

Constitutive heterogeneity and response diversity of microglia in pathological conditions

Doctoral Thesis

In partial fulfillment of the requirements for the degree
“Doctor rerum naturalium (Dr. rer. nat.)“
in the Molecular Medicine Study Program
of the Georg-August University School of Science (GAUSS)
at the Georg-August University Göttingen

submitted by Ulla Gertig

born in Burg

Göttingen, 2016

Members of the Thesis Committee:

Supervisors

Prof. Dr. Uwe. K. Hanisch†
Department of Neuropathology, University Medical Center Göttingen

Prof. Dr. Wolfgang Brück
Department of Neuropathology, University Medical Center Göttingen

Second member of the thesis committee

Prof. Dr. Dr. Hannelore Ehrenreich
Department of Clinical Neurosciences, Max Planck Institute of Experimental Medicine, Göttingen

Third member of the thesis committee

Prof. Dr. Fred Wouters
Department of Neuropathology, University Medical Center Göttingen

Further members of the examination board:

Prof. Dr. med. Jutta Gärtner
Department of Neuropediatric, University Medical Center Göttingen

Prof. Dr. Ralf Heinrich
Department of Cellular Neurobiology, Schwann-Schleiden-Forschungszentrum, Göttingen

Dr. Hauke Werner
Department of Neurogenetics, Max Planck Institute of Experimental Medicine, Göttingen

Date of Disputation: 12.12.2016

Affidavit

Here I declare that my doctoral thesis entitled "Constitutive heterogeneity and response diversity of microglia in pathological conditions" has been written independently with no other sources and aids than quoted.

Ulla Gertig

Acknowledgments

I would like to sincerely thank my supervisor Prof. Dr. Uwe K. Hanisch for giving me the opportunity to work in his laboratory on this wonderful project. It was always inspiring to brainstorm about new ideas, methods and the possible mechanisms behind. I would also like to thank Prof. Dr. Wolfgang Brück for stepping in as a supervisor after the tragic and unexpected death of Prof. Hanisch. Thank you for allowing me to continue my project, for the support, ideas and especially the very time efficient meetings.

Special thanks goes to my thesis committee members Prof. Hannelore Ehrenreich and Prof. Fred Wouters for their supporting comments and ideas, their time and appreciation.

My deepest gratitude goes to my colleagues Insa Dammann, Kim Bleuel, Sarah Traffehn, Nasrin Saiepour, Christin Fritsche and Linda Feldmann. I never would have survived all the hardships, struggles and desperations without you girls. Thank you for the daily coffee, the encouragement and most importantly the free sarcasm. Special thanks goes to Basti for being the substitute during a breakdown once no girl was available ;-)

I am also grateful for the help, support and understanding of our technical assistances Elke Pralle and Susanne Kiecke.

Apart from my colleagues of the neuropathology department, I want to thank my family and friends as well. You were always there for me, cared for me, supported me in every imaginable way and accompanied me during all my studies.

My biggest hug and thanks goes to my beloved husband Michael Gertig. Thank you for enduring me, supporting me, loving me, and for gifting me with our lovely daughter Emily. I would have never made it this far without you.

Abstract

Microglia, resident myeloid cells of the CNS, execute an enormous variety of different functions like tissue surveillance, nursing of synapses, phagocytosis of foreign material or debris, and initiation of appropriate immune responses upon CNS infection and damage (Hanisch and Kettenmann, 2007; Kettenmann et al., 2011). The duration of an immune response is thereby self-limiting as it resolves with a successful combat of the threat. A sustaining threat, however, can lead to an over-activation of microglia which switches their initially beneficial effect to a rather detrimental outcome. This disturbed microglia phenotype leads to a variety of neuropsychiatric disorders or neurodegenerative diseases and aggravates the disease outcomes, mostly resulting in neurotoxicity (Gold and Khoury, 2015; Hickman et al., 2008; von Bernhardi et al., 2015). Targeting microglia is therefore a promising therapeutic approach to oppose those diseases (Chen et al., 2014; Wes et al., 2016). Though, microglia functions are in most cases performed by a mere subpopulation, a drug targeting the whole microglia population would thereby effect not only the subsets causing the neurotoxicity but also the subsets which try to resolve the disease (Biber et al., 2016; Marshall et al., 2014; Olah et al., 2012; Venkatesan et al., 2010). Thus, to develop a useful drug, which specifically targets a harmful subpopulation of microglia, the microglial organization principle needs to be unraveled beforehand.

This study focused on the functional heterogeneity of a microglial immune response by investigating cytokine producing microglia subsets confronted with a variety of stimuli conditions in different environmental contexts. I observed a highly specific adaptation of those subsets. The degree of adaptation is thereby dependent on the investigated function, the used stimulus, the stimulus intensity and the microglia density. Further analysis revealed that the subpopulations are not performing one single function but multiple functions at once. Function specific subpopulations are thereby composed of subpopulations which perform other functions as well. These results demonstrate an almost infinite organization complexity of microglia subsets, highlighting the importance of further research to fully understand the nature of microglia.

1. Introduction

1.1 Microglia

Microglia are brain-resident myeloid cells and execute an enormous variety of different functions within the central nervous system (CNS) including surveillance of the tissue, nursing of synapses, phagocytosis of debris, cells or foreign material, and initiation of appropriate immune responses upon damage or infection. They are highly motile cells involved in proper brain development but also implicated with a variety of neurodegenerative and inflammatory diseases (Hanisch and Kettenmann, 2007; Kettenmann et al., 2011). Microglia vary by local densities and functional properties which makes them a very heterogeneous population of cells with the potential to perform their huge repertoire of functions simultaneously by multitasking and division of labor (Gertig and Hanisch, 2014; Hanisch and Kettenmann, 2007; Lawson et al., 1990).

1.2 Origin of microglia

Microglia are the prime innate immune cells of the CNS, comprising approximately 10% of its total cell number (Aguzzi et al., 2013). They form a robust, long living and self-renewing population of immune cells (Kierdorf et al., 2013) with no contribution from bone-marrow derived progenitors under physiological conditions (Ajami et al., 2007). In a healthy environment microglia turnover is rather rare, but if microglia are depleted from brain or spinal cord they are able to repopulate completely within 14 days from a small population of surviving microglia or nestin-expressing microglial progenitor cells (Bruttger et al., 2015; Elmore et al., 2014; Yao et al., 2016).

Unlike neurons and other glial cells which derive from the neuroectoderm, microglia are of mesodermal origin (Chan et al., 2007; Prinz and Mildner, 2011). They derive from erythromyeloid precursor cells in the yolk sac which transform into yolk sac macrophages during primitive hematopoiesis and subsequently migrate into the brain where they become microglia cells (Ginhoux et al., 2010; Hoeffel et al., 2015; Kierdorf et al., 2013; Masuda and Prinz, 2016). As

microglia start to colonize the murine brain already at embryonic day 8.5-9.5 they play a crucial role in shaping the CNS during development (Ginhoux et al., 2010).

1.3 Role of microglia in development

During embryogenesis, microglia are already present in the brain when neurons are still in the process of migration, proliferation and differentiation. During this time, approximately 50% of the newborn neurons undergo programmed cell death and do not become mature (Schafer and Stevens, 2015). This process involves microglia which are responsible for phagocytosing these newly generated non-surviving cells, as it was shown by various studies conducted in mice, rats and zebrafish (Ferrer et al., 1990; Peri and Nüsslein-Volhard, 2008; Sierra et al., 2010).

Additionally, microglia regulate the number of neural precursor cells in the developing cerebral cortex by phagocytosing a proportion of viable cells with no signs of cell death, apoptosis or nuclear breakdown (Cunningham et al., 2013). In contrast, some findings also indicate a neuro-protective role of microglia necessary for the survival of specific types of neurons (Ueno et al., 2013). An *in vitro* study was even able to demonstrate the involvement of microglia on neural precursor cell differentiation (Aarum et al., 2003), which was later confirmed *in vivo* (Xavier et al., 2015).

Microglia are crucial for the synaptic maturation as well. Microglial processes reach developing synapses and remove redundant ones in a process called “synaptic pruning”. A deficiency in this function leads to a rather immature brain circuitry and is assumed to be involved in neurodevelopmental and neuropsychiatric disorders (Hoshiko et al., 2012; Paolicelli et al., 2011; Schafer et al., 2012; Squarzoni et al., 2014; Zhan et al., 2014). A similar function of microglia called “synaptic stripping” which persists beyond development removes synapses from injured neurons (Kettenmann et al., 2013). Studies on mice suggest an additional role of microglia in the modification and elimination of synaptic structures upon alterations in visual experience and multiple learning tasks, indicating a contribution to learning and memory (Parkhurst et al., 2013; Tremblay et al., 2010).

Other studies have shown that microglia support neurogenesis and oligodendrogenesis by

secreting specific cytokine mixtures into the subventricular zone of developing rat brains (Shigemoto-Mogami et al., 2014). However, apart from their role in the developing brain, microglia exhibit also important functions to maintain the CNS homeostasis through lifetime. The support of neurogenesis, for instance, lasts even beyond embryogenesis since microglia are required for proper adult neurogenesis as well (Ziv et al., 2006).

1.4 Microglia functions

Under normal physiological conditions microglia have a ramified appearance that is characterized by extended, branched processes. Even though the somata are rather fixed, their processes are highly motile. They extend and withdraw continually, allowing the microglia to scan the whole brain parenchyma for signs of disturbance within hours (Davalos et al., 2005; Nimmerjahn et al., 2005). Simultaneously, they monitor synapse function of neurons and are involved in their elimination and restoration (Wake et al., 2009).

It is assumed that once microglia recognize an injured cell, debris or even a dying cell, they respond appropriately by repair, support or phagocytosis (Hanisch and Kettenmann, 2007; Nimmerjahn et al., 2005; Streit, 2002). However, when microglia recognize tissue injury or infection, they shift rapidly from their surveilling state to a rather activated phenotype (Davalos et al., 2005). In this state, microglia have a more amoeboid appearance which allows them to migrate actively to the side of injury or infection by following chemotactic gradients (Davalos et al., 2005; Haynes et al., 2006; Honda et al., 2001; Koizumi et al., 2007; Liu et al., 2009). Once microglia arrive at the site of disruption, they start to initiate a range of situation-specific activities like phagocytosis, proliferation, antigen presentation or secretion of cytokines and chemokines in order to recruit additional immune cells from the periphery (Buttini et al., 1996; Graeber et al., 1988; Hanisch, 2002; Kettenmann et al., 2011; Streit, 2002; Streit et al., 1989). To be able to detect all kinds of threats and to adapt a proper immune response, microglia express a vast range of different receptors allowing this discrimination.

