other cases this is clearly stated.

To maintain viability of primary hippocampal cell and organotypic slice culture during particular experiments, the artificial cerebrospinal fluid (ACSF) was used. It was composed of (in mM) 130 NaCl, 3.5 KCl, 1.25 NaH₂PO₄, 24 NaHCO₃, 1.2 CaCl₂, 1.2 MgSO₄ and 10 dextrose. During the entire experiment, the ACSF was constantly aerated with carbogen (95% O₂, 5% CO₂) in order to guarantee the constant oxygenation of cell and slice cultures, and to preserve a stable pH of 7.4.

In order to challenge cell and slice cultures by various oxidizing and reducing conditions, different drugs were administered. These include: H₂O₂ (30% stock solution in H₂O), diethyldithiocarbamic acid (DEDTC), 1,4-dithio-DL-threitol, (DTT, Fluka), antimycin A (AMC, 20 mM stock solution in ethanol, stored at -20°C), dimethyl sulfoxide (DMSO), propionate, tert-butylhydroperoxide (tBHP, 70% stock solution in H₂O), forskolin (20 mM stock solution in DMSO, stored at -20°C, Bio Trend), carbonyl cyanide-4(trifluoromethoxy)phenylhydrazone (FCCP, 10 mM stock solution in DMSO, stored at 4°C, Tocris Bioscience), diphenyleneiodonium chloride (DPI, 10 mM stock solution in DMSO, stored at -20°C, Tocris Bioscience) and cyanide (CN⁻, 1 M stock solution in H₂O, stored at -20°C). Glutamate (5 mM stock solution in H₂O, stored at -20°C), norepinephrine, serotonin, dopamine and allopurinol were immediately dissolved in ACSF in their final concentrations right before use.

To calibrate the pH-sensitive optical sensor SypHer, a calibration solution was prepared from (in mM) 130 KCl, 1.2 CaCl₂, 1.2 MgCl₂, 10 glucose, 20 4-(2-hydroxyethyl)piperazine-1-ethanesulfonic acid (HEPES) and adjusted up to pH 7.0 by NaOH, in order to mimic intracellular ionic conditions. The final calibration solutions were adjusted with KOH to the respective pH: 7.0, 7.2, 7.4, 7.6, 7.8. To disrupt the membrane potential in neurons, 5 μ M nigericin (2.5 mM stock solution in DMSO and 100% ethanol in proportion 1:1, stored at -20°C) was used.

3.2. Mouse model of Rett syndrome

The *Mecp2*-deficient mouse model represented by the ‘Bird strain’ *Mecp2*^{tm1.1Bird} was used for the current work (Guy et al. 2001). The heterozygous (*Mecp2*^{+/-}) female mice were provided by Jackson Laboratories (Bar Harbor, Me.) and next bred with C57BL/6J WT males (Figure 5). Mice were maintained in the central animal facility of the University of Göttingen in a stable 12 h light-dark cycle, and they had a constant access to food and water. In order to genotype WT and *Mecp2*^{-/-} mice, the polymerase chain reaction (PCR) was performed on a tail biopsy material. For all hippocampal cell and slice culture preparations, *Mecp2*^{-/-} mice at PD 2-4 were used.

Figure 5. The ‘Bird strain’ *Mecp2*^{tm1.1Bird} mouse model of Rett syndrome.

A) During development, *Mecp2*^{-/-} mice start developing a very obvious phenotype from ~ PD 20 and this includes markedly reduced gain of body weight, lower body temperature, loss of mobility and irregular breathing.

B) Most of symptomatic *Mecp2*^{-/-} mice show also an obvious hind-limb clasping.

3.3. Preparation of dissociated cell and organotypic cultures

Preparation of primary hippocampal dissociated neuronal cultures was performed according to the previous protocol from our group (Weller et al. 2014). Neonatal *Mecp2*^{-/-} males at PD 1-4 were decapitated and the whole brain was isolated from the skull into ice-cold Hanks' balanced salt solution (HBSS), containing 20% FCS (fetal calf serum, Biochrom). Hippocampi were then dissected, cleaned from additional cortical tissue and the meninges, and next cut into several pieces. After two washing steps with HBSS, containing 20% FCS, and three further washing steps with HBSS without serum, hippocampi were treated with freshly prepared digestion solution for 10 min at 37°C in a humidified (5% CO₂) incubator. After trypsinization, hippocampi were washed again with HBSS with 20% FCS and HBSS only. They were triturated in a freshly prepared dissociation solution, and the neuronal cell suspension obtained was then centrifuged (1500 rpm, 10 min, 4°C). The cell pellet was redissolved in ice-cold plating medium and neurons were plated on sterile glass coverslips, coated beforehand with Matrigel (BD Biosciences). Final culturing was done in four-well plates (Nunc). The cell density of the plated neurons was at about 30.000-40.000 cells per well. At first, the dissociated primary neurons were incubated at humidified conditions (37°C, 5% CO₂) for a minimum of 24 h. After one day, plating medium was replaced by growing medium. In the following culturing period, 50% of medium was replaced by pre-warmed and fresh growing medium every 2-3 days.

To prepare organotypic slice culture, earlier protocols from our group were used (Fischer et al. 2009; Kron and Müller 2010; Großer et al. 2012). The *Mecp2*^{-/-} and WT mice at PD 2-5 were decapitated and the whole brain was isolated directly into ice-cold HBSS without serum. Hippocampi were dissected, gently cleaned from the meninges without disturbing the tissue, and next placed on a McIlwain tissue chopper (Stoelting Co.) while protecting the tissue from drying out too much. Hippocampi were completely chopped into 350 µm-thick slices, which were gently separated in HBSS and transferred onto the porous support membranes of 6-well culture plates (Transwell Permeable Support, Corning). Excess of HBSS medium was

removed using a pipette without disturbing the membranes. A maximum of 4 slices were cultured in each single well. Slices were incubated in sterile and humidified conditions (37°C, 5% CO₂). To maintain organotypic slice cultures, over a longer period half of the growing medium was replaced every 2-3 days.

3.4. Culturing media

The HBSS medium, used during tissue dissection, contained Hanks powder, NaHCO₃ 0.35 g/l, HEPES 0.238 g/l and H₂O. The pH was adjusted to 7.3-7.4.

To trypsinize dissected hippocampi, the digestion solution was used. It contained (in mM) NaCl 137, KCl 5, Na₂HPO₄ 7, and HEPES 25. Before use, digestion solution was additionally supplemented with trypsin 0.5 g/100 ml and DNase 0.05 g/100 ml, and filtered. The pH was adjusted to 7.2.

Dissociation solution was required during the triturating procedure of hippocampal tissue fragments in order to obtain a cell suspension. Dissociation solution consisted of Hanks and 12 mM of MgSO₄ was enriched with DNase 0.05 g/100 ml, and filtered before use.

Plating medium was served for the initial plating of neuronal cell cultures, and it consisted of minimum essential medium (MEM) (Invitrogen) plus 10% FCS, 5 mg/ml glucose, 0.2 mg/ml NaHCO₃, 0.1 mg/ml transferrin (Calbiochem), 2 mM L-glutamine and 25 µg/ml insulin.

Growing medium was used for both cell and slice cultures and it contained MEM, 5 mg/ml glucose, 0.2 mg/ml NaHCO₃, 0.1 mg/ml transferrin, 5% FCS, 0.5 mM L-glutamine, 20 µl/ml B27 50x supplement including antioxidants (Invitrogen), 2 µM cytosine arabinoside and 100 µg/ml penicillin-streptomycin (Biochrom).

All culturing media were filtered and stored sterile at 4°C. Experiments were performed between 7-16 days *in vitro* (DIV).

3.5. Preparation of brain acute slices

To prepare acute brain slices, earlier protocols from our group were followed (Fischer et al. 2009; Großer et al. 2012). Transgenic mice, carrying cytosolic roGFP1 sensor specifically in neurons (roGFP1c) (Wagener et al. 2016) at PD 47-52, were anesthetized by using di-ethyl ether and then decapitated. The brain was isolated and placed in ice-cold ACSF for ~ 2 min. After a sufficient chilling period of a few min, the brain was sliced in 400 µm thick coronal slices by a vibroslicer (752 M Vibroslice, Campden Instruments, Loughborough, Leicester, UK). The slices were then gently placed in a well oxygenated submersion-style chamber. They recovered at room temperature (RT) for a minimum duration of at least 90 min. Afterwards, slices were transferred into the recording chamber, which was constantly supplied (flow rate 3-4 ml/min) with aerated (95% O₂ / 5% CO₂) and pre-warmed (37°C) ACSF.

3.6. Transduction

Primary hippocampal cell and organotypic slice cultures were transduced with the genetically-engineered optical sensor roGFP1. The roGFP1 expressing plasmid and its sequences were obtained from the University of Oregon under the permission of the inventor Prof. S. James Remington. The respective adenoviral constructs (AAV-6-syn roGFP1 virus), selectively targeting mitochondria (mito-roGFP1) and cytosol (cyto-roGFP1) in neurons, have been provided by Dr. Sebastian Kügler (viral vector platform, CNMPB, University Medical Center Göttingen). The human synapsin-1 promoter guaranteed a specific neuronal expression of the cyto-roGFP1 and mito-roGFP1.

Dissociated hippocampal neurons were transduced with cyto-roGFP1 or mito-roGFP1 viral vectors (stock dilution 1:50) in phosphate buffered saline (PBS) on DIV 2, respectively. To transduce neuronal cultures, 2.5 µl of diluted constructs were directly added into 800 µl of growing medium.

Organotypic hippocampal slice cultures were transduced on DIV 3-4. The 2.5 μ l of the cyto-roGFP1 or mito-roGFP1 (stock dilution 1:50) construct were directly applied onto the surface of each slice. Primary cell and slice cultures were left undisturbed for another 5-7 days until a sufficient roGFP1 expression (~15%) of neurons was obtained.

3.7. Transfection

In order to assess, whether the genetically-encoded hydroxyl peroxide sensor HyPer is pH susceptible, primary neuronal cultures were transfected with the pH-sensitive, but redox-insensitive variant of the original HyPer sensor (SypHer, pC1-HyPer-C199S, Addgene Plasmid 42213) (Poburko et al. 2011). This sensor was expressed in the cytosol of neurons and glial cells.

On DIV 2, primary neuronal cultures were transfected with the SypHer vector plasmid by using Lipofectamine 2000 (Invitrogen). In detail, plating medium (see section 3.4.) was removed and 200 μ l of transfection solution was added into each well. Transfection solution (OptiMEM, Invitrogen) was complemented with 1% Lipofectamine and 1 μ g/ml DNA of the SypHer vector. Cells were placed for 1 h at 37 °C in a humidified and 5% CO₂-containing incubator. Transfection solution was next replaced by fresh and pre-warmed (37°C) growing medium (see section 3.4.). A sufficient fraction of SypHer-expressing primary cells (2-3%) was obtained within 48 h.

3.8. Visualizing of mitochondria *in vitro* using MitoTracker RED FM

To identify mitochondrial compartments within neurons, the mitochondria-specific synthetic fluorescent dye MitoTracker RED FM (Life Technologies) was used. To visualize intact mitochondria *in vitro*, growing medium was removed and pre-warmed (37°C) ACSF containing MitoTracker RED FM (1 μ M) was added to primary neuronal cultures. Cells were incubated for 20 min (37°C, 5% CO₂). Neuronal mitochondria were imaged using a 2-photon microscope equipped with a 63x 1.0NA objective (Zeiss Plan-Apochromat VIS-IR) and a wavelength of 860 nm.

3.9. Immunostaining of neurons with MAP2

To confirm the neuronal specificity of roGFP1, primary hippocampal cultures were stained with the neuronal marker anti-microtubule associated protein 2 (MAP2) antibody (Cell Signaling).

Cultured neurons were gently washed two times with a pre-warmed PBS (37°C) for 3 min and fixed in 4% paraformaldehyde (PFA) for ~20 min at RT. Cells were washed again two more times in PBS in order to remove any remaining PFA. To permeabilize cellular membranes, cells were washed two times with 0.2% triton in PBS for 3 min. Neurons were then incubated with MAP2 antibody (stock dilution 1:300) overnight (o/n) at 4°C or 1 h at RT. The next day, primary cultures were washed two times with 0.2% triton in PBS for 3 min and incubated with the secondary antibody (anti-rabbit Cy3, Sigma-Aldrich) for 1 h at RT and protected from light. To remove an excess of Cy3, cells were washed twice with 0.2% triton and two times in PBS, respectively. Coverslips with primary cultures were dried gently and mounted with a proper mounting medium (DakoCytomation). Neurons were visualized using a fluorescence microscope (Olympus BX51WI) and a 60x/0.90 objective (Olympus LUMPlanFI), and an excitation wavelength of 525 nm.

3.10. Optical recordings

To perform dynamic and semi-quantitative recordings of redox changes specifically in neurons, the genetically-engineered optical redox probe roGFP1 was used. Native GFP protein became redox-sensitive by inserting two cysteines, between which a functional disulfide (S-S) bond forms, depending on the surrounding environmental oxidation/reduction conditions. These structural changes of roGFP1 modulate its absorption and fluorescence (Figure 6 A) (Hanson et al. 2004). The response principle of roGFP1 relies on two absorption peaks, which respond oppositely to redox modulation. Upon oxidation, the roGFP1 light absorption increases at 395 nm and decreases at 470 nm, and this is the opposite upon reduction. Already in real time during the experiment, the roGFP1 fluorescence emission ratio (F_{395}/F_{470}) is calculated (Figure 6 B). Since individual neuronal cell bodies

and/or parts of the dendrites were used as regions of interest, several cells within the field of view could be recorded at the same time. To visualise the dynamics of redox changes, neurons were imaged every 10 s.

Alternatively, to assess cellular ROS/redox changes, also the genetically-encoded hydroxyl peroxide sensor HyPer may be used. HyPer consists of circularly permuted YFP (cpYFP) linked to OxyR-RD – the regulatory domain of the H₂O₂ sensitive *Escherichia coli* transcription factor. However, it was suggested to be quite pH sensitive (Eislinger et al. 1999; Wachter et al. 2000; Schwarzländer et al. 2011). To monitor pH-mediate responses of HyPer, a plasmid vector carrying a modified redox-insensitive variant of HyPer – SypHer (HyPer C199S) – was used, which only shows the artifactual pH responses associated with a given (redox challenging) treatment. To image SypHer responses, primary cell cultures were viewed by using a 60x 0.9 NA water immersion objective (LUMPlanFI; Olympus). The SypHer sensor was excited alternatively at 420 nm and 490 nm, and the ratio of 420 nm/490 nm was calculated.

To ensure dynamic live-imaging of primary cell and slice cultures *in vitro*, an optical recording set-up was used. It consisted of a suitable light source (Polychrome II; Till Photonics) and a sensitive CCD camera (Imago QE; PCO Imaging), which was fixed to the microscope. To perform optical recordings, cell and slice cultures were placed in a submersion-style chamber, which was constantly supplied with a pre-warmed ACSF at a solution flow rate of 4.5 ml/min. All recordings were performed by using the TILLvisION software and device-control package (version 4.0.1; TILL Photonics).

Figure 6. Ratiometric response properties of roGFP1.