1.5 Microglia signaling

In order to sense any threat in form of pathogen-associated molecular patterns (PAMPs) or damage/danger associated molecular patterns (DAMPs), microglia express pattern-recognition receptors (PRRs) (Saijo and Glass, 2011). These receptors are able to recognize lipids, lipoproteins, proteins and nucleic acids derived from bacteria, viruses, parasites and fungi as well as intra- or extracellular proteins released by injured cells. One form of these PRRs are Toll-like receptors (TLRs), which are also present in microglia.

TLRs are transmembrane proteins that have leucine-rich repeats on their extracellular domains to recognize PAMPs and Toll-interleukin 1 (IL-1) receptor (TIR) domains on their intracellular domains to transduce downstream signaling (Kawai and Akira, 2010). There are 12 functional TLRs in mouse (TLR1-TLR9; TLR11-TLR13) and 10 in humans (TLR1-TLR10) (Akira et al., 2006).

TLRs divide into two subgroups depending on their cellular localization and the patterns they recognize. The first group resides on the cell surface and consists of TLR1, TLR2, TLR4, TLR5, TLR6 and TLR11. Those TLRs recognize mainly microbial membrane components. The second group comprising TLR3, TLR7, TLR8 and TLR9 are exclusively intracellular, expressed on endosomes, the endoplasmic reticulum, endolysosomes or lysosomes, where they recognize mainly microbial nucleic acids. TLRs can signal through two routes, they use either the MyD88 (myeloid differentiation primary response gene 88) dependent signalling pathway which is used by all TLRs except for TLR3 or the TRIF (TIR-domain containing adaptor protein inducing Interferon- β) dependent signaling pathway which is used by TLR4 and TLR3. TLR4 is thereby an exception, since it is able to signal through both pathways (Takeda and Akira, 2004).

TLR4 recognizes bacterial lipopolysaccharide (LPS), a cell wall component of gram-negative bacteria such as *escherichia coli* (Hoshino et al., 1999; Poltorak et al., 1998). To do so, the receptor forms a complex with MD2 (myeloid differentiation factor 2), which allows binding of LPS (Schromm et al., 2001; Shimazu et al., 1999). A multidimer composed of two copies of the aforementioned LPS-receptor complex recruits the TIR domain-containing adaptor protein (TIRAP) and MyD88 which initiates the signaling for early-phase activation of NF- κ B (nuclear factor κ B) (Akira et al., 2006). A subsequent internalization of the receptor complex recruits TRAM

(TRIF-related adaptor molecule) and TRIF and initiates late-phase activation of NF- κ B and induction of type I interferons. Activation of NF- κ B through the described MyD88- and TRIF-dependent pathways regulates inflammatory processes by the induction of inflammatory cytokines (see figure 1.1, p.7) (Kawai and Akira, 2010) .

TLR2 forms heterodimers with either TLR1 or TLR6 (Ozinsky et al., 2000). Upon binding of triacyl-lipopeptides from Gram-negative bacteria and mycoplasma (TLR2-TLR1 heterodimer) or of diacyl-lipopeptides from Gram-positive bacteria and mycoplasma (TLR2-TLR6 heterodimer), both heterodimers signal through the MyD88-dependent pathway to induce the production of inflammatory cytokines (Jin et al., 2007; Kawai and Akira, 2010; Schwandner et al., 1999; Takeuchi et al., 1999).

TLR3 recognizes mainly double stranded RNA (dsRNA) from viruses and virus infected cells (Alexopoulou et al., 2001). It signals through the TRIF-dependent pathway to express type I interferons and inflammatory cytokines (Akira et al., 2006).

TLR5 is known to recognize flagellin, a protein produced by flagellated bacteria. It forms a homodimer and induces NF- κ B-dependent production of cytokines by the recruitment of MyD88 (Hayashi et al., 2001).

TLR7 and TLR8 detect single stranded RNA (ssRNA) from viruses and recruit MyD88 for the induction of cytokine secretion and interferon regulatory factor 7 (IRF7) for the induction of type I interferons (Heil et al., 2004; Hemmi et al., 2002).

TLR9 signals the same way as TLR7 and TLR8 but detects unmethylated cytidine-phosphate guanosine (CpG) DNA from bacteria and viruses (Hemmi et al., 2000).

This repertoire of different receptors is necessary to induce situation specific immune responses by microglia. However, a whole range of other receptor proteins besides TLRs are expressed in microglia, but not all receptors are expressed in each cell which leads ultimately to the formation of subpopulations carrying different receptor combinations. This heterogeneity of microglia is not restricted to the expression of receptors, in fact, microglia heterogeneity can be found in nearly each area of investigation.

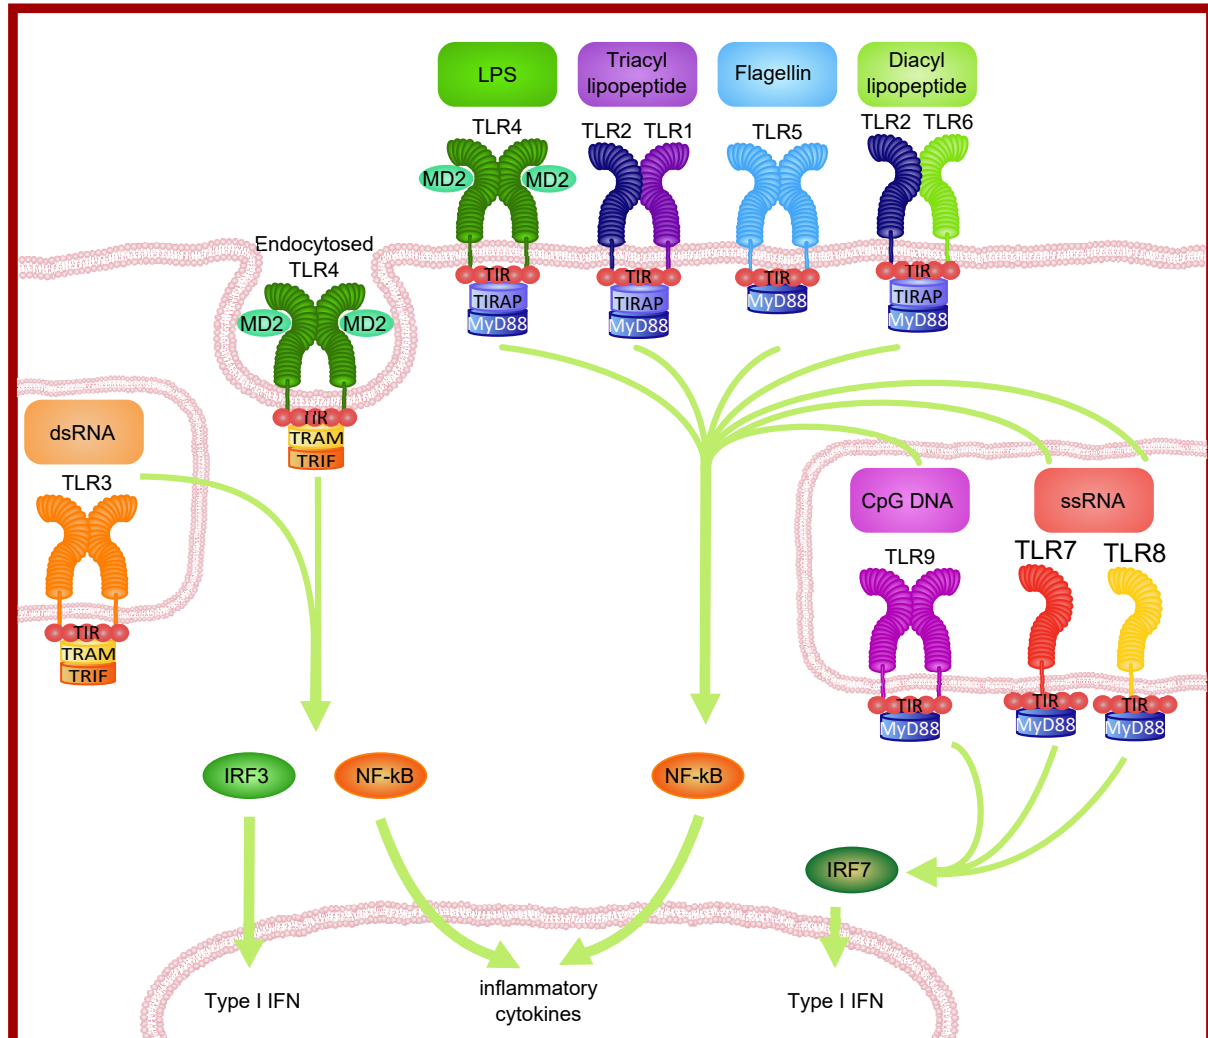

Figure 1.1 – Toll-like receptor signaling: TLR4 binds LPS by forming a complex with MD2. A multidimer composed of two copies of this LPS-receptor complex recruits the TIR domain-containing adaptors TIRAP and MyD88 which initiates the signaling for activation of NF- κ B. A subsequent internalization of the receptor complex recruits TRAM and TRIF and initiates once more activation of NF- κ B which leads to the induction of inflammatory cytokines. Additional activation of IRF3 induces inductions of type I interferon. TLR2 forms heterodimers with either TLR1 or TLR6. Both heterodimers signal through the MyD88-dependent pathway to induce the production of inflammatory cytokines upon binding of triacyl lipopeptides or diacyl lipopeptides. TLR3 recognizes mainly dsRNA. It signals through the TRIF dependent pathway to recruit type I interferons and inflammatory cytokines. TLR5 forms a homodimer after recognition of flagellin. It induces NF- κ B dependent production of cytokines by the recruitment of MyD88. TLR7 and TLR8 detect ssRNA whilst TLR9 detects CpG DNA. They recruit MyD88 and IRF7 to induce cytokine secretion and production of type I interferons, respectively.

1.6 Microglia heterogeneity

Microglia contribute simultaneously to proliferation, maturation, survival and cell death within the CNS. To perform these various activities, it is likely that microglia fall into subpopulations depending on brain region and/or function.

1.6.1 Regional heterogeneity

Even though microglia are present in the whole CNS they are not uniformly distributed (Lawson et al., 1990). As a result, microglia densities vary highly within the individual brain regions. It was already shown in 1990 that mouse microglia compose approximately 5 % of all cells in the cerebral cortex and corpus callosum. In the whole brain, this proportion rises region-dependently up to 12 % as seen in the substantia nigra (Lawson et al., 1990). This region-dependent microglia density was also demonstrated in the healthy human brain parenchyma where the proportion of microglia ranged from 0.5 % up to 16 % (Mittelbronn et al., 2001). Recent data show that there is not only regional heterogeneity in microglia density but also in their gene expression profile (Grabert et al., 2016). Genome-wide analysis of microglia from cerebellum, hippocampus, cortex, and striatum of mice indicate that microglia from the first two regions have a more immune-alerted state than the latter two, and that they show a greater expression of genes involved in energy metabolism (Grabert et al., 2016).