A) Cytosol-targeted roGFP1 responded to oxidant challenge, which was induced by H₂O₂. In the displayed ratiometric images oxidation is indicated by “warm” pseudocolors and reduction by “cold” pseudocolors.

B) The redox sensor roGFP1 exhibits two absorption peaks, which show opposite changes upon redox modulation. Fluorescence excited at 395 nm (F₃₉₅) increased, while fluorescence excited at 470 nm (F₄₇₀) decreased under oxidation. As a result, the roGFP1 ratio (F₃₉₅/F₄₇₀) increases upon oxidation.

3.11. The 2-photon laser scanning microscope

In order to visualize primary hippocampal neurons as well as organotypic hippocampal slices transduced with mito-roGFP1 and cyto-roGFP1 at an optical higher resolution, cell and slice cultures were imaged by a 2-photon laser scanning microscope (LaVision BioTec TriMScope II with BX51WI, Olympus). Excitation of roGFP1 was performed at a wavelength of 890 nm, using a 63x 1.0 NA objective (Zeiss Plan-Apochromat VIS-IR). The 3-dimensional reconstructions of images were assembled with Metamorph Offline Software (version 6.1; Molecular Devices).

To enable ratiometric imaging of the cyto-roGFP1 ratio in neurons from hippocampal acute slices of adult roGFP1c transgenic mice, the recently established dual laser-based ratiometric 2-photon excitation approach was used (Wagener et al. 2016). Alternating excitation of roGFP1c slices was performed at wavelengths 910 nm (provided by the MaiTai eHP laser system, Newport-Spectra Physics) and 740 nm (provided by the Millennia-pumped Tsunami laser system, Newport-Spectra Physics), and a 40x 0.8NA IR-optimized objective (IR Achromplan, Zeiss) was used.

3.12. Local redox challenge

To evaluate sub-cellular redox changes, primary neurons were transduced with the cyto-roGFP1 optical sensor. Patch clamp-shaped capillaries (GC150F-10 borosilicate glass, Harvard Part no. 30-0057, Harvard Apparatus) were mounted in a pipette holder of a 3-axis step micromanipulator (Luigs & Neumann) and used for a local pressure puff application of redox stimulants. Tips of these capillaries were trimmed to a resistance of ~5 MΩ. Application of local stimuli was performed by the pneumatic drug ejection system (PDES-02D np). Applied pressure was 50 mbar and stimulation of neurons was performed for various durations. In parallel, images of cells were taken every 2 s.

3.13. Electrical stimulation

The extracellular stimulating electrode was made from the same type of capillaries used for pressure puff application. A chlorided silver wire (Science Products) was attached to a microconnector and connected to the stimulus isolation unit (PSIU-6, Grass Instrument Co.). The wire was inserted into the glass capillary, which was filled with ACSF. The stimulation electrode was mounted to the 3-axis step motor micromanipulator and carefully positioned close to a neuronal soma without actually touching the cell membrane.

In order to establish the electrical stimulation procedure, neurons were first loaded with a calcium indicator Fluo-3 AM (2 mM stock solution in DMSO,

stored frozen at -20°C, Molecular Probes). To stain neuronal cultures *in vitro*, Fluo-3 AM (5 µM) was added directly to growing medium with primary cell cultures and incubated for 30 min (37°C, 5% CO₂). To induce any neuronal responses, cells were stimulated using the following parameters: 10-100 µA current, 1 s stimulation only, 1 ms pulses at 1-5 Hz frequencies. Extracellular electrical stimulation was elicited by using a S88 stimulator (Grass Instruments). The Fluo-3 targeted neurons were visualised at a wavelength of 470 nm.

For the comparison of the responses of WT and *Mecp2*^{-y} hippocampal neurons, primary neuronal cultures transduced with cyto-roGFP1 were used.

3.14. Statistics

For statistical calculations a two-tailed, unpaired Student *t* test was used, with a significance level of 5%. Significant changes have been indicated by asterisks (* *p*<0.05; ** *p*<0.01; *** *p*<0.001). All values constitute mean ± standard deviation (SD). The number of trials (*n*) represents the number of cells taken for the experiments, unless stated otherwise.

4. Results

The current thesis aimed to assess the potential redox changes in *Mecp2*^{-/-} hippocampal primary neurons and organotypic hippocampal slices by taking advantage of genetically-encoded redox sensors. Local sub-cellular redox differences within single neurons were monitored in cytosol and mitochondria, and redox changes associated with neuronal activity were investigated. Also, the effects of various physiological stimuli on cellular redox homeostasis were compared among WT and *Mecp2*^{-/-} neurons to define Rett syndrome associated differences in cellular redox balance.

4.1. Challenge to select the ideal optical redox indicator

Among the genetically-encoded redox sensors only HyPer and roGFPs are ratiometric by excitation, thereby enabling also quantitative analyses. The cytosol and mitochondria expressing plasmids of HyPer are commercially available and allow evaluating cellular redox dynamics within these two cellular compartments. The advantage of HyPer is that it detects H₂O₂ directly, which is not possible with other sensors, such as roGFPs, which report general thiol redox balance.

Unfortunately, chromophores based on YFP and cpYFP are pH sensitive (Eisliger et al. 1999; Wachter et al. 2000; Schwarzländer et al. 2011). Since pH may change during hypoxia and neuronal stimulation, the pH-sensitivity of HyPer was assessed in order to decide, whether HyPer sensor is indeed suitable and sufficiently reliable for the planned experiments. To monitor pH changes, arising from various treatments and stimuli, a plasmid vector, which carries a modified variant of HyPer – SypHer – was used (Figure 7). It is no longer redox-sensitive but it shows only the artifactual pH responses.

Figure 7. Hippocampal primary cell transfected with SypHer.

Cultured hippocampal cell expressing the cytosol-targeted SypHer sensor. Sufficient expression of SypHer was achieved within DIV 3-4. In accordance to HyPer, also SypHer exhibits two absorption peaks at 420 nm and 490 nm.

4.1.1. Calibration of the SypHer sensor

To define the SypHer response kinetics as well as response magnitudes in different pH conditions, primary hippocampal cells were transfected with the SypHer vector and exposed to pre-warmed pH-calibration solutions, starting from pH 7.0 to pH 7.8. As soon as the cells had reached a stable baseline, the cellular membrane potential was disrupted by the K^+/H^+ ionophore nigericin (5 μ M) and the SypHer ratio responses were recorded for ~ 25 min (Figure 8). Once the cells reached a stable plateau, 10 successive images were averaged to calculate the final SypHer ratio. In these trials, a given cell was only exposed to one of the pH calibration solutions.

To record the entire response range, SypHer-transfected primary hippocampal cells were exposed successively to all pH solutions, applying each respective pH for ~4 min (Figure 9; Table 1). For reliable analyses, ratiometric calculations were corrected for cell movements in these trials.

pH	SypHer ratio (ΔR_{SypHer})
7.0	$0.5 \pm 0.03\%$
7.2	$0.7 \pm 0.02\%$
7.4	$1.0 \pm 0.05\%$
7.6	$1.5 \pm 0.09\%$
7.8	$1.9 \pm 0.2\%$

Table 1. SypHer ratio changes induced by various pH.

Listed are averages \pm SD of 7 cells.

Figure 8. The pH-calibration of the SypHer sensor.

A) The SypHer ratio adjusts to current extracellular pH conditions within 1-2 min once the membrane integrity is challenged by nigericin. Time scaling applies to all traces.

B) Summary of the SypHer responses to different pH conditions.

Figure 9. Full range calibration of SypHer recorded as an example in a single cell.

Starting from pH 7.4, the SypHer ratio reliably increased with a rising pH, whereas it decreased when pH was lowered.

4.1.2. Challenging SypHer by various redox stimuli

The next set of experiments addressed pH-changes resulting from e.g. redox stimuli, and they were recorded in cells with intact all membranes. Hippocampal cell cultures of WT mice were transfected with the cytosolic SypHer construct and exposed to pH challenge, which was induced by propionate (30 mM). Also, different redox stimuli such as H_2O_2 (50 μM and 5 mM), tBHP (20 μM), DEDTC (50 μM), CN^- (1 mM), glutamate (50 μM , 1 mM), DTT (10 mM) and hypoxia were applied. Hypoxic conditions were induced by applying the oxygen scavenger sodium sulfite (Na_2SO_3 ; 1 mM, 15 min) and nitrogen aerated ACSF (95% N_2 / 5% CO_2 ; 15 min). In accordance to the previous experiment, an increase of the SypHer fluorescence ratio indicates an alkalinization, whereas a decrease of the SypHer ratio corresponds to an acidification.

First of all, the responses of HyPer and SypHer were directly compared. In the case of HyPer, administration of propionate (30 mM, 15 min) resulted in an initial and transient decrease of the HyPer ratio, which was followed by an increase when propionate was removed again (Figure 10 A; Table 2). Upon the same treatment, the SypHer ratio showed a similar pattern of responses, indicating intracellular acidification and alkalinization, respectively (Figure 10 B; Table 2). This shows that a large part of the HyPer response simply does

not represent redox changes but rather artifactual responses due to pH changes.

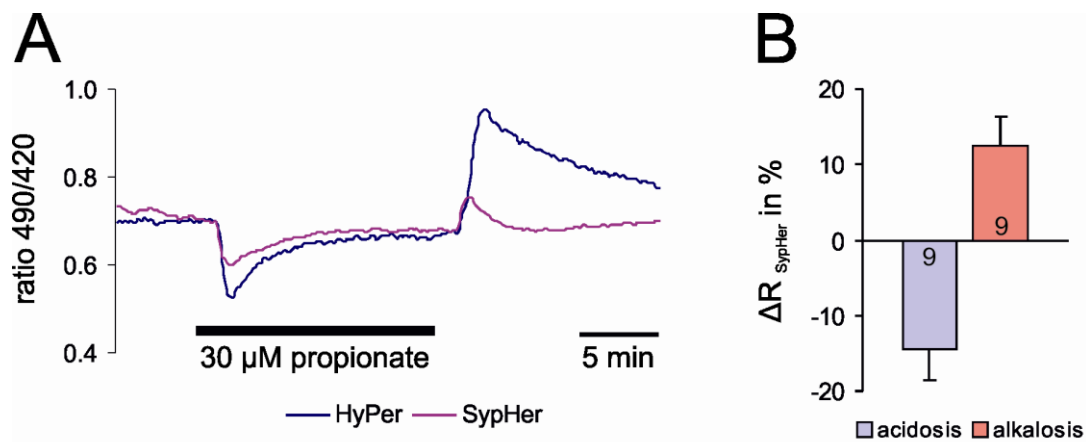

Figure 10. HyPer and SypHer responses to modulation of cellular pH.

A) The HyPer ratio initially decreased and recovered back to baseline in the presence of propionate (30 mM), and then increased upon wash out. Note that SypHer shows the same response pattern. The HyPer trace included here as a reference, was recorded already earlier by others (Weller et al. 2014).

B) The summary of the SypHer responses shows that application of propionate induced an acidification, which was then followed by an alkalinization.

Propionate (30 mM)	HyPer ratio (ΔR_{HyPer})	SypHer ratio (ΔR_{SypHer})
Acidosis	$-23.5 \pm 4.5\%$ $n = 8$ (Weller et al. 2014)	$-14.5 \pm 4.2\%$ $n = 9$
Alkalosis	$50.5 \pm 20.2\%$ $n = 8$ (Weller et al. 2014)	$12.5 \pm 3.9\%$ $n = 9$

Table 2. The pH changes of redox-insensitive sensor SypHer.

Treatment with propionate (30 mM, 15 min) triggered pH changes, which can be measured as the SypHer ratio. However, these pH changes are also detected by the redox sensor HyPer, giving rise to non-reliable results.

Administration of low (50 μ M) concentrations of H_2O_2 induced an increase in the SypHer ratio (Figure 11 A, Figure 13; Table 3). Interestingly, a short initial increase in the SypHer ratio, induced by a high dose (5 mM) of H_2O_2 , was followed by marked decrease. Oxidant challenge by tBHP (20 μ M, 5 min) revealed a marked alkalinization (Figure 11 B, Figure 13; Table 3). Also, treatment with DEDTC (50 μ M, 10 min) evoked a slight increase in the SypHer ratio (Figure 11 C, Figure 13; Table 3). Induction of reducing conditions by DTT (10 mM, 10 min), also increased the SypHer ratio (Figure 11 D, Figure 13; Table 3). During hypoxia (15 min), the SypHer ratio was only slightly decreased and then it increased during reoxygenation (Figure 12 A, Figure 13; Table 3). CN^- (1 mM, 5 min) elicited a biphasic response, an alkalinization followed by an acidification (Figure 12 B, Figure 13; Table 3). Pronounced acidification was induced by glutamate (50 μ M, 3 min), which was even more obvious upon application of a high dose of glutamate (1 mM, 3 min) (Figure 12 C, Figure 13; Table 3).

Figure 11. SypHer responses to redox challenge.

A) Low dosage (50 μ M) of H_2O_2 increased the SypHer ratio, while high concentrations (5 mM) of H_2O_2 induced a pronounced acidification. All traces are displayed at the same time scaling.

B) Oxidant challenge provoked by tBHP revealed an increase in the SypHer ratio.

C) Alkalinization was evoked by DEDTC treatment.

D) The SypHer ratio revealed an increase upon reducing conditions induced by DTT.

Figure 12. SypHer responses to hypoxia and excitotoxicity.

A) The SypHer ratio was only slightly decreased during hypoxia. This was then followed by a minor increase upon reoxygenation. All traces are displayed at the same time scaling.

B) Chemically-induced hypoxia by CN^- caused a short and reversible alkalinization followed by an acidification.

C) Administration of glutamate elicited a reversible and pronounced acidification.

Figure 13. Summary of SypHer responses to changes in redox balance.

The SypHer ratio responded with an acidification during treatments with H_2O_2 (5 mM), CN^- , N_2 and glutamate. Administration of H_2O_2 (50 μM), tBHP, DEDTC, reoxygenation upon hypoxia and DTT evoked alkalization.

Treatment	SypHer ratio (ΔR_{SypHer})	
	Acidosis	Alkalosis
H ₂ O ₂ (50 μ M)	-	14.4 \pm 6.9% <i>n</i> = 11
H ₂ O ₂ (5 mM)	-21.5 \pm 7.6% <i>n</i> = 11	6.4 \pm 4.5% <i>n</i> = 11
tBHP (20 μ M)	-	12.9 \pm 5.6% <i>n</i> = 6
DEDTC (50 μ M)	-	4.8 \pm 2.8% <i>n</i> = 7
CN ⁻ (1 mM)	-5.2 \pm 3.3% <i>n</i> = 7	3.2 \pm 1.2% <i>n</i> = 7
Hypoxia	-8.3 \pm 4.6% <i>n</i> = 9	4.7 \pm 2.2% <i>n</i> = 9
Glutamate (50 μ M)	-19.6 \pm 8.2% <i>n</i> = 7	-
Glutamate (1 mM)	-28.4 \pm 5.9% <i>n</i> = 7	-
DTT (10 mM)	-	14.9 \pm 8.5% <i>n</i> = 6

Table 3. The pH changes of SypHer sensor upon various redox stimuli.

The pH-sensitive, redox-insensitive optical sensor SypHer showed very clear pH changes, indicating acidosis and/or alkalosis, which were associated with the different redox stimuli.

4.2. Redox changes in primary neuronal cell culture and organotypic slice culture

Since the HyPer sensor has been found not to be a suitable redox indicator as its responses were markedly disturbed by pH changes, the genetically-encoded roGFP1 sensor was used for all further experiments. For roGFP1 it has been confirmed earlier that it is hardly affected by pH changes (Funke et al. 2011).

To assess any changes in the redox homeostasis specifically within neurons, primary cell and slice cultures were transduced with a neuron-specific viral expression vector AAV-6, carrying roGFP1 and targeting it to mitochondria (mito-roGFP1) as well as the cytosol (cyto-roGFP1). At first, proper expression of roGFP1 in cytosolic and mitochondrial compartments of cell and organotypic culture preparations was confirmed (Figure 14). Since roGFP1 gives excitation ratiometric responses, variations in redox balance could be measured and analysed quantitatively.

Figure 14. Transduction of primary cell and slice cultures with cyto-roGFP1 and mito-roGFP1.

Viral transduction ensured neuron-specific expression of roGFP1. Sufficient expression levels were obtained within DIV 6-7. Mito-roGFP1 reported the redox changes in mitochondrial matrix of individual mitochondria in neuronal cell cultures and organotypic slice cultures. Cyto-roGFP1 was distributed homogenously in cytosol, reporting redox conditions in the cytosolic sub-compartments. The scale bar applies to all images displayed.

4.2.1. Confirming proper sub-cellular localization of mito- and cyto-roGFP1 in neurons

The mitochondria-specific synthetic dye MitoTracker RED FM was used to certify specific targeting of mito-roGFP1 to intact mitochondria of primary neurons (Figure 15 A-C). To confirm the specific targeting of cyto-roGFP1 to neuronal cells, primary cell cultures were fixed and stained with MAP2-directed antibody as MAP2 is present only in neurons, in their perikarya and dendrites in particular (Figure 15 D-F).

Figure 15. Sub-cellular localization of mito-roGFP1 and cyto-roGFP1.

A) Cyto-roGFP1 was expressed homogenously within hippocampal neurons as confirmed by MAP2 immunolabeling. The scale bar applies to all images.

B) Mito-roGFP1 specifically targeted mitochondrial compartments in neurons. MitoTracker RED FM confirmed the proper location of mito-roGFP1 in neuronal mitochondria.

4.2.2. Calibration of cyto- and mito-roGFP1

To perform semi-quantitative analyses, the ratiometric fluorescence responses of mito-roGFP1 and cyto-roGFP1 were calibrated to maximum oxidation and reduction. Complete oxidation was induced by applying saturating doses of H_2O_2 (5 mM, 3 min) and full reduction was obtained by DTT (10 mM, 3 min) (Hanson et al. 2004; Funke et al. 2011; Großer et al. 2012). According to the assumption of linear roGFP1 responses, the relative amount of oxidation/reduction of the respective construct was estimated (Figure 16 A), and *Mecp2*^{-/-} and WT genotypes as well as primary cell culture and organotypic slice culture preparations could be compared. Calibrations were performed for each sensor construct as well as in each type of *in vitro* preparation. Both genotypes responded similarly to the calibration treatments. However, the response ranges of mito-roGFP1 in *Mecp2*^{-/-} and WT neurons in slice cultures were somewhat decreased in comparison to cultured dissociated cells (Figure 16 B; Table 4).

Figure 16. Response range of mito-roGFP1 and cyto-roGFP1.

A) Calibration of mito-roGFP1 responses in a hippocampal neuron to full oxidation and reduction. Upon reduction, induced by DTT, the fluorescence of mito-roGFP1 decreased and it increased upon oxidation, which was mediated by H_2O_2 .

B) Calculated response ranges of mito-roGFP1 and cyto-roGFP1 in primary cell and organotypic hippocampal slice cultures.

		roGFP1 ratio (F_{395} / F_{470})		
		WT	<i>Mecp2</i> ^{-/-}	Treatment
Mitochondria	Cell culture	1.5 ± 0.2 <i>n</i> = 14	1.5 ± 0.3 <i>n</i> = 18	H ₂ O ₂
		0.7 ± 0.1 <i>n</i> = 14	0.8 ± 0.1 <i>n</i> = 19	DTT
	Slice culture	1.0 ± 0.1 <i>n</i> = 12	1.0 ± 0.1 <i>n</i> = 46	H ₂ O ₂
		0.6 ± 0.1 <i>n</i> = 15	0.6 ± 0.1 <i>n</i> = 25	DTT
Cytosol	Cell culture	1.7 ± 0.1 <i>n</i> = 9	1.8 ± 0.4 <i>n</i> = 10	H ₂ O ₂
		0.8 ± 0.1 <i>n</i> = 6	0.8 ± 0.0 <i>n</i> = 6	DTT
	Slice culture	1.6 ± 0.4 <i>n</i> = 35	1.7 ± 0.3 <i>n</i> = 39	H ₂ O ₂
		0.6 ± 0.1 <i>n</i> = 13	0.7 ± 0.1 <i>n</i> = 33	DTT

Table 4. Calibration of the roGFP1 redox sensors in mitochondrial and cytosolic compartments.

Listed are the peaks and nadirs recorded in response to oxidation and reduction, respectively.

4.2.3. The roGFP1 pre-treatment baseline ratio in mitochondria and cytosol

Previously, it has been shown that the roGFP1 pre-treatment baseline ratio was significantly increased in the cytosol of neonatal *Mecp2*^{-/-} hippocampi (Großer et al. 2012). In these trials the roGFP1-coding DNA was delivered by lipofectamine, which certainly resulted in a mixed population of roGFP1 expressing neurons and glial cells. In the present thesis, redox conditions were monitored specifically in neurons, and analyses were not only performed in the cytosol, but also extended to the mitochondrial matrix. This was done in a comparable fashion in WT and *Mecp2*^{-/-} hippocampal primary neurons as

well as in organotypic slice cultures. The specific delivery of roGFP1 to neurons was achieved by the AAV-6 viral vector, which mediated a highly efficient and specific roGFP1 expression under the control of the human synapsin I promoter.

Differing redox conditions in WT and *Mecp2*^{-/-} mice were especially obvious in organotypic slice cultures under control conditions. In the cultured hippocampal tissue, *Mecp2*^{-/-} neurons revealed more oxidized roGFP1 baseline ratios both in their mitochondria ($p < 0.05$) and in cytosol ($p < 0.001$) than WT neurons. Significant changes were also observed not only between WT and *Mecp2*^{-/-} genotypes, but also between mitochondrial and cytosolic compartments. Interestingly, the roGFP1 pre-treatment baseline ratio was significantly ($p < 0.001$) decreased in the cytosol of neuronal cultures from WT and *Mecp2*^{-/-} hippocampus as compared to mitochondria. In contrast, it was markedly ($p < 0.001$) increased in cytosol as compared to mitochondria in organotypic slice cultures of these both genotypes (Figure 17; Table 5).

Figure 17. The cytosolic and mitochondrial pre-treatment baseline ratio responses.

In all dissociated cell cultures no differences of the cytosolic and mitochondrial roGFP1 baseline ratio between WT and *Mecp2*^{-/-} neurons were observed. However, in organotypic slice cultures, the roGFP1 baseline ratio was significantly increased in mitochondria ($p < 0.05$), and in cytosol of ($p < 0.001$) *Mecp2*^{-/-} mice as compared to WT. Also, the roGFP1 baseline was significantly ($p < 0.001$) decreased in cytosol compared to mitochondria in dissociated cell cultures, which was opposite in organotypic slices.

		roGFP1 ratio (F_{395} / F_{470})	
		WT	<i>Mecp2</i> ^{-/-}
Cell culture	Mitochondria	1.3 ± 0.2 <i>n</i> = 75	1.3 ± 0.2 <i>n</i> = 70
	Cytosol	1.1 ± 0.1 <i>n</i> = 110	1.1 ± 0.1 <i>n</i> = 177
Slice culture	Mitochondria	0.8 ± 0.2 <i>n</i> = 75	0.9 ± 0.1 <i>n</i> = 101
	Cytosol	1.0 ± 0.2 <i>n</i> = 125	1.0 ± 0.1 <i>n</i> = 209

Table 5. Mito-roGFP1 and cyto-roGFP1 ratio baselines under control conditions in WT and *Mecp2*^{-/-} neurons.

4.2.4. Mitochondrial and cytosolic redox status

In order to screen for redox changes of *Mecp2*^{-/-} hippocampus during hypoxia, oxygen (O₂) was removed by applying the O₂ scavenger sodium sulfite (Na₂SO₃; 1 mM, 10 min) together with ACSF, which was aerated with nitrogen (95 % N₂ / CO₂; 10 min) (Figure 18 A). To assess any alterations in the redox homeostasis of *Mecp2*^{-/-} hippocampal neurons, hippocampal cell and slice cultures were challenged by acute oxidative stress, induced by a transient application of H₂O₂ (200 μM, 3 min) (Figure 18 B). The efficiency of cellular scavenging systems in *Mecp2*^{-/-} neurons was rated by SOD scavenging enzyme inhibition, which was triggered by DEDTC (5 mM, 5 min) (Figure 18 C). Also, changes in mitochondrial ROS production were provoked by blocking the oxidative phosphorylation with the complex III inhibitor AMC (20 μM, 10 min) (Figure 18 D).

Figure 18. Rating of cellular redox homeostasis.

A) Severe hypoxia was induced by O₂ withdrawal (95% N₂ / CO₂) in the presence of the O₂ scavenger Na₂SO₃. The roGFP1 ratio decreased towards more reducing conditions in *Mecp2*^{-/-} hippocampus as compared to WT. The scale bar applies to all panels.

B) Direct oxidative challenge by H₂O₂ induced a clearly more intense oxidation in mitochondria of *Mecp2*^{-/-} mice as compared to WT.

C) Inhibition of SOD by DEDTC evoked a less intense oxidation in *Mecp2*^{-/-} neurons than in WT.

D) Inhibition of mitochondrial electron transport chain by administration of AMC induced a slight oxidation, however, differences between WT and *Mecp2*^{-/-} were not obvious.

Upon redox challenge, more obvious differences between WT and *Mecp2*^{-/-} mice were detectable in hippocampal organotypic slice culture rather than in cell culture preparations. These changes were seen in both mitochondrial and cytosolic compartments (Figure 19).

In primary cell cultures, upon induction of hypoxia, the mito-roGFP1 ratio clearly ($p < 0.01$) shifted towards more reducing conditions in *Mecp2*^{-/-} neurons as compared to WT (Figure 19 A; Table 6). However, application of H₂O₂, DEDTC and AMC did not reveal any significant differences among mitochondria of WT and *Mecp2*^{-/-} neurons. Also, the cyto-roGFP1 ratio did not

show any differences between WT and *Mecp2*^{-/-} neurons during application of hypoxia, DEDTC and AMC (Figure 19 B; Table 6). Only H₂O₂ evoked a shift to more (p<0.05) oxidizing conditions in *Mecp2*^{-/-} neurons as compared to WT.

Exaggerated redox responses were, however, found in organotypic slice cultures. During hypoxia, the mito-roGFP1 ratio reached more reducing levels in *Mecp2*^{-/-} slices as compared to WT (p<0.05). Also, the mito-roGFP1 ratio clearly (p<0.01) shifted further towards oxidation in *Mecp2*^{-/-} slices due to H₂O₂ application as compared to WT. Treatment with DEDTC evoked a less intense (p<0.05) oxidation of mito-roGFP1 in *Mecp2*^{-/-} slices as compared to WT. Moreover, the mito-roGFP1 ratio tended to increase more upon application of AMC in *Mecp2*^{-/-} slices as compared to WT (Figure 19 C; Table 6).

Pronounced differences in the redox responses between WT and *Mecp2*^{-/-} slices were especially seen in the cytosol. Hypoxic conditions elicited clearly (p<0.01) more reducing responses in *Mecp2*^{-/-} slices as compared to WT. Redox challenge, induced by H₂O₂, resulted in a significantly (p<0.05) more intense oxidation in *Mecp2*^{-/-} slices as compared to WT. Furthermore, the cyto-roGFP1 ratio was notably (p<0.001) less effected in *Mecp2*^{-/-} slices due to SOD inhibition as compared to WT. Surprisingly, blockade of the mitochondrial transport chain by AMC did not evoke any obvious differences in the cytosolic responses of WT and *Mecp2*^{-/-} slices (Figure 19 D; Table 6).

Figure 19. Summary of redox responses in mitochondria and cytosol.

A) Mito-roGFP1 ratio did not respond differently between WT and *Mecp2*^{-/-} mice, when H₂O₂, DEDTC and AMC were applied. However, *Mecp2*^{-/-} neurons were more ($p < 0.01$) susceptible to hypoxia when compared to WT.

B) *Mecp2*^{-/-} and WT neurons responded equally to hypoxia as well as to DEDTC and AMC. Yet, the cyto-roGFP1 ratio shifted towards more ($p < 0.05$) oxidizing conditions in *Mecp2*^{-/-} neurons due to H₂O₂ treatment as compared to WT.

C) The mito-roGFP1 ratio shifted towards more ($p < 0.05$) reducing conditions during hypoxia and showed more ($p < 0.01$) exaggerated responses to H₂O₂ in *Mecp2*^{-/-} organotypic slices as compared to WT. Moreover, DEDTC evoked a shift of the mito-roGFP1 ratio towards oxidation, which was less ($p < 0.05$) intense in *Mecp2*^{-/-} organotypic slices as compared to WT. Also, *Mecp2*^{-/-} slices showed a tendency towards more intense oxidation upon AMC administration as compared to WT.

D) Cyto-roGFP1 showed significantly lowered ($p < 0.01$) reducing responses during hypoxia and markedly ($p < 0.05$) increased oxidation in response to H₂O₂ in *Mecp2*^{-/-} organotypic slices as compared to WT. Also, a weaker ($p < 0.001$) shift of the cyto-roGFP1 ratio towards oxidation was found in *Mecp2*^{-/-} slice cultures due to DEDTC administration as compared to WT. However, no obvious differences between WT and *Mecp2*^{-/-} organotypic slices were observed when AMC was applied.

			Evoked changes in roGFP1 ratio (F_{395} / F_{470}), ΔR_{roGFP1}			
			Hypoxia	H ₂ O ₂	DEDTC	Antimycin A
Mitochondria	Cell culture	WT	-5.5 ± 2.2% <i>n</i> = 10	14.6 ± 4.3% <i>n</i> = 13	12.0 ± 5.1% <i>n</i> = 12	14.6 ± 9.9% <i>n</i> = 5
		<i>Mecp2^{-/-}</i>	-8.3 ± 1.5% <i>n</i> = 9	15.6 ± 6.3% <i>n</i> = 11	14.9 ± 6.5% <i>n</i> = 14	12.4 ± 3.7% <i>n</i> = 6

Table 6. Overview of the mito-roGFP1 and cyto-roGFP1 ratio responses in cultured neurons and hippocampal organotypic slices upon various redox stimuli.