It was also shown, that neurons of different brain regions show diverse susceptibility to LPS-induced neurotoxicity which is most probably related to the different abundance of microglia in those regions (Kim et al., 2000). Other studies which investigated the expression of various microglial immunoregulatory markers indicated that the expression level of each marker was highly heterogeneous even though all of them were expressed within the tested brain regions (de Haas et al., 2008; Ren et al., 1999; Smith et al., 2013). Investigation of several microglial purinergic P2X receptors revealed not only a brain-region specific heterogeneity of their expression levels, but also an age- and even a sex-specific dependency (Crain and Watters, 2015). The high complexity of regional microglia heterogeneity was even more validated by a study conducted in the olfactory bulb of rats which could demonstrate that microglia expression levels of

various markers differed even between the different layers of the tissue, highlighting the impact of the microenvironment (Schmid et al., 2009; Wu et al., 1997).

1.6.2 Functional heterogeneity

Even though it was already shown in the 1990s that only subpopulations of microglia express immunologically important molecules like Major histocompatibility complex (MHC) class II (Streit and Graeber, 1993) or specific neurotrophins (Elkabes et al., 1996), it was long believed that all microglia behave or react rather homogeneously. The functional heterogeneity became more and more evident within the recent years and draws increasing attention.

As such, it is nowadays known that the most essential microglial functions are performed by mere subsets of microglia rather than the entire population at once. The phagocytosis of myelin is only one example of these functions, performed by a subpopulation of microglia and plastic in regards to the size of their population (Venkatesan et al., 2010). Microglia can also be classified into proliferative and non-proliferative populations with differing sizes, dependent on the respective brain region and on the surrounding cellular environment (Marshall et al., 2014).

The expression patterns of receptors were found to be organized in a subpopulational manner as well since only a fraction of microglia in rodents express GABA_B-, glutamate-, dopamine- or noradrenaline-receptors (Färber et al., 2005; Kuhn et al., 2004; Noda et al., 2000). Interestingly, the fraction of cells that express these receptors varies with microglial activity. In accordance, the highly important immunological factor TREM2 (triggering receptor expressed on myeloid cells 2) is only expressed in subpopulations of resting microglia and its expression is brain-region- and most likely microenvironment-dependent (Schmid et al., 2002).

Microglia sensitivity towards neurotransmitters and neurohormones like histamine, serotonin, somatostatin, angiotension II or dopamine is conveyed via subpopulations as well. The neurotransmitter/neurohormone-dependent subpopulations can represent up to 20% of all microglia, and while some of the subpopulations are just able to react to one substance, some can even react to two or three substances after sequential exposure (Pannell et al., 2014b).

An advancing knowledge on microglia subpopulations may also increase our understanding of

a variety of central nervous diseases. In a mouse model of Alzheimer's disease, for instance, application of IL-4 (interleukin 4) leads to the expression of CD11c in a subpopulation of microglia that specifically counteracts the inhibitory effects of beta-amyloid on microglia leading to improved plaque phagocytosis and increased neurogenesis (Butovsky et al., 2006). In an ischemic stroke mouse model, researchers identified distinct subpopulations of microglia producing TNF α (Tumor necrosis factor α) or IL-1 β (interleukin 1 β) respectively after stroke induction (Clausen et al., 2008). Keratan sulfate, an inhibitor of axonal regeneration, was also demonstrated to be expressed by a microglia subpopulation in a mouse model of Wallerian degeneration (Shinjo et al., 2014). In Hoxb8 mutant mice, the transgene is expressed by a subpopulation of about 40 % of microglia and a loss of function mutation in this gene leads to excessive grooming and sensory defects. This phenotype is similar to the obsessive-compulsive disorder which was observed in humans (Chen et al., 2010). Taken together, studies regarding microglia subsets strongly suggest a vast impact of microglia heterogeneity on the CNS immune system but also subsequent functions of the CNS (Baalman et al., 2015; Bisht et al., 2016; Fang et al., 2014; Kobayashi et al., 2013; Kocur et al., 2015; Pannell et al., 2014a; Pepe et al., 2014; Trias et al., 2013; Włodarczyk et al., 2015).

Apparently, the findings on functional heterogeneity in microglia are not limited to rodents, as the complexity of microglial organization was successfully demonstrated in a study using microglia cultures from different human donors as well, since the culture cells showed similar gene profiles but very diverse responses to a challenge. The differences elicited by the same challenge even resulted in opposed gene expression changes between the cultures (Meeuwssen et al., 2005).

The heterogeneity of microglia is not only restricted to areas, functionalities or expression patterns, but also depends on age. Studies conducted in young vs. old mice showed an altered pro-inflammatory profile that comes with age (Godbout et al., 2005; Ritzel et al., 2015; Sierra et al., 2007). These age-dependent alterations, which include microglial functions, self-renewal and vitality are collectively termed as "microglial senescence" (Streit, 2006). Interestingly, this phenomenon as well as other microglia features are linked to a variety of neurodegenerative diseases in which microglia seem to play an essential role (Block and Hong, 2005; Hickman et al., 2008; Prokop et al., 2013).

1.7 Microglia and diseases

Microglia are constantly screening the brain parenchyma for threats and disturbances (Nimmerjahn et al., 2005). Once they encounter a disruption of homeostasis, i.e. due to a pathology, they try to resolve it (Davalos et al., 2005). Though, microglia stay activated as long as the pathology sustains this could switch beneficial to detrimental outcomes or vice versa. In Alzheimer's disease for instance, microglia are able to clear the toxic amyloid beta that accumulates in affected brains. However, if they are confronted with amyloid beta continuously, they lose the ability to clear it. This results in microglial activation, a massive release of pro-inflammatory cytokines and production of reactive oxygen species, that ultimately lead to neurotoxicity and neurodegeneration (Gold and Khoury, 2015; Hickman et al., 2008). This over-activation of microglia was also demonstrated in other neurodegenerative diseases like multiple sclerosis, frontotemporal lobe dementia, Parkinson's disease, hypoxia, stroke and amyotrophic lateral sclerosis (reviewed in Block and Hong, 2005).

Even though the total impact of microglial activation on those diseases is still under investigation, it is already clear that targeting microglia to oppose the diseases is very promising (Chen et al., 2014; Wes et al., 2016). Nonetheless, using anti-inflammatory drugs has a lot of side-effects since they are targeting the whole system, outmaneuvering even the beneficial functions (Biber et al., 2016; Olah et al., 2012). Thus, understanding microglia as a heterogeneous population of immune cells and identification of respective markers to differentiate between the subgroups would be crucial to counteract the strong inflammatory response in those diseases. The development of drugs or tools that are specifically targeting subpopulations of interest while leaving the others unaffected would be of most benefit (Ferreira and Bernardino, 2015).

1.8 Aim of the thesis

Even though the consciousness of microglial heterogeneity is advancing, research specifically investigating microglial subpopulations is still in its infancy. So far, most studies that identified microglial subgroups were primarily interested to address completely different issues. Thus, the existence of microglial subpopulations is known and mostly accepted, their organization and behavior, however, is completely unknown. Thus, this study aimed to investigate the organization of specific subpopulations and their behavior in different conditions. By focusing on two main functions of microglia, namely cytokine secretion and proliferation, I addressed the following research questions:

1. How do microglia subpopulations behave in front of a challenge? Is an increased cytokine release caused by an increased cell number or by a higher cytokine production per cell?
2. Can microglia subpopulations secrete multiple cytokines? How are the cytokine-specific subgroups organized?
3. Occurs secretion and proliferation simultaneously in the same microglia cell?
4. How are microglia subpopulation sizes organized?

2. Methods

2.1 Animals

C57Bl/6J wildtype mice were bred and housed under normal conditions in the Central Animal Facility of the University Medical Center Göttingen (UMG). Mutant strains (*myd88*^{-/-} and *trif*^{Δps2}, both on C57Bl/6J background) were bred and maintained under specific pathogen-free conditions in the same facility. The *myd88*^{-/-} mice were kindly provided by Prof. Dr. Marco Prinz (Department of Neuropathology, University of Freiburg, Germany) and described by Adachi and colleagues (Adachi et al., 1998). The *trif*^{Δps2} mice were provided by Dr. Bruce Beutler (University of Texas Southwestern Medical Center, USA), carrying a mutation in the C terminus of TRIF which abolishes TRIF-mediated functions (Hoebe et al., 2003). All animals were supplied with food and water ad libitum. Experiments were performed in accordance with the guidelines for animal welfare and protection of the University Göttingen and the German Animal Protection Law.

2.2 Primary Mouse Microglia Preparation

Primary cultures were prepared from whole brains of newborn (P0/P1) wildtype C57Bl/6J, or *myd88*^{-/-} and *trif*^{Δps2} mutant mice as described by Regen et al. 2011. Mice were decapitated, the brains were extracted and immediately transferred into petri-dishes containing ice-cold Hanks balanced salt solution (HBSS) (Biochrom; #L2012). Following the removal of blood vessels and meninges from the brains with help of a binocular stereo microscope, brain tissue was collected in a Falcon tube containing ice-cold HBSS. After being washed twice, the brains were digested with 100 μl 2.5% Trypsin/brain (Biochrom; #L2133). The tubes were gently vortexed and incubated for 10 minutes in a 37°C water bath with additional vortexing in between. The digestion was stopped by addition of 1 ml/brain medium (Dulbecco's modified Eagle's medium (DMEM) (Gibco; #41965-062)) containing 10% fetal calf serum (FCS) (Invitrogen), 100 U/ml penicillin, and

100 µg/ml streptomycin (Biochrom; #A2213). Next, 40 µl/brain deoxyribonuclease (DNase) (Worthington; #2139) was added to avoid excessive DNA aggregation. Brain structures were dissolved carefully by pipetting up and down several times. A subsequent incubation for 3 minutes at 37°C in a water bath ensured a complete decomposition of the tissue. Afterwards, samples were centrifuged at 900 rpm (163 g) for 10 minutes at 4°C. For culturing, the cells were resuspended in 15 ml medium/2 brains in a F75 cell culture flask (Greiner; #658175). Flasks were pre-coated with Poly-L-Lysin (PLL) (Sigma Aldrich; #P1274). To pre-coat the flasks with PLL, they were incubated for 20 minutes with 10 ml PLL and washed thrice with sterile ddH₂O and once with medium. Flasks containing cells were incubated overnight at 37°C with 5% CO₂.

The next day, cells were washed thrice with phosphate buffered saline (PBS) (Gibco; #14190-094) and once with medium. Cells were washed again with medium on day 3 and 4. On day 9, cells were shaken for 20 minutes at 37°C at 90 1/min and the medium was substituted with 10 ml fresh medium and 5 ml conditioned L-929 medium. The first microglia could be harvested on day 14. Therefore, flasks were shaken for at least 30 min at 37°C at 900 rpm (163 g) and the microglia containing supernatant was transferred into a falcon tube. The remaining cells in the flask were supplied with 10 ml medium and 5 ml L-929 medium and incubated at 37°C with 5% CO₂ till the next harvest. The tube containing the microglia was centrifuged at 4 °C and 900 rpm (163 g) for 10 min. The supernatant was discarded and cells were resuspended in a small amount of medium. Afterwards, cells were counted (cellometer™ Auto T4; Nexcelom Bioscience), resuspended and plated (cell-culture plates CellstartR, Greiner bio-one) at the desired densities needed for the individual experiments. Additional harvests were performed on day 16, 21 and 23.