4.3. Sub-cellular redox changes under control conditions and upon oxidative challenge.

To investigate the redox conditions of somata and dendrites in *Mecp2*^{-/-} neurons under control conditions, cyto-roGFP1 transduced neurons were imaged and analyzed for sub-cellular differences in their steady state roGFP1 ratios. For this, a line of interest (LOI) was drawn along the neurons, starting from the centre of the somata up to the periphery of single dendrites (Figure 20 A). For statistical calculations, redox ratios were normalized to the mean of first ten pixels of the respective LOI. Furthermore, to reduce pixel noise, a moving average (5 data points wide) was applied. These analyses revealed a more increased cyto-roGFP1 baseline ratio in somata than in dendrites in WT and *Mecp2*^{-/-} neurons (Figure 20 B). Genotypic differences in this sub-cellular redox gradient were not observed.

Figure 20. Oxidation level changes between somata and dendrites in WT and *Mecp2*^{-/-} neurons under control conditions.

A) To analyze redox baselines in somatic and dendritic areas of hippocampal neurons, a LOI was drawn along a neuron from the middle of the soma into a well pronounced dendrite.

B) The cyto-roGFP1 ratio showed an increased steady state oxidation in somata, which was progressively decreasing towards the periphery of the dendrites.

To assess any differences in the redox responses to oxidative challenge between somatic and dendritic areas of *Mecp2*^{-/-} and WT neurons, H₂O₂ (200 µM, 3 min) was applied to cyto-roGFP1-transduced cell cultures. As a result, the cyto-roGFP1 ratio shifted towards more (p<0.01) oxidizing conditions in somata than in dendrites of WT and *Mecp2*^{-/-} neurons (Figure 21; Table 7).

As expected, upon H_2O_2 treatment, the cyto-roGFP1 ratio increased also more intensively in *Mecp2*^{-/-} neurons than in WT, and this was observed in neuronal dendrites ($p < 0.001$) and somata ($p < 0.05$).

Figure 21. Local redox changes in response to oxidation challenge.

Upon H_2O_2 (200 μM , 3 min) application, more increased ($p < 0.01$) cyto-roGFP1 ratios were apparent in the somata of WT and *Mecp2*^{-/-} neurons than in their dendrites. Furthermore, *Mecp2*^{-/-} neurons showed significantly higher shifts of the cyto-roGFP1 ratios towards oxidation in dendrites ($p < 0.001$) and in soma ($p < 0.05$) as compared to WT.

H_2O_2 (200 μM)	Evoked changes in roGFP1 ratio (F_{395} / F_{470}), ΔR_{roGFP1}	
	WT	<i>Mecp2</i> ^{-/-}
Dendrites	14.6 ± 4.4% $n_{\text{dendrites}} = 40$	19.9 ± 4.9% $n_{\text{dendrites}} = 32$
Soma	21.0 ± 12.4% $n = 28$	28.8 ± 13.5% $n = 28$

Table 7. Relative changes in the cyto-roGFP1 ratio in somatic and dendritic areas of WT and *Mecp2*^{-/-} neurons upon oxidative challenge.

Usually, 1-2 dendrites were analyzed per cell.

To evaluate the changes in SOD efficiency specifically among soma and dendrites of *Mecp2*^{-/-} neurons, the cyto-roGFP1-transduced neuronal cultures were also treated with DEDTC (5 mM, 5 min) in order to inhibit SOD. Upon

such treatment, *Mecp2*^{-/-} neuronal dendrites showed more increased ($p < 0.01$) cyto-roGFP1 ratios when compared to WT. Moreover, the cyto-roGFP1 ratio shifted towards more oxidation in somata than in dendrites, which was especially pronounced ($p < 0.001$) in WT (Figure 22; Table 8).

Figure 22. Local neuronal changes in response to SOD inhibition.

Upon SOD blockade, *Mecp2*^{-/-} dendrites showed a marked ($p < 0.01$) oxidizing shift in the cyto-roGFP1 ratio as compared to WT. Furthermore, more oxidized ($p < 0.001$) responses were observed in the somatic areas of WT neurons than in their somata.

DEDTC (5 mM)	Evoked changes in roGFP1 ratio (F_{395} / F_{470}), ΔR_{roGFP1}	
	WT	<i>Mecp2</i> ^{-/-}
Dendrites	22.5 ± 9.6% $n_{dendrites} = 30$	30.7 ± 7.0% $n_{dendrites} = 16$
Soma	41.4 ± 18.2% $n = 14$	39.8 ± 17.9% $n = 12$

Table 8. Differences in oxidation levels of somatic and dendritic areas between *Mecp2*^{-/-} and WT neurons in response to DEDTC.

Usually, 1-2 dendrites were analyzed per cell.

4.4. Local redox stimulation of primary neurons

In order to better understand the cellular redox physiology, it is crucial to challenge neurons with different redox stimuli. However, since neurons constitute a group of very sensitive and energy demanding cells, too high drug concentrations and/or long neuronal stimulation might contribute to cellular impairment, and result in unreliable observations. It is therefore important also to apply more subtle and localized stimuli. Hence, the next set of experiments aimed to establish the local neuronal stimulation by using a pneumatic drug ejection system, and to assess the sub-cellular changes in the roGFP1 ratio of *Mecp2*^{-/-} neurons in response to oxidative challenge.

First, tests of the drug ejection system were performed to confirm proper and reproducible ejection of small volumes from a pipette tip once a pressure was applied. A glass pipette was filled with the highly fluorescing dye rhodamine 123 (Rh123), which was then ejected either in a constant or pulsed (100 ms, 5 Hz) mode for durations of 5 s and 10 s. Applied pressure was 20 mbar, and both single and repeated pressure puff stimulations resulted in a reliable Rh123 release (Figure 23).

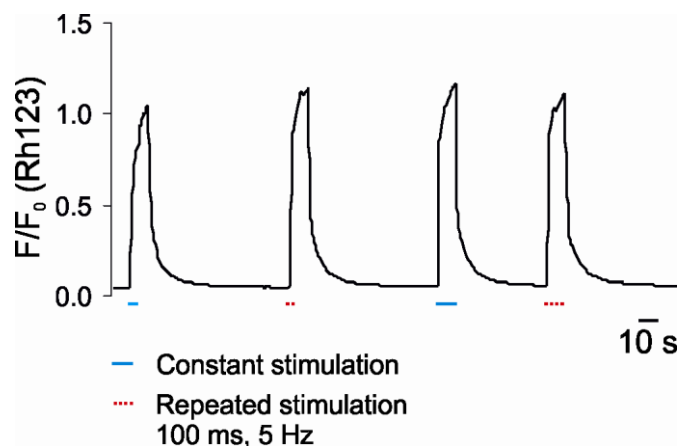

Figure 23. Rh123 release from a pipette tip by using pulsed puff stimuli.

Application of single (blue mark) and pulsed (red dashed mark) pressure puffs reliably induced Rh123 release from the pipette into the recording chamber. Plotted fluorescence was recorded with a region of interest placed in front of the pipette tip at a distance ~5 μm .

Next, to rule out any unwanted mechanical effects that might appear upon puff stimulation of neurons, the pipette was filled with ACSF and positioned in

close proximity to a dendrite of a cyto-roGFP1-transduced neuron (Figure 24 A) without actually touching the cell membrane (Figure 24 B). Single puffs with durations of 100 ms, 200 ms and 300 ms and 50 mbar pressure were applied. No changes were observed in the cyto-roGFP1 ratio by such local ACSF puffs (Figure 24 C). Now, to redox challenge hippocampal neurons, a glass pipette was filled with H_2O_2 (5 mM) and placed closely to a proximal dendrite and the soma. The cell body was stimulated by pressure puffs in a repeated (100 ms, 5 Hz) mode for 10 s, 30 s and 1 min. Upon local H_2O_2 puffs, the cyto-roGFP1 ratio clearly increased and recovered to the pre-treatment baseline (Figure 24 D).

Figure 24. Local redox stimulation of a cyto-roGFP1-transduced neuron.

A) Cyto-roGFP1 transduced neurons were used for local redox stimulation. The scale bar applies to both images displayed.

B) The patch pipette was positioned in close proximity to a neuronal dendrite of a cyto-roGFP1 transduced neuron, allowing therefore for a localized redox challenging.

C) When neurons were exposed to ACSF pressure puffs for 100 ms, 200 ms and 300 ms, no changes in the cyto-roGFP1 ratio were detected, ruling out mechanical artefacts.

D) The cyto-roGFP1 ratio clearly increased to local H_2O_2 (5 mM) puffs. Local redox challenge was achieved by applying repeated pressure puffs (100 ms, 5 Hz) for 10 s (red mark), 30 s (blue mark) and 1 min (green mark). Displayed changes were quantified in the soma region.

To optimize the parameters of local redox stimulation, dendrites of neurons were puffed by lower concentrated H_2O_2 (1 mM) in a single puff of 100 ms. Again, the cyto-roGFP1 ratio increased, which was especially obvious in the soma (Figure 25 A). To visualise cytosolic redox kinetics during redox challenge, a LOI along the neurons was drawn, starting from the lower dendrite through the soma, up to the upper dendrite (Figure 25 B). Based on the time course of the cyto-roGFP1 ratiometric responses along this LOI, a kymograph was calculated to create a graphical representation of the evoked redox changes in the somatic and dendritic areas of a single neuron in time (Figure 25 C).

Figure 25. Sub-cellular changes within a single neuron upon local oxidant challenge.

A) The cyto-roGFP1 ratio revealed clear redox changes in the soma during H_2O_2 (1 mM) treatment.

B) To analyze the neuronal kinetics upon redox challenging induced by H_2O_2 , and to calculate a kymograph, the LOI was drawn along the cell. Triangles indicate the particular areas of a neuron, whose redox changes are presented in panel A.

C) The kymograph summarizes the cyto-roGFP1 ratio changes within a single neuron in respect to the LOI from panel B in time. The cyto-roGFP1 ratio increased especially in the cell body due to H_2O_2 application.

To prevent a potential spillover of high concentrated H_2O_2 (1 mM), even more subtle stimuli were performed by applying doses of 200 μM H_2O_2 in a single puff (200 ms). The cyto-roGFP1 ratio shifted towards more oxidizing conditions, which was especially pronounced in the soma (Figure 26 A). Similar to the previous experiment, a LOI was drawn along the neuron to obtain the sub-cellular kinetics during treatment (Figure 26 B). Again, based on these data, a kymograph was created (Figure 26 C).

Figure 26. Local stimulation of a neuron with low doses of H_2O_2 .

A) The cyto-roGFP1 ratio responded to redox modulation induced by 200 μM H_2O_2 , which was applied as a local 200 ms pressure puff.

B) To calculate the kymograph and to analyze the neuronal kinetics, the LOI was drawn along the cell, starting from the upper dendrite. Triangles indicate the positions at which the displayed traces were extracted.

C) The kymograph represents the temporal changes in redox balance within the displayed neuron. The H₂O₂ puff evoked an oxidation especially in the soma.

After confirming the feasibility of local puff application and the sensitivity of roGFP1 to even single puffs, sub-cellular changes in the cyto-roGFP1 ratio were now analyzed in more detail. For redox challenge of neurons, H₂O₂ (200 μ M) was locally applied in a single puff mode for 200 ms in close proximity to a dendrite, and the resulting changes in sub-cellular redox balance were analyzed at different regions of interest to compare soma and dendrites.

As seen earlier (Figure 20), the cyto-roGFP1 pre-treatment baseline ratio was significantly ($p < 0.001$) higher in somata than in dendrites of WT and *Mecp2*^{-/-} hippocampal neurons. Surprisingly, the cyto-roGFP1 pre-treatment baseline ratio was lower ($p < 0.001$) in *Mecp2*^{-/-} dendrites as compared to WT dendrites (Figure 27 A; Table 9).

However, the cyto-roGFP1 ratio shifted towards more oxidation in WT and *Mecp2*^{-/-} dendrites than in somata in response to local H₂O₂ application. This change was significant ($p < 0.05$) especially in WT neurons, but also evident as a solid trend in *Mecp2*^{-/-} neurons (Figure 27 B; Table 9).

Figure 27. Relative redox changes in dendrites and soma of neurons.

A) Already under control conditions, the cyto-roGFP1 baseline ratio within the soma region was more ($p < 0.001$) oxidized in comparison to dendrites. This was observed in both WT and *Mecp2*^{-/-} hippocampal neurons (see also Figure 20).

B) Upon local puff stimulation of cultured neurons with H₂O₂ (200 μ M, 200 ms), the cyto-roGFP1 ratio was shifted to more oxidized levels in dendrites than in soma. This was especially obvious ($p < 0.05$) for WT neurons.

		WT	<i>Mecp2</i> ^{-/-}
Pre-treatment cyto-roGFP1 ratio	Dendrites	1.3 ± 0.1% <i>n</i> _{dendrites} = 27	1.1 ± 0.1% <i>n</i> _{dendrites} = 26
	Soma	1.6 ± 0.4% <i>n</i> _{somas} = 9	1.5 ± 0.2% <i>n</i> _{somas} = 8
Local stimulation (H ₂ O ₂ , 200 ms) ΔR_{roGFP1}	Dendrites	2.6 ± 2.1% <i>n</i> _{dendrites} = 27	3.3 ± 2.8% <i>n</i> _{dendrites} = 26
	Soma	0.9 ± 1.4% <i>n</i> _{somas} = 9	1.5 ± 0.9% <i>n</i> _{somas} = 8

Table 9. Oxidative changes in dendrites and soma in response to locally stimulated neurons.

The soma was more oxidized in comparison to dendrites under control conditions in WT and *Mecp2*^{-/-} hippocampal neurons. However, upon local neuronal stimulation with H₂O₂ (200 μ M, 200 ms), the cyto-roGFP1 ratio showed more intense oxidative responses in dendrites than in the soma.

4.5. Electrical stimulation of neurons

Since even defined sub-cellular redox changes could be detected in somatic and dendritic areas of cultured neurons, it was interesting to assess the local changes due to more physiological stimuli. Therefore, to evaluate the interplay of neuronal activity and redox balance, extracellular monopolar electrical stimulation was established.

For proof of principle, intact primary neuronal cultures were bulk loaded with 5 μ M of calcium (Ca²⁺) dye Fluo-3 in sterile and humidified (37°C, 5% CO₂) conditions for 30 min (Figure 28 A). The cultures were next placed into the submersion style recording chamber, and an extracellular stimulation electrode was positioned close to a dendrite (Figure 28 B). For electrical stimulation, 100 μ A current, 1 ms pulses, 5 s train duration and frequencies of 2 Hz and 5 Hz were applied. In response to such stimuli, Fluo-3 fluorescence

markedly increased, confirming successful activation of this neuron. However, after a second stimulation, cell rupture was frequently observed, which was indicated by a marked and rapid drop of Fluo-3 fluorescence (Figure 28 C).

Figure 28. Principle of electrical stimulation.

A) Primary hippocampal neurons were stained with the calcium-sensitive dye Fluo-3. The extracellular recording electrode was positioned closely to a neuronal dendrite. The scale bar applies to both images.

B) Fluorescence responses were evoked by 100 μ A of current, 1 ms pulse, 5 s train duration, and 2 Hz and 5 Hz frequency. Note that the Fluo-3 fluorescence increased immediately upon electrical stimulation.

In order to quantify the Fluo-3 responses upon massive neuronal depolarisation and the related strong Ca^{2+} influx, neurons were depolarised by ACSF containing 40 mM potassium (K^+). To prevent any osmotic stress, ACSF with only 90 mM sodium (Na^+) was used in these tests. The Fluo-3 fluorescence increased by a total of $505.4 \pm 145.4\%$ ($n = 16$), and it fully recovered after the treatment (Figure 29).

Figure 29. Fluo-3 responses upon massive neuronal depolarisation.

A) Depolarisation (40 mM K^+) of neurons induced pronounced transient Ca^{2+} influx indicated by a marked increase in Fluo-3 fluorescence.

B) On average, K^+ -mediated depolarisation caused an increase of Fluo-3 fluorescence by $505.4 \pm 145.4\%$ ($n = 16$).

After confirming that electrical stimulation does in principle work and elicits a much more moderate Ca^{2+} influx than general cellular depolarisation, this approach was next applied to the cyto-roGFP1-transduced hippocampal primary neurons. Parameters of 100 μA current, 1 ms pulse, 5 s duration and frequencies of 2 Hz and 5 Hz were applied. Against expectation, after a first electrical stimulation, the cyto-roGFP1 ratio fluorescence decreased and a second electrical stimulation induced neuronal cell loss (Figure 30).

Figure 30. The cyto-roGFP1 ratiometric response to extracellular electrical stimulation.

Upon electrical stimulation (100 μA current, 1 ms pulse, 5 s duration, 1 Hz and 2 Hz frequency), the cyto-roGFP1 ratio fluorescence decreased. A second electrical stimulation induced a marked fluorescence drop, suggesting massively impaired neuronal integrity.

In an attempt to maintain cellular viability, stimulation intensities were reduced. Indeed, the contrary neuronal responses could now be observed, at least in some trials. In some neurons, the cyto-roGFP1 ratio increased upon

electrical stimulation when 20 μ A current in a single 10 ms pulse was applied (Figure 31 A). In others, the cyto-roGFP1 ratio markedly decreased right after the stimulation (Figure 31 B). Stimulation of neuronal cultures with even more gentle parameters (10 μ A current, 1 ms pulse) still induced quite variable responses. The cyto-roGFP1 ratio shifted towards more oxidizing conditions in some cells (Figure 31 C), whereas in others it rapidly decreased upon electrical stimulation (Figure 31 D). Therefore, one might speculate that roGFP1-transduced neurons are more fragile to electrical stimulation than Ca^{2+} loaded neurons, which tolerated the procedure.

Figure 31. Variability of cyto-roGFP1 ratio responses to extracellular electrical stimulation.

A) Electrical stimulation of neurons (20 μ A, 10 ms pulse) resulted in an increase of the cyto-roGFP1 ratio, indicating oxidation. A second stimulation did not noticeably affect the cyto-roGFP1 ratio.

B) Stimulation of another neuronal cell induced a rapid decrease in the cyto-roGFP1 ratio and cell loss.

C) Stimulation of a neuron with a more gentle current (10 μ A, 1 ms pulse) increased the cyto-roGFP1 ratio, which then reached a plateau stage.

D) Yet, even gentle electrical stimulation of neurons sometimes resulted in cell loss.

4.6. The effect of neurotransmitters on cellular redox balance

In order to compare the redox responses of WT and *Mecp2*^{-/-} hippocampal neurons, evoked by various neurotransmitters, glutamate, serotonin, norepinephrine and dopamine were applied to cyto-roGFP1-transduced primary cultured neurons.

Glutamate (50 μ M, 5 min) caused biphasic responses, consisting of an initial decrease followed by a marked increase of roGFP1 ratio. Since glutamate induced continuously rising responses of the cyto-roGFP1 ratio, which did not recover upon wash-out, the redox-level reached after 30 min was taken for statistical calculations. Genotypic comparison revealed that the initial drop was more ($p < 0.001$) intense in WT than in *Mecp2*^{-/-} neurons. The secondary increase was more pronounced ($p < 0.001$) in *Mecp2*^{-/-} neurons in comparison to WT (Figure 32 A, F; Table 10).

The cyto-roGFP1 ratio increased also more intensively ($p < 0.001$) in *Mecp2*^{-/-} neurons when norepinephrine (200 μ M, 3 min) was applied as compared to WT (Figure 32 B, F; Table 10). Moreover, after only partial recovery upon wash-out of norepinephrine, the cyto-roGFP1 ratio continued to rise. Similar, but even stronger effects occurred in *Mecp2*^{-/-} neurons exposed to a higher dose of norepinephrine (500 μ M, 3 min) (Figure 32 C, F; Table 10). An increase of the cyto-roGFP1 ratio was also induced by serotonin (100 μ M, 10 min), which was again more pronounced ($p < 0.05$) in *Mecp2*^{-/-} than in WT neurons (Figure 32 D, F; Table 10). Furthermore, in contrast to WT, the cyto-roGFP1 ratio of *Mecp2*^{-/-} cells did not recover to its pre-treatment baseline after serotonin treatment. Application of dopamine (500 μ M, 3 min) shifted the roGFP1 ratio towards more oxidizing conditions, which was also intensified ($p < 0.05$) in *Mecp2*^{-/-} neurons (Figure 32 E, F; Table 10). In contrast to the other tested neurotransmitters, the redox changes evoked by dopamine readily recovered in both genotypes after wash out. Nevertheless, the oxidative shift reduced, was again more intense in *Mecp2*^{-/-} neurons.

Figure 32. The cyto-roGFP1 ratio responses to neurotransmitters.

A) Under treatment with glutamate, the cyto-roGFP1 ratio shifted towards more ($p < 0.001$) oxidizing conditions in *Mecp2*^{-/-} neurons as compared to WT. Also, application of glutamate caused an initial drop in the cyto-roGFP1 ratio, which was markedly less ($p < 0.001$) intense in *Mecp2*^{-/-} neurons than in WT. Time scaling is identical for all of the traces shown.

B and C) Smaller (200 μ M) and higher (500 μ M) doses of norepinephrine resulted in an increase in cyto-roGFP1 ratio, which was more pronounced ($p < 0.001$) in *Mecp2*^{-/-} neurons.

D) Treatment with serotonin elicited a shift towards oxidation, which was intensified ($p < 0.001$) in *Mecp2*^{-/-} neurons.

E) Also, dopamine induced a more intense ($p < 0.05$) oxidation in *Mecp2*^{-/-} neurons.

F) Statistical overview of the quantified cyto-roGFP1 responses to neurotransmitters in WT and *Mecp2*^{-/-} neurons.

Neurotransmitter	Evoked changes in roGFP1 ratio $(F_{395} / F_{470}), \Delta R_{roGFP1}$	
	WT	<i>Mecp2</i> ^{-/-}
Serotonin	7.5 ± 3.6% n = 11	14.0 ± 8.8% n = 12
Norepinephrine (200 µM)	7.9 ± 2.5% n = 10	18.9 ± 7.2% n = 11
Norepinephrine (500 µM)	14.2 ± 4.7% n = 8	38.5 ± 11.8% n = 6
Glutamate (initial drop)	-3.3 ± 0.5% n = 7	-1.7 ± 0.5% n = 8
Glutamate (secondary increase)	18.8 ± 6.4% n = 7	34.6 ± 2.2% n = 8
Dopamine	12.3 ± 3.0% n = 13	15.7 ± 5.0% n = 14

Table 10. Effects of neurotransmitters on the cyto-roGFP1 ratio in hippocampal cultured neurons.

4.7. Mechanisms of transmitter-mediated redox changes

To identify the very molecular mechanisms, which play a role in neuronal redox events in response to neurotransmitters, potential candidate processes such as Ca^{2+} influx, mitochondrial respiration, NADPH oxidase (NOX) and xanthine oxidase (XO) activation as well as altered cyclic adenosine monophosphate (cAMP) levels were evaluated. In these experiments, the neuronal responses to glutamate (50 µM, 5 min) and dopamine (500 µM, 3 min) were assessed. These two transmitters were chosen, since glutamate evoked the most intensified and continuously rising responses of the cyto-roGFP1 ratio, which did not recover upon wash-out, whereas dopamine responses always fully recovered in both genotypes.

Treatment of neurons with glutamate under Ca^{2+} free conditions still caused a marked ($p < 0.001$) shift of the cyto-roGFP1 ratio towards oxidation in *Mecp2*^{-/-}

neurons, whereas the oxidizing redox response in WT neurons was almost completely abolished (Figure 33 A, E; Table 11). Interestingly, the initial drop upon glutamate application was now significantly ($p < 0.05$) larger in *Mecp2*^{-/-} than in WT neurons (Figure 33 F; Table 11). A continuous shift towards oxidation was still induced by glutamate in WT and *Mecp2*^{-/-} neurons when mitochondria were uncoupled by FCCP (1 μ M, 8 min) (Figure 33 B, E; Table 11). Yet, upon inhibition of NOX by DPI (20 μ M, 8 min) the glutamate-mediated redox responses were almost abolished. Only a tiny shift towards oxidation remained (Figure 33 C, E; Table 11). The responses to glutamate were also suppressed when XO was blocked by allopurinol (200 μ M, 10 min); instead, a very small reducing shift could now be observed (Figure 33 D, E; Table 11).

Figure 33. Mechanistic deciphering of the glutamate-mediated roGFP1 responses.

A) Glutamate caused an increase in the roGFP1 ratio under free Ca^{2+} conditions, which was especially obvious ($p < 0.001$) for *Mecp2*^{-/-} neurons. In WT neurons, the redox responses to glutamate were markedly dampened. The scale bar is equal for all traces displayed.

B) After mitochondrial uncoupling, the roGFP1 baseline slightly decreased, but still glutamate induced a clear oxidizing response of the roGFP1 ratio in WT and *Mecp2*^{-/-} neurons. Also, the cyto-roGFP1 ratio showed a solid tendency towards more intense oxidation in *Mecp2*^{-/-} neurons as compared to WT.

C) Blocking of NOX by DPI almost completely abolished the roGFP1 response to glutamate in WT and *Mecp2*^{-/-} neurons.

D) Inhibition of XO by allopurinol fully blocked the responses of the roGFP1 ratio to glutamate in WT and *Mecp2*^{-/-} neurons. Note that the roGFP1 ratio now even decreased slightly.

E) Statistical overview of the quantified responses of WT and *Mecp2*^{-/-} neurons to glutamate under Ca^{2+} free conditions, mitochondrial uncoupling and inhibition of NOX and XO. The bar plot of the control conditions under ACSF were included again as a reference of the original response magnitude.

F) Summary of the initial reducing shifts under the respective physiological conditions. The bar plot of the control conditions under ACSF were included for comparison.

Application of dopamine still induced a marked shift of the cyto-roGFP1 ratio towards oxidation in WT and *Mecp2*^{-/-} neurons under Ca²⁺ free conditions (Figure 34 A, D; Table 11). Also, an increase of the cyto-roGFP1 ratio occurred when glutamate was applied upon mitochondrial uncoupling (Figure 34 B, D; Table 11). Surprisingly, under these conditions, this shift of the cyto-roGFP1 ratio towards oxidation was now more ($p < 0.05$) intense in WT than in *Mecp2*^{-/-} neurons. Supplementation of neurons with dopamine upon NOX blockade evoked only a very slight residual shift of the cyto-roGFP1 ratio towards oxidation in WT and *Mecp2*^{-/-} neurons (Figure 34 C, D; Table 11).

Figure 34. Mechanistic analysis of dopamine-mediated redox responses.

A) Administration of dopamine evoked a shift of the cyto-roGFP1 ratio towards oxidation under Ca²⁺ free conditions in WT and *Mecp2*^{-/-} neurons. The time scaling is identical for all traces displayed.

B) Application of dopamine during mitochondrial uncoupling by FCCP still induced a clear shift of the cyto-roGFP1 ratio towards more oxidizing conditions in WT neurons, which was, however, less intense in *Mecp2*^{-/-} neurons.

C) Inhibition of NOX by DPI almost completely abolished the dopamine reduced oxidative shifts in both genotypes.

D) Statistical overview of the quantified responses of WT and *Mecp2*^{+/y} neurons to dopamine upon Ca²⁺ withdrawal, mitochondrial uncoupling and inhibition of NOX. Dopamine responses under control conditions (ACSF) are shown as a reference.

		Evoked changes in roGFP1 ratio (F_{395} / F_{470}), ΔR_{roGFP1}	
Treatment	Neurotransmitter	WT	Mecp2^{-/-}
Ca ²⁺ free	Glutamate (initial drop)	-0.9 ± 0.6% n = 11	-2.5 ± 1.6% n = 4
	Glutamate (secondary response)	4.5 ± 2.6% n = 10	45.4 ± 22.5% n = 4
	DA	10.7 ± 0.7% n = 4	10.0 ± 2.5% n = 4
FCCP	Glutamate (initial drop)	-0.2 ± 0.8% n = 5	-0.4 ± 0.3% n = 5
	Glutamate (secondary response)	27.7 ± 2.7% n = 5	41.4 ± 13.3% n = 5
	DA	11.3 ± 2.1% n = 5	5.1 ± 1.3% n = 4
DPI	Glutamate (initial drop)	-1.3 ± 0.5% n = 5	-0.1 ± 0.3% n = 4
	Glutamate (secondary response)	1.6 ± 1.1% n = 5	1.1 ± 1.0% n = 3
	DA	4.8 ± 1.3% n = 9	4.2 ± 0.3% n = 5
Allopurinol	Glutamate (1 st peak)	-0.7 ± 1.6% n = 7	-0.9 ± 2.0% n = 9
	Glutamate (2 nd peak)	0.8 ± 2.0% n = 7	-1.7 ± 1.5% n = 9
	Glutamate (1 st drop)	-3.2 ± 0.6% n = 7	-3.4 ± 1.3% n = 9
	Glutamate (2 nd drop)	-3.1 ± 1.3% n = 7	-5.8 ± 3.0% n = 9

Table 11. Redox changes in response to glutamate and dopamine upon Ca²⁺ depletion, mitochondrial uncoupling, NADPH oxidase inhibition and xanthine oxidation blockade.

To assess briefly, whether G-protein and cAMP mediated signalling is involved in redox changes, the cyto-roGFP1 transduced neurons were treated with forskolin (10 μ M, 10 min) in order to activate G-proteins and hence, adenylate cyclase. Promotion of the cAMP pathway did, however, not contribute to redox changes under control conditions, since the cyto-roGFP1 ratio only barely increased by $3.6 \pm 1.4\%$ ($n = 6$).

To assess a particular contribution of the respective ROS generating candidate mechanisms to steady state baseline redox conditions, the cyto-roGFP1 baseline ratios under Ca^{2+} free conditions and mitochondrial uncoupling as well as NADPH and xanthine oxidases inhibition were calculated and compared with the control cyto-roGFP1 baseline ratios. The largest change in cyto-roGFP1 ratio was observed under mitochondria uncoupling as it decreased by 0.4 % in WT and *Mecp2*^{-y} neurons (Table 12).