The purity of microglia preparations was routinely >98%, based on nuclear staining (DAPI), immunocytochemistry for CD11b, Iba1 and *Griffonia simplicifolia* isolectin B4 (Regen et al., 2011; Scheffel et al., 2012).

2.3 L929 fibroblast cultures

To stimulate microglial proliferation in culture, cells were provided with supernatant from L929 fibroblasts as described by Regen et al. 2011. Fibroblasts were cultured in medium (DMEM containing 10% FCS; 100 U/ml penicillin and 100 µg/ml streptomycin) and passaged (1:5) every 2 weeks. After 14 days of cultivation, the medium was collected and centrifuged at 1200 rpm (290 g) for 10 min at 4°C. Finally, the cell pellet was discarded and the supernatant was stored at -20°C until usage. Fibroblasts were discarded after 30 passages and fresh L929 cultures were established.

2.4 Cytokine and chemokine measurements

The amount of secreted cytokines and chemokines by microglia was measured by using enzyme-linked immunosorbent assay (ELISA). For ELISA, the DuoSet ELISA Development Kits (R&D systems) were used for IL6 (interleukin 6) (#DY406), MCP-1 (monocyte chemotactic protein 1) (#DY471), MIP1α (macrophage inflammatory protein 1α) (#DY450), RANTES (regulated upon activation normal T-cell expressed and presumably secreted) (#DY478) and KC (keratinocyte-derived chemokine) (#DY453). For TNFα and for IL12-p40 (Interleukin 12), antibody pairs from BioLegend (#430902) and eBioscience (#88-7120-88) were used respectively.

In brief, microglia were plated in a 96-well plate with a density of 15000 cells/well. After incubation overnight at 37°C with 5% CO₂, cells were stimulated for 18 hours (if not stated differently) at 37°C with 5% CO₂. Subsequently, supernatants were transferred into new 96-well plates (Sarstedt; #82.1581) and stored at 4°C or -20°C for immediate or later processing, respectively. ELISA plates (Maxisorp; Nunc; #456537) were coated with 50 µl/well of the specific capture antibody solutions and incubated overnight at room temperature (RT) with a gentle agitation. Then, plates were washed 3 or 4 times (antibody dependent) with wash buffer (0.5% Tween 20 in PBS) and blocked with 300 µl/well of reagent diluent 1 (RD1) (1% BSA in PBS) for 1 hr at RT or overnight at 4°C. Supernatants were diluted 1:10 (IL6; MCP-1; IL12-p40; RANTES; TNFα) or 1:20 (KC; MIP1α) in RD1 in dilution plates (Sarstedt; #82.1582) and series of standard solutions provided by the kits were prepared. After discarding the block solution, plates were washed as mentioned above and

50 µl/well of the diluted supernatants as well as the standards were added and incubated for 2 hours at RT or overnight at 4°C. Next, plates were washed and 50 µl/well of the detection antibody solution was added for 2h at RT. After washing, wells received 50 µl of a Streptavidin-HRP solution (R&D; #893975) for 20 minutes at RT protected from light. Following the next washing, 100 µl substrate solution (TMB; Moss Inc. #TMBUS-1000) was added and the color development was stopped by addition of 50 µl/well of 1N H₂SO₄. Absorbance was measured at 450 nm with 540 nm reference by an iMark microplate reader (Bio-Rad). The amount of secreted cytokines and chemokines was calculated using a Microsoft Excel macro, specifically developed for this purpose by Dr. Jörg Scheffel and optimized at the department of neuropathology at the University Medical Center Göttingen.

2.5 Cell viability assessment

To determine any possible toxicity of the stimuli used for ELISA experiments on microglia, the cell viability test was performed routinely. To do so, microglia received fresh medium supplemented with 10 % of water soluble tetrazolium salts (WST-1) reagent (Roche Applied Science) immediately after the transfer of the supernatant. The absorbance was quantified as a measure for viability after 3 hours of incubation at 37°C with 5% CO₂ using a microplate reader (iMark; BioRad) at 450 nm with 655 nm as the reference wavelength.

2.6 Bromodeoxyuridine (BrdU) Cell Proliferation ELISA

To assess microglia proliferation, the BrdU Cell Proliferation ELISA kit (Roche; #11647229001) was used. Microglia were plated in a 96 well-plate with a density of 15000 cells/well and incubated for 24 hours at 37°C with 5% CO₂. Subsequently, the medium was replaced by various stimuli solutions including LPS (#ALX-581-007, Alexis Biochemicals), Pam₃CSK₄ (#165-066-M002; Alexis Biochemicals) and Fibronectin (FN) (#F-1141; Sigma) of different concentrations (0.01 ng/ml; 1 ng/ml; 100 ng/ml for LPS and Pam₃CSK₄, 25 µg/ml; 50 µg/ml; 100 µg/ml for FN) mixed with 10 µM BrdU. Medium containing 10 µM BrdU was used as control. Incubation for 6, 12, 24 or 48 hours followed by further processing as described by the BrdU Cell Proliferation

ELISA assay. In brief, supernatants were removed and cells were fixed with 200 µl/well FixDenat (provided by the assay) for 30 minutes at RT on a shaker. Next, supernatants were discarded and cells were incubated with 100 µl/well anti-BrdU-POD working solution for 90 minutes at RT on a shaker. Cells were washed thrice with 200 µl/well PBS and incubated with 100 µl/well substrate solution for 5 minutes at RT. The reaction was stopped by addition of 25 µl 2N H₂SO₄ for 1 minute on a shaker. Absorbance was measured by an iMark microplate reader (Bio-Rad) at 450 nm (reference wavelength 690 nm or higher).

2.7 Enzyme Linked Immuno Spot Assay (ELISpot)

Production of TNFα and RANTES by individual microglia was quantified via ELISpot.

For TNFα ELISpot experiments, the ELISpot assay against mouse TNFα (# EL410; R&D) or the TNFα/TNFSF1A ELISpot Development Module (R&D; #SEL410) were used. RANTES experiments were performed with the Mouse CCL5/RANTES ELISpot Development Module (R&D; #SEL478). Both development modules were combined with the ELISpot Blue Color Module (Strep-AP and BCIP-NBT) (R&D #SEL002) on Multiscreen HTS IP sterile plates (Millipore #MSIPS4510).

The ELISpot plates were prepared as described by the manufacturer's instructions and a cell suspension mixed with different concentrations of LPS (Alexis Biochemicals; #ALX-581-013), Pam₃CSK₄ (Alexis Biochemicals; #165-066-M002) or MALP-2 (Macrophage-activating lipopeptide-2) (Axxora/Apotech; #APO-54N-018) was plated with a cell density of 1000, 2000 or 3000 cells/well. ELISpot plates were incubated at 37°C with 5% CO₂ for 24 hours and the development process was assessed according to the manufacturer's instructions. Spots were counted by the ELISpot reader ELI.Scan and analyzed using Eli.Analyse (both A.EL.VIS GmbH; Hannover). The obtained spot number was used for calculating the sizes of the subpopulations. The readouts for Spot intensities as well as the spot sizes were ranked in values between 1 to 17 and 1 to 10, respectively.

As controls, cells with the same density and stimulation conditions as used for the ELISpot plate were plated on a separated plate (CellstartR, Greiner bio-one) simultaneously. This control plate was used for ELISA analysis of the cytokine secretion and viability tests.

2.8 Fluorescence-activated cell sorting (FACS)

FACS was performed to quantify microglial subpopulations. For intracellular FACS staining of microglia, cells were plated at a density of 300000 cells/well in a 12-well plate unless otherwise stated. After an overnight incubation at 37°C with 5% CO₂ cells were stimulated with 0.01 ng/ml; 0.1 ng/ml; 1 ng/ml; 10 ng/ml; 100 ng/ml or 1000 ng/ml LPS (Alexis Biochemicals; #ALX-581-013) for 8 hours.

The protein transport inhibitor Monensin (BioLegend, #420701; 1:1000) was added after a stimulation period of 3 hr (for RANTES staining or a RANTES/TNF α double staining) or 5 hr (for TNF α staining) respectively. The stimulation was stopped by washing steps with medium and PBS. Cells were detached via incubation with 300 μ l 0.05 %/0.02 % Trypsin/EDTA (Biochrom; #L2143) for 5 minutes at 37°C. This reaction was stopped by adding 600 μ l medium. Cells were scraped carefully and transferred to 2 ml Eppendorf tubes placed on ice. Subsequently, tubes were centrifuged at 800 g for 10 min at 4°C and the supernatant was discarded. Cells were resuspended in 1 ml FACS buffer (PBS containing 2% FCS, 0.1% NaN₃ and 0.01 M EDTA pH 8.0) and centrifuged again. Supernatants were discarded and cells were incubated with 40 μ l Fc-Block (BioLegend; #101310; 1:100 in FACS buffer) for 10 min at 4°C to prevent unspecific antibody binding. 40 μ l CD11b-Allophycocyanin (Cd11b-APC) (eBioscience; #17-0112-83) or CD11b-Pacific Blue (CD11b-PB) (BioLegend; #101224) both diluted 1:100 in FACS buffer were added to the respective wells and incubated for 20 min at 4°C protected from light. Afterwards, cells were washed with 1 ml FACS buffer and centrifuged at 800 g for 10 min at 4°C. A resuspension of the cells in 200 μ l Cytofix/ Cytoperm (BD; #51-2090KZ) was performed after discarding the supernatants. Cells were incubated for 20 min at 4°C protected from light, washed with 1 ml saponin buffer (0.1% Saponin (Sigma Aldrich; #S-4521) in PBS) and centrifuged at 800 g for 10 min at 4°C. Supernatants were removed and cells were incubated with 40 μ l Fc-Block (1:100 in saponin buffer) for 5 min followed by addition of RANTES-Phycoerythrin (RANTES-PE) (BioLegend; #149104), TNF α -PE (BioLegend; #506305) or TNF α -Alexa Fluor 488 (BioLegend; #506315), all 40 μ l, 1:100 in saponin buffer for 40 min at RT protected from light. Cells were washed with saponin buffer and centrifuged for at 800 g for 10 min at RT. Finally, cells were re-suspended in 170-200 μ l FACS buffer and analyzed via the FACS Canto II (BD) and Flowjo (Tree Star, V10) software. For FACS analysis only Cd11b

positive events were included.