Evoked changes in roGFP1 ratio (F_{395} / F_{470})		
WT	Ca^{2+} free	$1.02 \pm 0.02\%$ $n = 16$
<i>Mecp2</i> ^{-y}		$1.03 \pm 0.03\%$ $n = 8$
WT	FCCP	$0.96 \pm 0.02\%$ $n = 11$
<i>Mecp2</i> ^{-y}		$0.96 \pm 0.01\%$ $n = 9$
WT	DPI	$0.99 \pm 0.01\%$ $n = 14$
<i>Mecp2</i> ^{-y}		$1.01 \pm 0.02\%$ $n = 11$
WT	Allopurinol	$1.02 \pm 0.01\%$ $n = 7$
<i>Mecp2</i> ^{-y}		$1.01 \pm 0.00\%$ $n = 9$

Table 12. RoGFP1 baseline changes upon arrest of potential cellular ROS sources.

Listed are changes of the cytosolic roGFP1 baseline ratios of WT and *Mecp2*^{-y} neurons in various redox conditions in respect to the control roGFP1 baseline ratio under ACSF.

4.8. The roGFP1-transgenic mice as a novel tool for cellular redox imaging during disease progression.

To overcome the limitations of cultured preparations and surgery interventions, and to allow for the more complex cellular redox imaging especially at older stages, our group has recently generated transgenic mice, carrying the neuronal specific mitochondrial roGFP1 (roGFP1m) and cytosolic roGFP1 (roGFP1c) sensors, respectively (Wagener et al. 2016).

To assess any potential redox alterations in *Mecp2*^{-y} neurons of adult symptomatic Rett mice, and to correlate the Rett syndrome disease

progression with impaired redox balance, the transgenic roGFP1c males were cross-bred with *Mecp2*^{-/+} females. The very first obtained two roGFP1c *Mecp2*^{-/-} mice were here tested for redox changes specifically in neurons. Acute brain slices from adult (PD 47-52) mice were prepared. Neurons of the hippocampal regions CA1, CA3 and dentate gyrus (DG) as well as cortical neurons were imaged and the cytosolic roGFP1 baseline ratio was calculated by using the recently developed dual laser based excitation ratiometric 2-photon imaging (Figure 35, (Wagener et al. 2016)).

Figure 35. Dual laser ratiometric 2-photon excitation of hippocampal and cortical neurons of roGFP1c transgenic *Mecp2*^{-/-} mice.

Cytosolic roGFP1 was homogenously expressed in the cytosol of hippocampal and cortical neurons. For ratiometric redox analyses, the cytosolic roGFP1 was alternatively excited at

740 nm and 910 nm wavelength by our novel dual laser based excitation ratiometric 2-photon imaging approach. Imaging was performed on acute 400 μ m thick cortico-hippocampal tissue slices.

This revealed that the cytosolic roGFP1 ratio was more oxidized in roGFP1c *Mecp2*^{-/-} neurons when compared to roGFP1c WT in CA1 ($p < 0.01$) and DG ($p < 0.001$) regions of the hippocampus (Figure 36, Table 13). In the CA3 subfield and the cortex, those very first tests did not reveal any significant differences of steady state redox balance.

Figure 36. Redox baselines in hippocampal and cortical neurons of adult roGFP1c mice.

The roGFP1c *Mecp2*^{-/-} hippocampal neurons from CA1 and DG regions showed a more oxidized redox steady state balance under control conditions than roGFP1c WT neurons.

Analyses were performed on acute tissue slices. Data were obtained from the very first two roGFP1c *Mecp2*^{-/-} mice that became available from the recently started cross-breeding of roGFP1c and Rett mice.

Evoked changes in roGFP1 ratio (F_{910} / F_{740})		
	roGFP1c WT	roGFP1c <i>Mecp2</i> ^{-y}
CA1	1.3 ± 0.4% <i>n</i> = 124	1.4 ± 0.2% <i>n</i> = 300
CA3	1.1 ± 0.1% <i>n</i> = 21	1.1 ± 0.1% <i>n</i> = 40
Cortex	1.3 ± 0.2% <i>n</i> = 65	1.3 ± 0.2% <i>n</i> = 113
DG	1.2 ± 0.2% <i>n</i> = 176	1.3 ± 0.2% <i>n</i> = 280

Table 13. RoGFP1 baselines of adult hippocampal and cortical neurons in acute tissue slices of roGFP1c transgenic *Mecp2*^{-y} mice.

5. Discussion

Changes concerning not only morphology, but also modulating the function of mitochondria were reported in Rett syndrome. These disruptions were obvious in Rett patients and representative mouse models (Ruch et al. 1989; Eeg-Olofsson et al. 1990; Coker and Melnyk 1991; Cornford et al. 1994; Kriaucionis et al. 2006; Gibson et al. 2010; Großer et al. 2012; Pecorelli et al. 2013). However, the previous analyses of mitochondrial metabolism, which had been performed by our group earlier on hippocampal tissue, likely represent mixed neuronal and glial responses from *Mecp2*^{-/-} mice (Großer et al. 2012). Therefore, the aim of the present study was to assess redox changes in mitochondrial and cytosolic compartments specifically in *Mecp2*^{-/-} and WT neurons. Since the hippocampus represents a major structure for studying metabolic and signalling dysfunction as well as neurodegeneration (Wilde et al. 1997; Wang et al. 2007), hippocampal primary cultured neurons as well as hippocampal organotypic slices of *Mecp2*^{-/-} mice were investigated in terms of redox imbalance.

5.1. The genetically-encoded sensors allow for ratiometric measurements of redox imbalance.

A wide range of synthetic oxidation-sensitive fluorescent dyes is available to investigate cellular redox changes (Gallop et al. 1984; LeBel et al. 1992; Mohanty et al. 1997). However, these dyes have many disadvantages and limitations, e.g. they respond only to oxidation but not reduction (Foster et al. 2006; Gerich et al. 2009; Funke et al. 2011). More advanced optical sensors such as genetically-encoded optical ROS/redox sensors, are based on fluorescent proteins, in particular GFP or YFP, and they become redox-sensitive due to an inclusion of reactive cysteine switch, which is inserted closely to the chromophore. While oxidation facilitates forming of a covalent connection between reactive thiols, reduction promotes a breakup of the S-S disulfide bridges. Such fully reversible structural changes modify the fluorescence of the optical redox sensors. Accordingly, these constructs behave as other endogenous redox-sensitive proteins.

One of the feasible optical redox sensors is HyPer. Based on functional cysteine residues, HyPer allows for the dynamic imaging of sub-cellular H_2O_2 levels (Belousov et al. 2006). Previously, HyPer was mostly applied in cell lines, e.g. COS-7, HeLa, PC-12, H4IIE, HThy-ori3.1, HEK 293 but also in rat pancreatic beta-cells primary cultures (Belousov et al. 2006; Markvicheva et al. 2008; Malinouski et al. 2011; Kratschmar et al. 2012; Roma et al. 2012; Weyemi et al. 2012). The detailed response properties of HyPer have been recently investigated in primary cultured hippocampal neurons in mice (Weller et al. 2014).

5.1.1. Diminished reliability of the redox sensor HyPer

The first aim of the current thesis was to choose a suitable and reliable redox indicator in order to analyse redox changes within neurons. Using the HyPer sensor would be advantageous to investigate ROS changes within cells as it directly and specifically detects H_2O_2 (Belousov et al. 2006). Since chromophores based on YFP are potentially pH-sensitive (Eisliger et al. 1999; Wachter et al. 2000; Belousov et al. 2006; Forkink et al. 2010; Schwarzländer et al. 2011), a crucial goal was to assess the properties of the HyPer sensor. For this, the responses of cytosolic HyPer to various oxidative challenges and different pH conditions have been evaluated by using the optical pH sensor SypHer. As shown earlier, this modified redox-insensitive biosensor SypHer can be targeted to the cytosol of hippocampal neurons as well as glial cells, and it reacts only to pH changes, but no longer to redox modulation (Poburko et al. 2011; Weller et al. 2014).

In the current study, exposure of SypHer-transfected hippocampal primary neurons to different types of stimuli such as propionate, H_2O_2 , tBHP, DEDTC, CN^- , glutamate, DTT, and hypoxia, caused clear pH responses. Treatment with a lower concentration (50 μM) of H_2O_2 induced a slight alkalization, whereas a higher concentration (5 mM) of H_2O_2 resulted in an acidification. Hence, the actual effect of H_2O_2 as well as cellular redox changes measured by HyPer upon oxidation might be mimicked by pH modulations. Interestingly, not only H_2O_2 (50 μM), but also tBHP, DEDTC and DTT as well as

reoxygenation after hypoxia revealed similar effects, shifting the SypHer ratio towards alkalization, whereas CN^- , hypoxia and glutamate elicited a marked acidification. Finally, the unequivocal confirmation of pH-sensitivity of the HyPer sensor was obtained with propionate – an intracellular pH modulator (Sharp and Thomas 1981; Schlue and Thomas 1985) – which caused a marked acidification as confirmed by SypHer responses, and which was followed next by an alkalization upon washout.

The high pH-sensitivity of HyPer is, however, not the only disadvantage of this redox sensor. Although HyPer has been shown to ensure a pronounced photostability and cell-retention, the unresponsiveness to reducing stimuli questions the reliability of this optical sensor for quantitative redox measurements (Weller et al. 2014).

5.2. The genetically-encoded optical redox sensor roGFP1 allows for detailed and quantitative monitoring of ROS/redox changes

Even though recent investigations increased our knowledge on the redox imbalance in Rett syndrome, the detailed role of the cellular redox conditions, and the very contribution of mitochondria to ROS-mediated signalling and pathology are still unclear. Fresh frozen and formalin fixed tissues of brain samples from Rett patients are stored in tissue banks and they are available for research investigations. However, using animal models, which reflect human-related diseases, overcomes many limitations, giving therefore a unique chance to study these disorders on organotypic, cellular and molecular levels. Taking into account, that most of the knowledge about redox modulations in brains of Rett mice has been gathered from mixed responses of neuronal and glial cells, it was important to assess such responses now specifically in *Mecp2*^{-/-} neurons.

Since mitochondria and the cytosol are the main areas, where most metabolic reactions take place within a cell, it was mandatory to investigate redox changes in both of these compartments. Hence, to determine the cellular

redox imbalance in *Mecp2*^{-/-} mice, the genetically-encoded optical sensor roGFP1 was used to perform quantitative analyses. Similarly to HyPer, roGFP1 is based on thiol groups and functional S-S bridge formation, enabling dynamic and reversible ratiometric measurements of redox modulation (Hanson et al. 2004). In comparison to other redox sensors and synthetic oxidation-sensitive fluorescent dyes, the roGFP1 indicator seems to be one of the most reliable current tools used for redox analyses, since its ratiometric properties cancel out potential artefacts (Bokman and Ward 1981; Funke et al. 2011).

In earlier studies of our group, roGFP1 expression within neurons has been mostly obtained by transfection procedures using lipofectamine (Funke et al. 2011; Großer et al. 2012). In the current thesis, in order to evaluate any defects in mitochondrial function and redox imbalance in *Mecp2*^{-/-} mice, the primary cultured neurons as well as organotypic hippocampal slices have been transduced with viral vectors (AAV-6) to express efficiently the optical sensors mito-roGFP1 and cyto-roGFP1, and to ensure a specific neuronal targeting. Counterlabeling with the neuronal marker MAP2 confirmed the specific localisation of the roGFP1 construct in neuronal cells. Likewise, the mitochondria-specific dye MitoTracker RED FM confirmed the mitochondrial targeting of mito-roGFP1.

Semi-quantitative analyses were possible by taking advantage of the two distinct excitation peaks (395 nm and 470 nm) of roGFP1, which respond oppositely to reduction and oxidation (Dooley et al. 2004; Hanson et al. 2004; Funke et al. 2011; Großer et al. 2012). Potential errors, which could arise from diverse fluorophore concentrations and/or illumination intensities, were ruled out by calculating the fluorescence intensity ratio (F_{395}/F_{470}) (Gryniewicz et al. 1985). At the very first, roGFP1 had to be calibrated to the specific optical components of the particular experimental set-up and the detailed recording conditions. The states of maximum reduction (0% oxidation) and maximum oxidation (100% oxidation) were forced by applying saturating doses of DTT and H₂O₂, respectively (Hanson et al. 2004; Funke et

al. 2011; Großer et al. 2012). Exposure to reducing agents decreased the roGFP1 fluorescence ratio, which was then increased upon oxidation.

Interestingly, the lowest ratio response of mito-roGFP1 occurred in organotypic hippocampal slices of all preparations. This might be due to a decreased O₂ supply by a diffusional barrier in slice cultures. Moreover, because of a more condensed neuronal network and the presence of glial cells, drug penetration inside the tissue could be slower and/or less efficient than in dissociated cell cultures. Furthermore, the cellular scavenging systems might have already intercepted part of the applied ROS during oxidative challenge before it actually reached the mitochondria. A diminished response range for the mito-roGFP1 ratio in hippocampal slices could have also result from technical aspects such as loss of focus and/or partial shifts of the area of interest due to mitochondrial motility. Indeed, mitochondria are mobile and dynamic organelles with changing shapes and sizes. They might be further modulated by fusion and fission processes. Such mitochondrial fission and arrest of mitochondrial motility have been observed during oxidative stress (Pletjushkina et al. 2006; Gerich et al. 2009; Fan et al. 2010).

5.3. Redox homeostasis and mitochondrial function are impaired in *Mecp2*^{+/y} neurons

Modulations not only in the mitochondrial morphology but also in the functional activity of mitochondria have been previously observed in Rett patients' brains (Coker and Melnyk 1991). Reported changes include for example lower levels of cytochrome c oxidase and succinate cytochrome c reductase. Furthermore, recent reports have suggested changes also on the gene level, showing diversities in the expression pattern of genes directly correlated with mitochondrial function (Pecorelli et al. 2013).

Since mitochondria are cellular power houses, the question arose, whether disturbed mitochondrial function might correlate with a lower ATP production and/or lower ATP content. Indeed, Saywell and colleagues showed disruptions in mitochondrial metabolism and reported lower ATP levels in

brain tissue of *Mecp2*^{-/-} mice (Saywell et al. 2006). However, these results could not be further confirmed by our group for acute adult *Mecp2*^{-/-} hippocampal slices, which did not contain a lowered cellular ATP content when compared to WT tissue (Fischer et al. 2009). Additionally, more recent findings have demonstrated even increased ATP formation, but also increased ATP consumption in neonatal *Mecp2*^{-/-} hippocampus (Toloe et al. 2014). Thus, altered mitochondria might run at higher turn-over rates in Rett mice.

The hypothesis of more intensively working mitochondria in Rett syndrome arose from the findings of Kraucionis and colleagues, who detected significantly increased respiration rates and a larger respiration capacity in *Mecp2*^{-/-} mice (Kraucionis et al. 2006). Since an appropriate proton gradient needs to be maintained between the intermembrane space and the mitochondrial matrix, the electron transport chain has been suggested to operate at higher rates and to consume more O₂ in an attempt to overcome the proton leak across the inner mitochondrial membrane (Kraucionis et al. 2006). This was also supported by our groups' recent observations of an increased mitochondrial O₂ consumption of isolated adult *Mecp2*^{-/-} hippocampal mitochondria (Menzfeld et al. 2014). Moreover, increased pyruvic and lactic acid levels were found in Rett patients, which might also correlate with functional disturbances in the mitochondrial respiratory chain and the urea cycle (Matsuishi et al. 1992; Dotti et al. 1993; Lappalainen and Riikonen 1994).

Such impaired mitochondria may in consequence activate a vicious circle, leading to additional ROS formation and redox imbalance, and further oxidative stress. In particular, these changes might be even more strengthened due to the impaired breathing in Rett syndrome, e.g. apnoeas, thus causing further cellular network damage and contributing to the disease progression (Figure 37).

Figure 37. Redox hypothesis of Rett syndrome disease progression.

Functional damage of mitochondria results in more intensified ROS and RNS generation in Rett syndrome. This may contribute to impaired cellular redox signalling and aberrant activity of various cellular proteins such as structural proteins, enzymes, ion channels and neurotransmitter receptors. Redox imbalance and oxidative stress lead further to cellular network dysfunction, thereby accelerating the progression of this neurodevelopmental disease.

This research was originally published in Portland Press Limited. Müller M, Can K. Aberrant redox homeostasis and mitochondrial dysfunction in Rett syndrome. 2014 Aug; 42(4):959-64, Biochemical Society Transactions.

5.3.1. *Mecp2*^{-/-} neurons are more oxidized already under control conditions

Changes in redox homeostasis in Rett syndrome have been previously verified by our group (Großer et al. 2012). First, mitochondrial alterations were demonstrated by performing optical imaging and ratiometric analyses of cellular NADH and FAD autofluorescence in acute hippocampal slices of *Mecp2*^{-/-} mice. The elevated FAD/NADH ratio indicates a shift towards oxidation already under control conditions in neonatal (PD 7-10) and adult *Mecp2*^{-/-} hippocampi (Großer et al. 2012). Furthermore, a more oxidized pre-treatment baseline ratio was also detected for *Mecp2*^{-/-} organotypic hippocampal slices, transfected with cytosolic roGFP1 (Großer et al. 2012).

Even more oxidizing conditions in *Mecp2*^{-/-} hippocampal tissue have been shown in the absence of B-27 supplement, which contains antioxidants and is commonly used in cell culture media (Großer et al. 2012). However, these results were gained from both glial cells and neurons, and represent responses of a mixed population (Großer et al. 2012).

The present thesis unequivocally confirms that mitochondria of *Mecp2*^{-/-} neurons suffer from an increased oxidative burden. Indeed, significant changes were found in organotypic hippocampal *Mecp2*^{-/-} slices, in which the mitochondrial roGFP1 baseline ratio was already markedly increased in comparison to WT hippocampus. A clear increase of redox baseline ratios was also verified for the cytosolic compartment of *Mecp2*^{-/-} slices. Since the cytosol constitutes of a complex mixture of macromolecules, metabolites, ions and other solutes, any changes in the redox conditions might further influence several signalling pathways, which control cellular processes such as cell cycle, cell proliferation, apoptosis, metalloproteinase function, oxygen sensing, protein kinases, phosphatases and transcription factors (Brookes et al. 2004).

5.3.2. Redox imbalance is more pronounced in somatic areas of hippocampal neurons

Several studies have previously shown changes in neuronal dendrites during aging and in neurodegeneration. For example, physiological and structural impairments of dendrites include a reduction in arborisation, a lower number of spines or higher mitochondrial oxidative stress (Dickstein et al. 2007; Greenwood et al. 2007; Gomez-Isla et al. 2008; Rocher et al. 2008; Dryanovski et al. 2013; Siskova et al. 2014; Hasel et al. 2015). Interestingly, the current investigation of redox status in *Mecp2*^{-/-} and WT hippocampal neurons revealed a significantly higher cytosolic baseline roGFP1 ratio in neuronal somata in comparison to dendrites, suggesting a more oxidized basal redox state in the somatic areas. However, neuronal exposure to oxidative challenge by a local neuronal stimulation (H₂O₂, 200 µM, 200 ms), shifted the roGFP1 ratio towards more oxidizing conditions in dendrites of

these cells, in particular. Similarly to these observations, recent findings have indicated more dramatic fluctuations in the redox potential in cortical dendrites in response to H₂O₂ treatment (Hasel et al. 2015). This was confirmed for mouse embryos E17.5 by using the genetically-encoded reporter of the glutathione redox potential Grx1-roGFP2 (Hasel et al. 2015).

Noteworthy, upon H₂O₂ administration, *Mecp2*^{-/-} neurons showed a tendency towards a higher oxidation in both dendritic and somatic areas as compared to WT. This indicates an increased vulnerability of the cytosolic redox homeostasis in somata and dendrites of *Mecp2*^{-/-} hippocampus. Indeed, similarly to other ROS, H₂O₂ impairs various cellular processes including mitochondrial ATP generation, regulation of Ca²⁺ levels, activity and gating of ion channels, and the axonal transport of mitochondria (Denu and Tanner 1998; Forte et al. 2007; Marino et al. 2007; Gerich et al. 2009; Fang et al. 2012).

Surprisingly, although H₂O₂ was locally applied to dendrites of primary neurons, the first and clear responses to redox modulation were observed rather in the soma. This was true for *Mecp2*^{-/-} and WT neurons. It is well known that H₂O₂ reacts very fast, affecting almost every single molecule. However, although H₂O₂ is highly membrane permeable, how exactly it crosses the cellular membrane of neurons, still remains unclear. It was considered that H₂O₂ is capable of crossing the membrane of mammalian cells via selected aquaporins (Bienert et al. 2006). Aquaporin-8 (AQP8), which is present in many tissues and organs, was found to have an increased sensitivity to H₂O₂ (Bienert et al. 2006). It was shown to be in the plasma membrane, but later studies have indicated that AQP8 is also expressed in the inner mitochondrial membrane (Calamita et al. 2005; Liu et al. 2006; Bienert et al. 2007). Therefore, AQP8 was suggested to be involved in cellular H₂O₂ diffusion. On the other hand, recently it has been reported that most neurons in the central nervous system, especially pyramidal neurons, do not express functional aquaporins, which might serve to prevent any unwanted cellular volume changes upon acute osmotic stress (Andrew et al. 2007).

No matter how H₂O₂ crosses the lipid bilayer of neurons, the pathways might differ between dendrites and soma. It would be also interesting to take a closer look at sub-cellular redox buffering capacities within neuronal cells, which might vary in dendritic and somatic compartments, and which may also be different between WT and *Mecp2*^{-/-} mice. On top of that, it would be also tempting to assess, whether the dendritic scavenging systems differ from the somatic ones, with special regards to the activity and localisation of catalase, as it is involved in the degradation of H₂O₂ to H₂O and O₂ (Luck 1954).

5.3.3. *Mecp2*^{-/-} neurons reveal altered responses to redox challenge and show less efficient superoxide dismutation

It has been previously shown by our group that the roGFP1 ratio was increased under oxidative challenge in *Mecp2*^{-/-} hippocampus (Großer et al. 2012). This finding could be extended and specified in the current work. First, it could be demonstrated that differences in response to redox challenge between *Mecp2*^{-/-} vs. WT mice were obvious especially in hippocampal organotypic slices as compared to neuronal cell culture preparations. It could be also shown that *Mecp2*^{-/-} neurons responded with increased oxidative shifts to H₂O₂ (200 µM) than WT. This was markedly visible in cytosolic and mitochondrial compartments. However, more excessive oxidation was found rather in cytosol than in mitochondria, suggesting either a higher ROS production and/or a less efficient ROS scavenging, and thus a more pronounced redox imbalance in this compartment. As an intensified extramitochondrial ROS generation in *Mecp2*^{-/-} hippocampus was earlier excluded by our group, and even less pronounced extramitochondrial ROS production was found in *Mecp2*^{-/-} neonatal slices (Großer et al. 2012). It therefore seems that especially the redox-maintaining cytosolic buffering systems are impaired in Rett syndrome.

In the current work, differing redox responses of *Mecp2*^{-/-} vs. WT neurons were detected upon SOD inhibition. Previously, the first suggestions towards an impaired SOD in Rett syndrome have been made as a reduced activity of this enzyme was found in blood samples of Rett patients (Sierra et al. 2001).

Changes in Cu-Zn-SOD (SOD1) – localized in cytoplasm, nucleus and lysosomes of mammalian cells (Chang et al. 1988; Keller et al. 1991; Crapo et al. 1992; Liou et al. 1993; Zelko et al. 2002) – have been also shown on the genetic level, e.g. the *SOD1* was upregulated in the adult *Mecp2*^{-/-} Cornu ammonis 1 (CA1) region of hippocampus (Großer et al. 2012).

Impairment of SOD could be also confirmed specifically in *Mecp2*^{-/-} hippocampal neurons in the current thesis, and this was especially obvious for slice cultures. Upon SOD inhibition, the roGFP1 ratio shifted towards oxidation, which was significantly less intense in *Mecp2*^{-/-} neurons in comparison to WT. This might be due to the assumed reduced activity of SOD in Rett syndrome. Interestingly, these modulations were obvious in cytosol as well as in mitochondria of *Mecp2*^{-/-} hippocampal neurons, thus suggesting alterations not only in cytosolic SOD1 but also in the mitochondrial Mn-SOD (SOD2) (Weisiger and Fridovich 1973; Zelko et al. 2002). Since a mitochondrion is surrounded by two-phospholipid bilayers, weaker responses to SOD inhibition might be an effect of a resistant barrier against drug diffusion. This might also apply to slice culture preparations, since mitochondria of WT and *Mecp2*^{-/-} slices reacted less to SOD inhibition. Mitochondria may be therefore more resistant to SOD blockade.

Also, sub-cellular cyto-roGFP1 ratio changes have been observed for hippocampal neurons in response to SOD inhibition. Interestingly, the DEDTC induced increase of the cyto-roGFP1 ratio was less pronounced in dendrites than in somata, suggesting less efficiency of SOD in dendrites than in the soma of hippocampal neurons. This change was especially clear for WT neurons.

5.3.4. *Mecp2*^{-/-} hippocampus is more susceptible to hypoxia and mitochondrial challenge

The *Mecp2*^{-/-} hippocampus has been previously confirmed to be more vulnerable to hypoxia (Fischer et al. 2009; Großer et al. 2012). An increased hypoxia-susceptibility could be now confirmed specifically for *Mecp2*^{-/-}

neurons. It could be shown that during hypoxia, the roGFP1 ratio decreased more in *Mecp2*^{-y} hippocampal organotypic slices and neuronal cultures as compared to WT. A substrate reduction and/or inhibition of NOX and/or XO might serve as a possible explanation of this observation. Indeed, NOX and XO have been reported to constitute extramitochondrial ROS sources and were shown to be O₂-dependent (Abramov et al. 2007; Funke et al. 2011). Along this line, NOX was suggested to be involved in ROS generation especially during reoxygenation after hypoxia. It was shown that O₂ and glucose deprivation as well as reoxygenation led to a cellular Ca²⁺ increase and further NOX activation (Abramov et al. 2007). Activation of XO also seems to require Ca²⁺ influx (Dykens et al. 1987). However, other studies questioned the Ca²⁺-dependent activity of XO (Abramov et al. 2007).

Yet, no clear changes in the roGFP1 ratio traces were observed upon reoxygenation in the current work. Nevertheless, it should be noted that changes in the expression of NOX, XO, ATPase and the rate of mitochondrial depolarization are not stationary processes and they represent an intense and progressive cross-talk between Ca²⁺, ATP consumption and mitochondrial membrane potential. Therefore, detection of generated ROS depends on how the mitochondrial potential is maintained. Well maintained mitochondria are constantly producing ROS, which might be untraceable though in case of fast depolarizing mitochondria under hypoxic conditions (Abramov et al. 2007). A significant role of mitochondria in hippocampal neurons during hypoxia was also confirmed by the present observations. More pronounced responses to hypoxia were found in mitochondria and cytosol in hippocampal slices, but also in mitochondrial compartments in cell culture, which was more intense in *Mecp2*^{-y} neurons as compared to WT. Such effects might be also supported by the fact, that the hippocampal network together with the neocortical and cerebellar circuits, constitute the most sensitive parts of the brain to hypoxic/ischemic conditions (Pulsinelli et al. 1982; Schmidt-Kastner and Freund 1991; Fischer et al. 2009).

Furthermore, morphological changes might also enhance hypoxic responses. Smaller and more densely packed neurons as well as less complex dendritic

arborizations and reduced spine numbers, observed in Rett syndrome (Belichenko et al. 1994; Bauman et al. 1995), could also go in line with a higher hypoxia vulnerability. However, the elevated levels of the hypoxia-inducible factor 1-alpha (HIF1 α) found in hippocampus, neocortex, cerebellum and lower brain stem of *Mecp2*^{-/-} mice, indicated that not only hippocampus, but also other parts of *Mecp2*^{-/-} brain seem to be more hypoxia-sensitive (Fischer et al. 2009).

5.4. Intact neurotransmission is required for a proper neuronal network functioning

In spite of the incomplete knowledge on detailed molecular mechanisms, regulating neuronal plasticity, there are indications, pointing to the involvement of neurotransmitters and neurotrophic pathways in neuroplasticity processes (Mattson 2007). Extensive studies have shown a pivotal role of mitochondria in plasticity-related mechanisms such as neuronal polarity formation and neurite outgrowth control (Vayssiere et al. 1992; Mattson and Partin 1999; Chada and Hollenbeck 2004; Lee and Peng 2006). Also, damaged mitochondria contribute to changes in neuronal plasticity as ROS serve signalling functions by modulating activities of kinases or the phosphatase calcineurin (Kamsler and Segal 2003; Hongpaisan et al. 2004).

Since the extracellular electrical stimulation of primary neurons was not suitable to perform detailed studies on neuronal activity, primary neurons were exposed to various neurotransmitters. It is well known that exaggerated ROS production, redox imbalance and further aberrant energy states, lead to neuronal network disturbances and functional changes within cells. Data on neuronal responses to glutamate, norepinephrine, serotonin and dopamine confirmed such disruptions by shifting the cellular redox conditions towards oxidation. With all transmitters tested, this was significantly more pronounced in *Mecp2*^{-/-} than in WT neurons.

The current thesis is the first study showing very clear redox responses of *Mecp2*^{-/-} neurons to neurotransmitters, which additionally confirms the cellular

redox impairment in *Mecp2*^{-/-} hippocampus. Therefore, another aim of the current work was to evaluate possible candidate processes, which might stand behind such redox alterations, e.g. activation of NOX and XO, Ca²⁺ influx, engagement of mitochondrial respiratory chain or increase of cAMP levels. Since glutamate is the principal excitatory neurotransmitter and mediates also neuronal excitotoxicity when excessively released (Atlante et al. 2001), it was interesting to assess the possible signalling pathways of redox changes in response to glutamate. Also, the responses to dopamine under above-mentioned conditions have been investigated as dopamine was the only one, which evoked redox responses with full recovery in *Mecp2*^{-/-} and WT neurons.