For Zombie Aqua staining, cells were treated as mentioned above until the first wash step which was performed with PBS instead of FACS buffer. Cells were incubated with Zombie aqua (1:200 in PBS) for 10 min at RT protected from light followed by addition of the Fc-Block (1:100) and the CD11b (1:100) antibody.

To stain the proliferating cells, the Click-iT[®] EdU (5-ethynyl-2'-deoxyuridine) Alexa Fluor[®] 647 Flow Cytometry Assay Kit (ThermoFischer SCIENTIFIC #c-10419) was used. Cells were stimulated with 1 ng/ml LPS (Alexis Biochemicals; #ALX-581-013) in combination with 5 μ M EdU (provided by the Kit) and harvested as mentioned before. Afterwards, cells were washed in 1 ml of 1% BSA in PBS and incubated with Fc-Block and CD11b-PB prepared in 1% BSA in PBS as well. Fixation, permeabilization, and EdU staining were performed as described by the proliferation kit. Intracellular antibodies were stained afterwards in Click-iT saponin based permeabilization and wash reagent instead of FACS buffer.

2.9 Supernatant transfer experiment

For the supernatant transfer experiment 200000 or 5000000 microglia cells were plated in a 12-well plate and incubated over night at 37°C with 5 % CO₂. The next day, wells received either fresh medium or LPS (1 or 10 ng/ml) for 8 hours. Afterwards supernatants were transferred to wells containing 200000 unstimulated microglia. Microglia which received supernatant from LPS stimulated cells were left untouched for 8 hours. Microglia which received supernatant from unstimulated cells were stimulated with 1 or 10 ng/ml LPS for 8 hours.

This paradigm generated 3 different treatment groups. The first, the control group, consisted of 200000 unstimulated cells and 200000 cells that received the supernatant of 500000 unstimulated cells for 8 hours. The second group consisted of 200000 LPS-stimulated (1ng/ml) cells or 200000 cells with the supernatant of 500000 unstimulated cells that were stimulated after the supernatant transfer with 1 ng/ml LPS for 8 hours. The third group was made up by 200000 cells, treated for 8 hours with supernatants of 200000 or 500000 cells that were already stimulated with 1 ng/ml LPS for 8 hours beforehand.

During the last incubation step microglia were supplemented with monensin for a subsequent FACS analysis for TNF α and RANTES as previously described.

2.10 Insert experiment

To evaluate the effect of the supernatant secreted by increasing numbers of microglia on microglia subpopulation sizes, an insert experiment was performed. Therefore, microglia were plated at a density of 200000 cells in a 12-well plate. Some of these wells received transmembrane cell-culture inserts (greiner bio-one #665640) containing additional 100000,

200000 or 300000 microglia. After an overnight incubation at 37°C with 5 % CO₂, microglia were stimulated with 1 ng/ml LPS for 8 hours. After the first three hours monensin was added to prevent cytokine secretion and after additional 5 hours microglia were further processed for FACS analysis of TNF α .

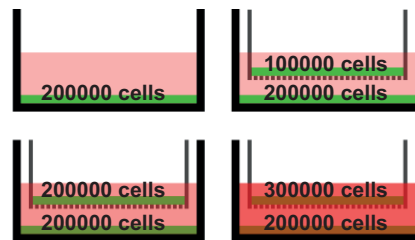

Figure 2.1 – Schematic plating overview of the insert experiment with microglia indicated as green lines, and supernatant concentrations indicated in red.

2.11 Ribonucleic acid (RNA) extraction

To extract RNA the RNeasy Mini Kit (Qiagen; # 74104) was used. 800000 microglia/well were plated in a 6-well plate and stored at 37°C with 5% CO₂. Next, microglia were incubated with 10 ng/ml TNF α for 1 or 12 hours at 37°C with 5% CO₂. Supernatants were discarded, cells were washed and incubated with 1 ng/ml LPS for 3 hours at 37°C with 5% CO₂. Afterwards, cells were washed with pre-warmed PBS and received 350 μ l RLT buffer (if not stated otherwise provided by the kit) containing 1% β -Mercaptoethanol. Cells were scraped carefully, the lysates were transferred into Eppendorf-tubes and after resuspension into QIAshredder Mini Spin Columns (Qiagen; #1011711). The columns were centrifuged at maximum speed for 2 minutes and 350 μ l

70% EtOH was added to the lysate containing collection tubes. Lysates were transferred after re-suspension to RNeasy Mini Spin Columns (Qiagen; #1011708) and centrifuged for 30 sec at 8000 g. Collection tubes were emptied, 350 µl RW1 buffer was added on top of the spin columns and a centrifugation at 8000 g for 30 sec followed. Then, 75 µl DNase mix (8,75 µl DNase + 61,25 µl RDD buffer) was added on top of the spin column membranes and incubated for 15 minutes at RT. Subsequently, 250 µl RW1 buffer was added and the column was centrifuged for 30 sec at 8000 g. Collection tubes were emptied, 500 µl RPE buffer was added and the column was centrifuges as before. Next, RPE buffer was added again and centrifuged for 3 min at 8000 g. The collection tube was replaced by a new one and the columns were centrifuged for 1 min at maximum speed. Finally, columns were placed in Eppendorf tubes, 25 µl nuclease-free water was added and centrifuged for 1 min at 8000 g. This step was repeated one more time and the obtained RNA concentration was measured using the NanoDrop ND-1000 Spectrophotometer (PEQLAB) and the corresponding software version 3.8.1. Samples were stored at -80°C until further processing.

2.12 Complementary deoxyribonucleic acid (cDNA) synthesis

For quantifying changes in gene expression upon stimulation, quantitative Real-Time Polymerase chain reaction (RT-PCR) was performed. cDNA for RT-PCR was synthesized by using the QuantiTect Reverse Transcription Kit (Qiagen; #205311) as followed: the template RNA was thawed on ice and the genomic DNA (Deoxyribonucleic acid) elimination cocktail was prepared. The composition was RNA concentration dependent and contained 300 ng RNA, 2 µl wipeout buffer and RNase- free water to make a total volume of 15 µl. This mixture was incubated for 2 minutes at 42°C and immediately placed on ice afterwards. Next, the reverse transcription master mix containing 1 µl Quantiscript Reverse Transcriptase, 4 µl Quantiscript RT buffer (5x) and 1 µl RT Primer mix per sample was prepared. 14 µl of the DNA elimination cocktail was mixed with the reverse transcription master mix and incubation at 42°C for 15 minutes and 95°C for 3 minutes followed. Finally, 100 µl RNase-free water was added to each sample (1:6 dilution) and samples were transferred to a 96-well plate and stored at -20°C until further processing by real-time PCR.

2.13 RT-PCR

For RT-PCR iTaq universal SYBR Green supermix (BIO-RAD; #172-5121) and cDNA was thawed at RT. For each desired sample, 10 µl iTaq universal SYBR Green supermix, 1 µl forward and reverse primer (see table 2.1) and 4 µl H₂O was mixed. 15 µl of this mixture was added in triplicates to a qPCR plate and 5 µl of the appropriate cDNA was added to the mixture. The plate was sealed with an optically transparent sealing tape (Sarstedt; #95.1994) and vortexed for 30 s. Next, the plate was centrifuged at maximum speed for 5 minutes to remove air bubbles within the wells. The plate was inserted into the real-time cycler QuantStudio 7 Flex (life technologies) and processed as described (see table 2.2). Results were analyzed using the QuantStudio Real-time PCR Software (version 1.1; life technologies). Relative mRNA expression for MCP-1, MIP1α, RANTES, KC and TNFα was calculated by $2^{-\Delta\Delta CT}$ to medium controls with Gapdh as the control gene.

Table 2.1 – RT-PCR primer

Name	Company	Number
PrimePCR™ SYBR® Green Assay: TNF, Mouse	BIO-RAD	qMmuCED0004141
PrimePCR™ SYBR® Green Assay: MIP1α, CCL3, Mouse	BIO-RAD	qMmuCED0003870
PrimePCR™ SYBR® Green Assay: RANTES, CCL5, Mouse	BIO-RAD	qMmuCID0021047
PrimePCR™ SYBR® Green Assay: Gapdh, Mouse	BIO-RAD	qMmuCED0027497
PrimePCR™ SYBR® Green Assay: KC, CXCL1, Mouse	BIO-RAD	qMmuCED0003898

Table 2.2 – RT-PCR cycler conditions

Cycles	Duration	Temperature	Step
1	2 min	95°C	Activation
40	15 sec	95°C	Denaturation
	45 sec	60°C	Anneling/extension
1	1 min	95°C	
1	1 min	55°C	Melt curve
80	10 sec	55-94.5°C	increase set point temperature after cycle 2 by 0.5°C
	hold	4°C	

2.14 Lactate dehydrogenase (LDH) assay

The LDH Activity Assay kit (Sigma-Aldrich; #MAK066) was used to assess the presence of damage or toxicity in microglia cells. The assay was performed according to the manufacturer's instructions. In brief, samples (microglia supernatants, taken after stimulation) were diluted 1:10 with LDH Assay buffer and the NADH standards were prepared in a 96-well plate with a volume of 50 μ l/sample or standard. Next, 50 μ l of the master reaction mix composed of 48 μ l LDH Assay Buffer and 2 μ l LDH Substrate Mix, was added on top and the plate incubated at RT on a horizontal shaker. After 2 minutes, the optical absorbance was measured at 450 nm by an iMark microplate reader (Bio-Rad) every five minutes until the value of the most active sample exceeded the value of the highest standard. Finally, the LDH activity was calculated as described by the manufacturer's instructions.

2.15 Statistical analysis

Data were presented as mean \pm SEM and analysed by GraphPad Prism[®] 6.01 (Graphpad Software). Data sets were analyzed via the Mann-Whitney test, multiple t-test or ANOVA and Tukey's multiple comparison. Differences of $p < 0.05$ were considered as significant.

3. Results

3.1 Subpopulation sizes are dependent on the severity of the challenge

The amount of cytokines like TNF α , released by microglia, correlates well with the severity of the challenge that they face, while only subsets of microglia are producing this respective cytokine (Regen et al., 2011; Scheffel et al., 2012). However, the principle of organization behind this phenomenon is still unknown. Here, I investigated the functional link between cytokine release and subpopulation size as well as a relative cytokine release per cell. Hence, I performed ELISpot and ELISA experiments for TNF α and RANTES on 1000 microglia cells mixed with increasing concentrations (0.01ng/ml; 0.1 ng/ml; 1 ng/ml, 10 ng/ml, 100 ng/ml and 1000 ng/ml) of LPS, Pam₃CSK₄ and MALP-2. The combination of both quantitative techniques allowed a correlation analysis between the cytokine secreting microglia number and the corresponding amount of secreted cytokines.

Evaluation of the ELISpot experiments for both TNF α and RANTES revealed that the cytokine secreting subpopulation size and the cytokine secretion increased significantly with increasing stimuli concentrations. At a certain stimuli concentration, the stimuli were not able to induce a further increase which resulted in a ceiling effect for both measured values (see figure 3.1A, p.25).