5.4.1. Activation of NADPH oxidase and xanthine oxidase contributes to ROS production in response to glutamate

Disruptions in various neurotransmitters have been already proposed for Rett syndrome (Hamberger et al. 1992; Lappalainen and Riikonen 1996; Viemari et al. 2005; Chao et al. 2010; Maezawa and Jin 2010). In the current thesis, it became evident that exposure to neurotransmitters glutamate, norepinephrine, serotonin and dopamine, induced redox alterations and shifted redox status towards more oxidizing conditions. It was especially *Mecp2*^{-/-} neurons, which overreacted and which did not show a proper recovery of the cyto-roGFP1 ratio to its pre-treatment baseline upon wash out of the tested compounds. This might suggest a persistent redox impairment in *Mecp2*^{-/-} neurons. Such changes have been particularly obvious during glutamate application as the cyto-roGFP1 ratio continued to increase even when the treatment was terminated.

Glutamate has been previously shown to induce an irreversible neuronal injury, leading to cell death (Choi 1988; Hamberger et al. 1992; Lappalainen and Riikonen 1996; Simonian and Coyle 1996; Meldrum 2000; Ha et al. 2009; Maezawa and Jin 2010). It was suggested to activate lactate production, causing neuronal acidification and damaging mitochondria by decreasing mitochondrial membrane potential and provoking mitochondrial uncoupling,

which gives rise to ROS generation. Moreover, a decrease in the efficiency of the cellular antioxidant defences by glutamate has been shown to enhance an oxidative stress (Ciani et al. 1996). Surprisingly, treatment with glutamate, in the presence of the mitochondrial uncoupler FCCP, failed to prevent the increase in cyto-roGFP1 ratio. This strongly suggests that the major redox response to glutamate is mediated by other cellular sources rather than mitochondria. However, it should be mentioned that mitochondrial uncoupling evoked the largest decrease of the cyto-roGFP1 ratio baseline in WT and *Mecp2*^{-/-} neurons when compared to ACSF conditions. Therefore, it indicates that mitochondria do contribute to redox changes and ROS production in hippocampal neurons, at least under control baseline conditions.

Glutamate was proposed to mediate its effects on different molecular levels, namely through ionotropic receptors, i.e. NMDA, α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) and kainate receptors in postsynapses (Nicholls and Budd 2000). Activation of NMDA and non-NMDA receptors leads to a neuronal injury due to intracellular Ca^{2+} overload (Olney 1969; Michaels and Rothman 1990; Nicholls and Budd 2000). In the current study, the cultured *Mecp2*^{-/-} neurons still markedly reacted to glutamate in Ca^{2+} free conditions, shifting the cyto-roGFP1 ratio towards oxidation. However, the responses of WT neurons to glutamate were almost abolished.

Glutamate may also operate through G-protein coupled glutamate metabotropic receptors (mGluR) by affecting ion channels or secondary messengers such as diacylglycerol and cAMP (Schoepp and Conn 1993; Pin and Duvoisin 1995; Conn and Pin 1997; Meldrum 2000). Yet, activation of the adenylate cyclase and hence, elevation of the intracellular cAMP concentration by forskolin, did not reveal any changes in the cyto-roGFP1 ratio, which excludes an involvement of cAMP-coupled mGluR in redox modulation during neuronal exposure to glutamate.

Interestingly, it could be also shown, that upon blocking NOX by DPI, glutamate did not cause any longer major redox changes. This indicates that NOX might be crucially engaged in redox responses to glutamate. The NOX

was earlier proposed to intensify ROS production by neurons, whereas the generation of $\cdot\text{O}_2^-$ was restrained upon NOX inhibition in the presence of glutamate (Brennan et al. 2009). Furthermore, ROS formation induced by NOX under glutamate administration, seemed to be independent on mitochondria. Neurons have been confirmed to generate ROS even upon an overexpression of the mitochondrial SOD2, whereas ROS output was markedly reduced in neurons lacking NOX (Brennan et al. 2009; Demaurex and Scorrano 2009).

Nevertheless, other studies suggested also a role of XO in the production of ROS due to glutamate neurotoxicity in cerebellar granule cells. This occurs via a conversion of xanthine dehydrogenase (XDH) to XO in response to Ca^{2+} influx (Atlante et al. 1997). Moreover, generation of peroxide was previously shown to be prevented by laupeptin, which inhibits the conversion of XDH to XO (Atlante et al. 1997). Indeed, the inhibition of XO by allopurinol prevented glutamate-mediated changes in the roGFP1 ratio, confirming a crucial XO involvement in these redox responses.

It should be mentioned, that XO seems to act as the most efficient catalyzer of $\cdot\text{O}_2^-$ production, since the time course of XO activity coincides with the generation of oxygen radicals after glutamate stimulation of cerebellar granule cells (Atlante et al. 1997). On top of that, the same studies showed that XO activity was lost in the presence of the NMDA receptor antagonist MK-801 or ethylene glycol tetraacetic acid (EGTA), which captures Ca^{2+} . This suggests that activation of XO, and therefore, conversion of XDH to XO, is mediated by NMDA receptors and Ca^{2+} influx. Thus, Ca^{2+} influx is a crucial trigger of ROS production as it may activate XO and NOX. This view is supported by the observation that WT neurons do not longer become oxidized when glutamate is applied under Ca^{2+} free conditions. However, the latest studies showed that NOX may be also active even in low magnesium (Mg^{2+}) and Ca^{2+} -free conditions (Kovac et al. 2014).

It should be mentioned, that glutamate was the only neurotransmitter, which induced an initial drop in the cyto-roGFP1 ratio traces. The reason of this

response changes is, however, not clear. It could be that there are other glutamate receptor subtypes, which mediate this only moderate response.

5.4.2. Dopamine modulates mitochondrial function in *Mecp2*^{-y} hippocampal neurons

The link between neuron-specific oxidative stress and dopamine was previously indicated by several studies (Cubells et al. 1994; Wrona et al. 1997; Cadet and Brannock 1998; Miyazaki and Asanuma 2008). In the current thesis, it was shown that clear cytosolic redox changes could be evoked by the dopaminergic system in *Mecp2*^{-y} and WT hippocampal neurons. Indeed, dopaminergic neurotoxicity was proposed to be strictly related with the generation of ROS and dopamine quinone formation (Graham 1978; Sulzer et al. 2000). Since dopaminergic neurons are enriched with iron and other transition metals, H₂O₂ may lead to the production of $\cdot\text{OH}$ in a Fenton reaction. Moreover, dopamine was suggested to provoke the mitochondrial impairment, e.g. dopamine has been shown to inhibit the mitochondrial complex I, demolish mitochondrial motility and dissipate the mitochondrial membrane potential (Ben-Shachar 2002; Brenner-Lavie et al. 2008; Miyazaki and Asanuma 2008). Such changes clearly suggest that dopamine indeed interacts with the mitochondrial respiration and may lead to cellular redox impairment. However, since dopamine shifted the roGFP1 ratio towards oxidation despite the presence of FCCP, mitochondria are not the only molecular player through which dopamine acts, although their contribution seemed to be higher in *Mecp2*^{-y} than in WT neurons. The Ca²⁺ free conditions did not prevent an increased cyto-roGFP1 ratio upon dopamine application, suggesting Ca²⁺ release from other cellular sources. Interestingly, the roGFP1 responses to dopamine were markedly dampened when NOX was inhibited by DPI in the current thesis, which again indicated a pronounced role of NOX in ROS producing signalling pathways.

Yet, the question remains, whether such pronounced responses of the cyto-roGFP1 ratio were simply due to high concentration of dopamine applied, as a concentration of 30 nM is considered to be within the physiological range

(Lee et al. 2000). Nevertheless, the 500 μ M dopamine used here, can be considered not to impair cell viability as the redox changes fully recovered upon wash-out. Also, studies on schizophrenia revealed that intact, coupled and respiring mitochondria could accumulate saturated doses of dopamine, and non-lethal dopamine-mitochondria interactions were detected (Brenner-Lavie et al. 2008).

6. Redox imbalance occurs not only in *Mecp2*^{-/-} neonates but also in neurons of adult and symptomatic Rett mice

Transgenic mice, carrying specifically mitochondrial (roGFP1m) and cytosolic (roGFP1c) roGFP1 sensors within neurons, could be recently successfully generated in our lab (Wagener et al. 2016). Cross-breeding of these mice with heterozygote *Mecp2*^{+/-} females will allow to obtain symptomatic *Mecp2*^{-/-} mice, which carry roGFP1 redox indicators for mitochondria and cytosol, specifically in neurons.

In the current work, the first tests towards an investigation of a redox imbalance under control conditions in hippocampal and cortical neurons of adult roGFP1c *Mecp2*^{-/-} mice could be performed. It could be confirmed, that roGFP1c *Mecp2*^{-/-} neurons (PD 47-52) of CA1 and DG regions of hippocampus were more oxidized as compared to the respective WT mice. Although a proper evaluation of neuronal responses to oxidative challenge conditions is lacking so far, these are the first tests confirming redox impairment by using functional redox imaging in living neurons of symptomatic, adult Rett mice.

6. Conclusion and future perspectives

Extensive research has been carried out to evaluate the redox changes in *Mecp2*^{-/-} neonatal hippocampus by taking advantage of the genetically-encoded optical sensor roGFP1. In the current thesis, it could be shown that *Mecp2*^{-/-} hippocampal organotypic slices suffer from an increased oxidative burden, which has been confirmed also for *Mecp2*^{-/-} dissociated neurons. They were more susceptible to hypoxia and revealed more intense oxidizing shifts in response to oxidative challenge. Moreover, *Mecp2*^{-/-} neurons possess less efficiently working cellular scavenging systems.

Upon redox challenge, genotypically different redox responses could be found in the cytosol as well as at the level of mitochondria. This confirms that Rett syndrome is indeed associated with early mitochondrial alterations. Although there are studies questioning that Rett syndrome constitutes a primary mitochondrial disease (Matsuishi et al. 2011), it could be confirmed that neuronal mitochondria of *Mecp2*^{-/-} hippocampus do show a more oxidized and a more vulnerable redox balance already at neonatal and pre-symptomatic stages. These findings therefore support the hypothesis, that mitochondria constitute a primary cause or at least very crucial events for disease progression.

Furthermore, the current thesis underlines the key role of neurotransmitters in neuronal redox events and provides evidence that even subtle changes in the neuronal activity may lead to a substantially modified redox balance. However, more knowledge must be gathered in order to better understand the fine molecular mechanisms by which neurotransmitters lead to intensified ROS production and cellular redox changes. Without doubt, the exaggerated redox responses seen in *Mecp2*^{-/-} neurons with all neurotransmitters tested, may shed a new light on disturbed neurotransmission in Rett syndrome. So far, the responses to the tested neurotransmitters have been assessed in individual *Mecp2*^{-/-} cultured neurons. Now, it would be interesting to investigate similar reactions in organotypic or even acute hippocampal *Mecp2*^{-/-} slices. It would be evenly tempting to assess redox changes in the

mitochondrial compartments of *Mecp2*^{-/-} and WT neurons under the treatment with these neurotransmitters.

Transfection and viral transduction procedures required to deliver roGFP1-coding DNA limited the current studies to cell and slice cultures, and hence neonates. The next crucial step would be therefore to use the novel transgenic redox-sensor mice. They specifically express roGFP1 in the cytosol and the mitochondrial matrix, and they will finally enable sub-cellular analyses of redox changes also in adult neurons (Wagener et al. 2016). Cross-breeding these transgenic lines with the *Mecp2*^{-/-} mice will provide the tremendous opportunity to assess redox imbalance of adult stages of *Mecp2*^{-/-} mice and to correlate it in detail with the disease progression of Rett syndrome.

Acknowledgements

I would like to express sincere gratitude to my supervisor Prof. Michael Müller for giving me the opportunity to work in his lab. I am gratefully thankful for his outstanding guidance, generous support, great leadership, good advice and critics.

I greatly appreciate my thesis committee members Prof. Detlev Schild and Dr. Sebastian Kügler for insightful discussions, advice and helpful suggestions to my project. I also thank Dr. Sebastian Kügler and Dr. Johan Tolö for their collaboration in order to make the viral vector available for my thesis.

I am very grateful to Prof. S. James Remington for making available to our group the roGFP coding plasmids.

I sincerely thank the DFG CNMPB for accepting my project to the CNMPB program.

I would like to truly thank Prof. Swen Hülsmann for his good advice and stimulating discussions about the project.

My special appreciation goes to Axel Zigan for his commitment in taking care of my mice. A big thank you goes also to all the people from the mechanical workshop.

I would like to gratefully acknowledge my friends and colleagues. Especially, I thank Belinda Kempkes for the best technical assistance, her abundant help during my whole work and for spreading her unique positive attitude in our lab ;) Furthermore, I would like to express my deepest thanks to my close friends Dr. Oliwia Janc, Dr. Christiane Menzfeld and Dr. Chiranjeevi Bodda for their precious time spent on valuable discussions and advice. Thank you all for your priceless support, patience and for your presence during my moments of weakness. Thank you that you have never doubted me. I will always appreciate your motivation and encouragement. My warm thanks go also to

Dr. Katharina Dietrich and Lukas Terwitte for helping me with slicing and taking images. Moreover, I thank Anja-Annett Grützner, Kerstin Wagener, Mark Hüser as well as all former students of MM and Swen Hülsmann's groups for their great company in the lab.

Finally, the absolutely biggest thank you I would like to address to people closest to my heart: Teresa Can, Jerzy Can and Katarzyna Can. Kochana Mamo, Kochany Tato, Kochana Siostró, dziękuję Wam za to, że nigdy we mnie nie zwątpiliście. Dziękuję Wam za Wasze nieocenione wsparcie. Jestem wdzięczna za Waszą nieustającą troskę, pomoc, poświęcenie oraz niegasnącą miłość. Dziękuję Wam za to, że zawsze jesteście dla mnie obecni i uczestniczycie w moim życiu każdego dnia, choć dzieli nas spora odległość. Dziękuję Wam za niekończącą się walkę o mnie. Dziękuję Wam również za to, że znacie mnie lepiej, niż ja samą siebie. Bez Was, bez Waszej dobrej rady, otuchy, jak również potrzebnych słów krytyki, poległabym na tej trudnej drodze.

I dedicate this work to my beloved and never forgotten Grandparents Weronika Can, Zofia Wróbel, Stanisław Can and Czesław Wróbel.

Curriculum vitae

Name Karolina Can
Address Leibnizstr.6
37083 Göttingen
Email karolina.can@gmail.com
Mobile +49 157 56744842

Date of birth 21.07.1987
Place of birth Bielawa
Nationality polish
Sex female

Education

Since 07/2012 Ph.D Student of the DFG research Center for Nanoscale Microscopy and Molecular Physiology of the Brain (CNMPB), Göttingen
Thesis: Redox imbalance and oxidative stress in *Mecp2* deficient neurons

10/2006-09.2012 Master of Science at Jagiellonian University in Cracow, Poland
Thesis: Identification of insertion site for the *Mecp2*^{R270_EGFP} transgene in mouse and functional characterization of *Mecp2*^{R270} mutant mouse models

11/2009-11/2011 Annual practice and Master thesis executing at the Institute of Human Genetics at Georg-August Universität Göttingen, Göttingen, Germany

09/2003-09/2006 I LO im. Jędrzeja Śniadeckiego, Dzierżoniów, Poland
Higher education entrance qualification, Matura