The microglia subpopulations which produced TNF α upon MALP-2 stimulation range from 41.3 % to 77.9 % with a cytokine production of up to 372.6 pg/ml. Stimulation with Pam₃CSK₄ showed an increase in the subpopulation size from about 32.5 % to 79.1 %, while the total produced amount of TNF α rose to a maximum of 688.9 pg/ml. LPS stimulation increased the microglia subpopulations from 45.1 % to about 87.0 % with a total production of up to 924.7 pg/ml. The increases in the TNF α -producing subpopulations as well as the TNF α production reached a plateau at concentrations above 0.1 ng/ml for MALP-2 and LPS, and 10 ng/ml for Pam₃CSK₄ stimulation.

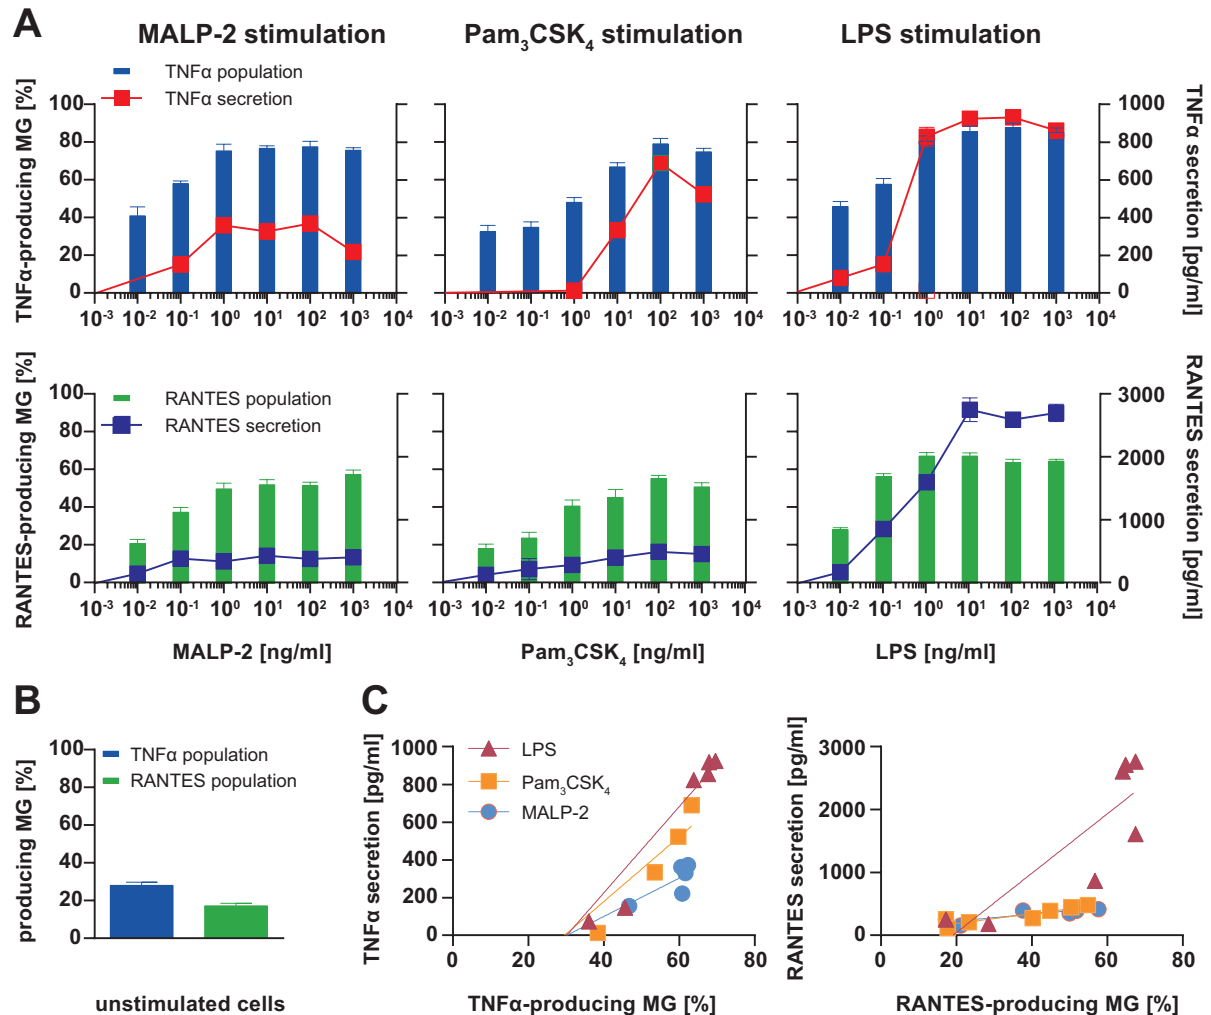

Figure 3.1 – ELISpot, ELISA and correlation analysis of TNFα and RANTES-producing microglia subpopulations: A) TNFα and RANTES producing subpopulation sizes obtained by ELISpot experiments for microglia plated at a density of 1000 cells/well. Microglia were stimulated with the indicated concentrations of LPS, Pam₃CSK₄ or MALP-2 for 24 hours (bars) and the corresponding amount of the secreted cytokines (lines) was obtained by ELISA. The stimuli dependent growth is significantly different for all tested conditions (ANOVA with $P < 0.0001$ for all subpopulations and TNFα secretions. RANTES secretion has P values of $P_{MALP-2}=0.0002$, $P_{Pam3CSK4}=0.0095$ and $P_{LPS} < 0.0001$). B) Corresponding TNFα and RANTES producing subpopulation sizes of unstimulated microglia. C) Stimuli-dependent correlation of the cytokine secretion vs. the associated subpopulation size for TNFα and RANTES analysed with pearson correlation. Data are presented mean \pm SEM. n=8-16

The microglia subpopulations positive for RANTES showed a similar pattern. MALP-2 stimulation led to an increase from 21.1 % to about 57.6 % with a maximum production of 440.9 pg/ml. Stimulation with Pam₃CSK₄ showed an increase from about 17.7 % to 54.8 % and a total cytokine production of up to 480.2 pg/ml. Stimulation with LPS increased the subpopulations from 28.4 % to 67.5 and the RANTES secretion to 2763.2 pg/ml. The plateau reached by the RANTES-producing subpopulations appeared at similar concentrations observed for the TNF α -producing subsets, while the cytokine secretion stagnates at concentrations above 0.1 ng/ml for MALP-2 and 10 ng/ml for Pam₃CSK₄ and LPS stimulation. The obtained results also revealed that a population of TNF α and RANTES producing microglia is already existing even if the cells were not exposed to a challenge (see figure 3.1B, p.25). While the subsets comprised 28.1 % of all microglia for TNF α and 17.3 % for RANTES, measurable cytokine secretion could not be demonstrated in the unstimulated cells.

The increase in both, subpopulation size and cytokine secretion highly correlates for all tested stimuli regarding TNF α , with R^2 values above 0.9 (see figure 3.1C, p.25) (see table 3.1). A weaker, though still considerable correlation was found regarding RANTES with R^2 values of 0.72 for MALP-2, 0.85 for Pam₃CSK₄ and 0.74 for LPS stimulation.

To validate the findings from ELISpot, FACS analysis was performed on microglia stimulated with the same concentrations of LPS. Thereby, I was able to confirm the concentration dependent cytokine producing subpopulation sizes for both, TNF α and RANTES (see figure 3.2, p.27). The subpopulations for TNF α -secreting microglia increased from 4.6 % at 0.01 ng/ml to 59.5 % while RANTES-secretion subpopulations increased from 4.7 % to 50.3 %. The significant increase in both, TNF α - and RANTES-producing subpopulations reached a plateau at LPS concentrations above 0.1 ng/ml.

A second factor besides subpopulation size that contributes to the overall cytokine release is the cytokine release per cell (see figure 3.3, p.27). TNF α secretion per cell increased significantly between MALP-2 concentrations of 0.01 ng/ml, 0.1 ng/ml and 1 ng/ml and stagnated at higher concentrations. LPS-stimulated microglia behaved similarly with significant increases between

Table 3.1 – R^2 of cytokine producing subpopulation sizes and cytokine secretion (obtained by pearson correlation)

	TNFα	RANTES
MALP-2	0.902	0.740
Pam₃CSK₄	0.917	0.845
LPS	0.938	0.720

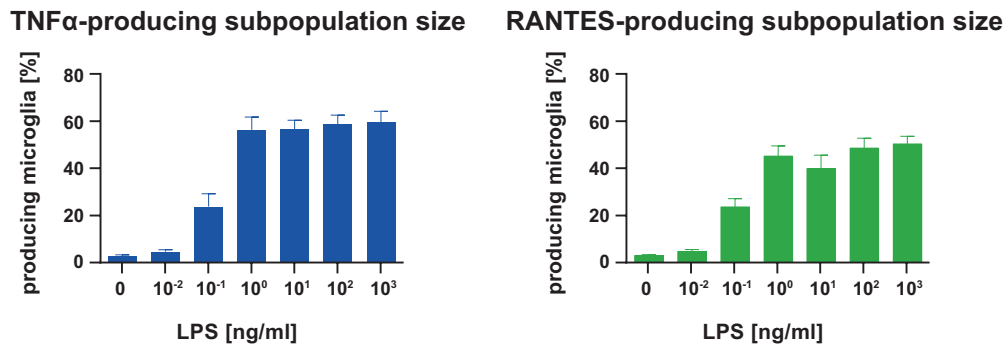

Figure 3.2 – FACS analysis of TNFα and RANTES-producing microglia subpopulations: FACS of microglia plated at a density of 300000 cells/well and stimulated with LPS for 8 hours was investigated for TNFα and RANTES producing subpopulation sizes. Subpopulation size progression is significant with $P < 0.0001$ for TNFα and RANTES (ANOVA). Data are presented as mean \pm SEM. $n=6$

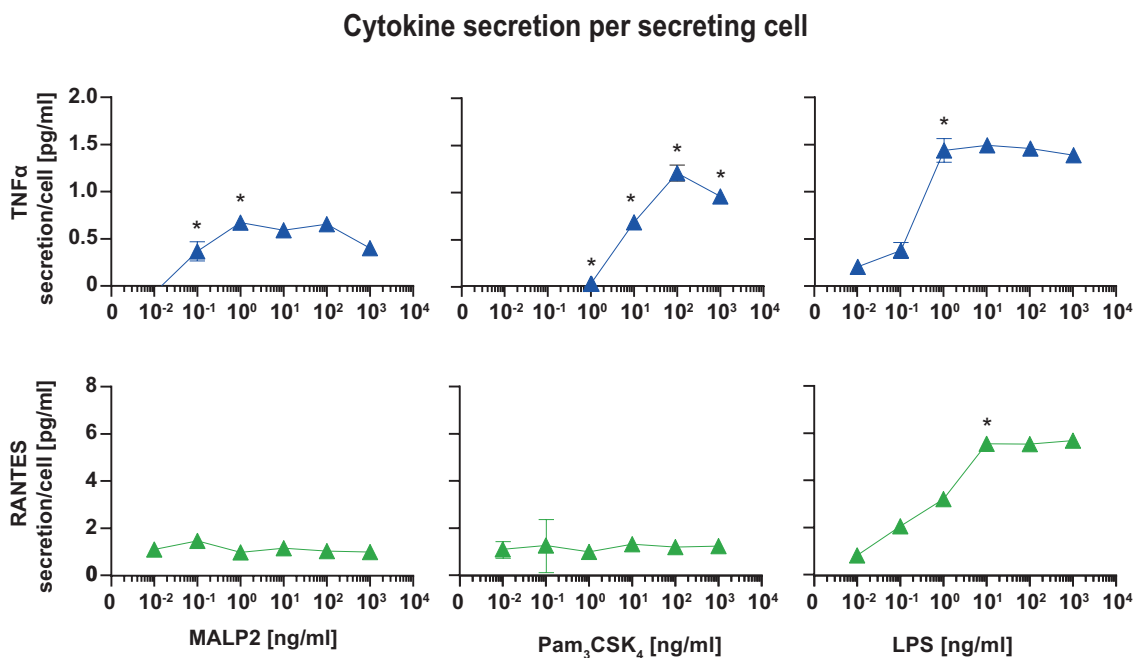

Figure 3.3 – Amount of cytokine secretion per cell of TNFα- and RANTES-producing microglia subpopulations. Asterisks indicate significant differences between the concentration and the next lower one. Significance was tested via ANOVA and Tukey's multiple comparison (ANOVA: $P < 0.0001$ for all TNFα and the RANTES LPS group). Data are presented as mean \pm SEM. $n=8-16$

0.1 and 1 ng/ml and a stabilization afterwards. Pam₃CSK₄ showed a rather dynamic progression with a gradual increase of secretion per cell and a peak around 100 ng/ml. No change of the cytokine secretion per cell could be observed after stimulation with MALP-2 and Pam₃CSK₄

regarding RANTES. LPS showed a significant increase from 1 ng/ml to 10 ng/ml and a stable secretion level at higher concentrations.

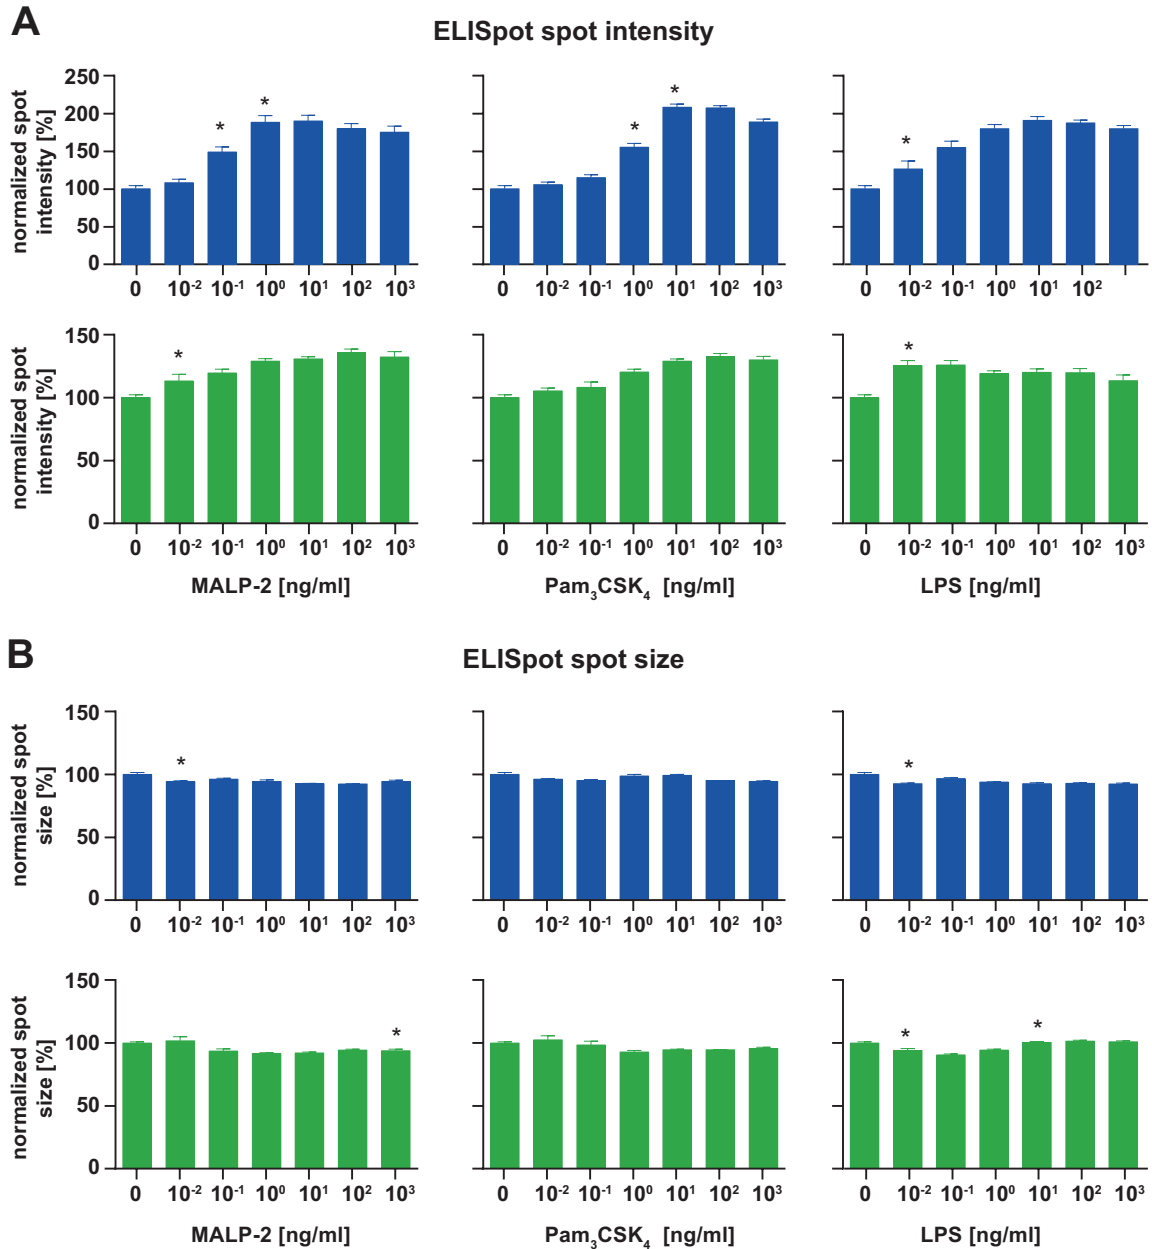

Figure 3.4 – Analysis of Spot intensity and Spot size of TNF α - and RANTES-producing microglia subpopulations: A) ELISpot intensities of the TNF α and RANTES spots normalized to medium control. B) ELISpot spot sizes for TNF α and RANTES normalized to medium control; n=6. Significance was tested via ANOVA and Tukey's multiple comparison. Asterisks indicate significant differences between the concentration and the next lower one with a P-value ≤ 0.05 . Data are presented as mean \pm SEM. n=8-16

The relationship between subpopulation size and secretion per cell could be validated by ELISpot as well. An elevation of the secreted amount could be reflected by an increase in spot size and/or spot intensity. Analysis of these factors revealed an increase in the TNF α ELISpot spot intensity for all stimuli and in the spot size for MALP-2 and LPS stimulation. The RANTES ELISPOT intensities as well as spot sizes grew significantly by MALP-2 and LPS stimulation. No effect of Pam₃CSK₄ could be detected considering RANTES (see figure 3.4, p.28). The TNF α spot intensity increased significantly between 0.01 ng/ml, 0.1 ng/ml and 1 ng/ml of MALP-2-stimulated microglia. Pam₃CSK₄ led to significant increases between 0.1 ng/ml, 1 ng/ml and 10 ng/ml and LPS between medium control and 0.01 ng/ml. RANTES-producing microglia stimulated with MALP-2 and LPS showed no significant differences in the spot intensity of 0.01 ng/ml compared to medium only, while Pam₃CSK₄ could not elicit an increase in the spot intensities.

Analysis regarding ELISpot spot size revealed sparse differences only (see figure 3.4B, p.28). Significant differences for TNF α were detected for 0.01 ng/ml of MALP-2 and LPS stimulated microglia compared to medium control. RANTES-producing microglia stimulated with MALP-2 showed significant differences between 100 ng/ml and 1000 ng/ml while the spot sizes of LPS

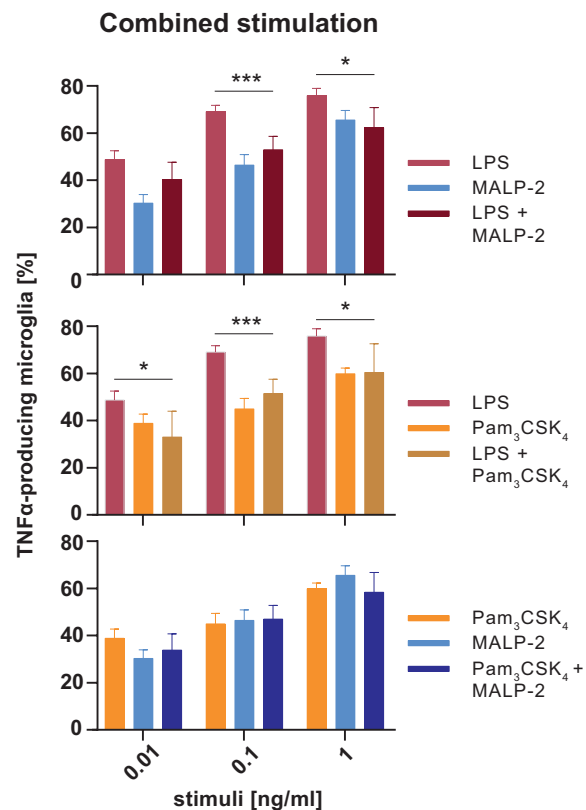

Figure 3.5 – ELISpot analysis of TNF α -producing microglia populations after combined stimulation: TNF α and RANTES producing subpopulation sizes obtained by ELISpot experiments for microglia plated at a density of 1000 cells/well, stimulated with the indicated concentrations of LPS, Pam₃CSK₄, MALP-2 or combinations of them for 24 hours; n=8. Asterisks indicate significant differences of LPS and MALP-2 or Pam₃CSK₄ combined stimulation to LPS only stimulation with p-values * ≤ 0.05 ; ** ≤ 0.005 ; *** ≤ 0.0005 obtained by multiple t-test. Data are presented as mean \pm SEM. n=8)

stimulated cells differed between medium and 0.01 ng/ml as well as 1 ng/ml and 10 ng/ml. No differences could be observed in Pam₃CSK₄ stimulated microglia, neither for TNF α nor for RANTES.

Next, a similar experiment with parallel stimuli was performed to investigate whether simultaneous stimulation has an additive effect on TNF α producing microglia subpopulations. Combinations of LPS and Pam₃CSK₄, LPS and MALP-2 as well as Pam₃CSK₄ and MALP-2 at concentration of 0.01 ng/ml, 0,1 ng/ml and 1 ng/ml were used for this experimental approach. However, no additive effect on the subpopulation sizes could be observed (see figure 3.5, p.29). The combination of LPS with another stimuli in most cases even lead to a slight reduction of the TNF α producing subpopulation size than a LPS only stimulation. Combination of Pam₃CSK₄ and MALP-2 showed no effect at all.

In summary, I could demonstrate a stimuli-dependent increase in TNF α and RANTES-producing microglia subpopulations via ELISpot and FACS. The subpopulations do not rise infinitely but reach a plateau at higher stimuli concentrations. The maximal subpopulation sizes could not be raised any further by a combination of different stimuli. The increase in the subpopulation sizes correlates highly with an increase in the cytokine secretion, which is more pronounced for TNF α than RANTES in stimulated microglia. An increase in the cytokine secretion per cell could also be demonstrated at higher stimuli concentrations, despite this correlation. This increase was primarily demonstrated in TNF α producing subsets, but also in LPS stimulated RANTES subpopulations. The increase in the cytokine secretion per cell correlates with an increase in the intensity of the spots obtained by the ELISpot experiments, which validates this observation even further.

3.2 Microglial subpopulation sizes are density dependent

Microglia are heterogeneously distributed throughout the brain, with densities reaching region dependently from 5 to 12 % (Lawson et al., 1990). To test whether microglia densities affect the specific subpopulation sizes, I performed ELISpot measurements for TNF α and RANTES in a similar approach as previously described, though, with higher cell densities (2000 and 3000 cells/well). The high RANTES production exceeded the detection limit, thus a precise spot discrimination was impossible (data not shown). Data from the TNF α ELISpot experiment revealed

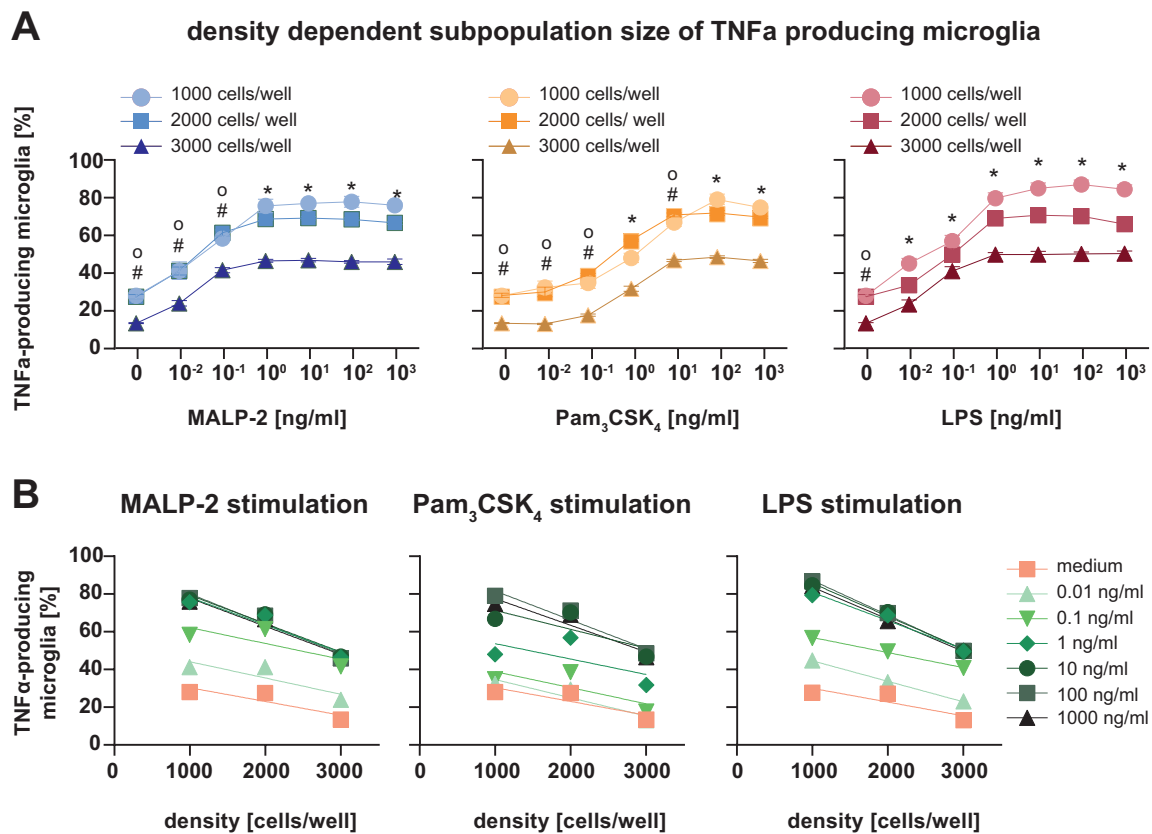

Figure 3.6 – Density dependency of microglia subpopulations analyzed by ELISpot: A) TNF α -producing microglia subpopulations obtained by ELISpot experiments with microglia densities of 1000, 2000 and 3000 cells/well. Significant differences obtained by ANOVA and Tukey's multiple comparison with a P-value ≤ 0.05 were indicated as followed: * difference between all densities; + differences between 1000 and 2000 cells/well; # differences between 1000 and 3000 cells/well; o differences between 2000 and 3000 cells/well. B) Correlation between TNF α -producing subpopulation sizes and microglia density analyzed with pearson correlation. Data are presented as mean \pm SEM. n=8

Table 3.2 – R^2 of TNF α producing subpopulation sizes vs. microglia density (obtained by pearson correlation)

	medium	0.01 ng/ml	0.1 ng/ml	1 ng/ml	10 ng/ml	100 ng/ml	1000 ng/ml
MALP-2	0,774	0,7552	0,6189	0,9188	0,9290	0,9453	0,9536
Pam₃CSK₄	0,7742	0,8684	0,5917	0,4120	0,6274	0,9270	0,8953
LPS	0,7742	0,9992	0,9963	0,9744	0,9883	0,9973	0,9976

that the TNF α -producing subpopulation sizes are negatively density-dependent as they increase with decreasing cell density (see figure 3.6, p.31). The previously observed concentration dependent increase in subpopulation size (see figure 3.1, p.25) was observed in densities of 2000 and 3000 cells/well as well, though, saturation was already reached at approximately 60 % and 40 % respectively. Significant differences between the densities could be demonstrated for all used stimuli. The differences could be either observed between 1000 and 2000 vs. 3000 cells, or between all densities which became more pronounced with higher stimuli concentrations (see figure 3.6A, p.31). Correlation analysis of the TNF α -producing microglia subpopulation size and the plated microglia density demonstrated a negative correlation for most conditions (see figure 3.6B, p.31) (see table 3.2). LPS stimulation resulted in R^2 values above 0.97 for all conditions except medium ($R^2 = 0.77$). MALP-2 stimulation revealed R^2 values of 0.774, 0.7552 and 0.6189 for medium control and the lower concentrations and R^2 values above 0.91 for the higher ones. The R^2 values for Pam₃CSK₄ were much more heterogeneous reaching from 0.41 up to 0.93.

FACS experiments performed with increasing microglia densities (200000, 300000, 400000 and 500000 cells/well) for TNF α validated these results by showing a similar pattern (see figure 3.7A, p.33). The higher the density, the lower the secreting subpopulation size which declines at the highest density to about 82 % of the lowest one. A similar correlation can be observed for RANTES positive microglia populations, since a significant difference could be demonstrated for 200000 and 300000 cells/well vs. 500000 cells/well; with a decrease to about 75 % of the lowest density. To rule out a possible effect of increased cell death caused by the relatively high cell densities, I stained for Zombie, a marker for dead cells. As seen in figure 3.7B, no differences among the various cell densities could be measured, confirming that none of the used cell densities biased the observed phenomenon by increased cell death.

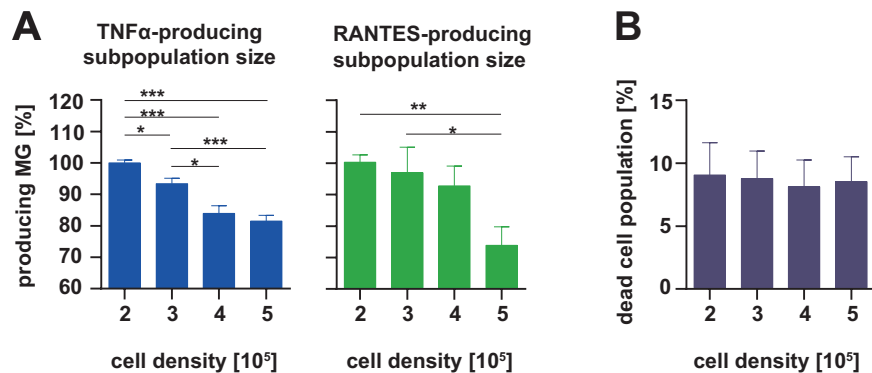

Figure 3.7 – Influence of the cell density on the microglia subpopulation sizes and cell death analyzed by FACS: FACS analysis of microglia plated at 200000, 300000, 400000 or 500000 cells/well. Microglia were stimulated with 1 ng/ml LPS for 8 hours and received monensin after 3 hours. Cells were screened for TNF α , RANTES (A) and Zombie (B) a marker for dead cells. Data was normalized to 200000 cells/well. Data was analyzed via Mann-Whitney test. Asterisks indicate p-values * ≤ 0.05 ; ** ≤ 0.005 ; *** ≤ 0.0005 . B) .Data are presented as mean \pm SEM. n=6

As I was able to confirm my hypothesis on density dependent subpopulation sizes of microglia, it was now of utmost interest to investigate the principle of organization. Thus, I investigated the progression of the subpopulation size increase for all densities. The analysis revealed that the relative increase of the subpopulation size is quite similar regardless of the densities with just few variations (see figure 3.8A, p.34). For MALP-2-stimulated microglia, significant differences between cell densities were primarily observed for the medium control and concentrations of 0.01 and 1 ng/ml while all the higher concentrations show no density-dependent differences. LPS-stimulated microglia show a similar increase, with significant differences for medium control, 0.1 ng/ml and 1 ng/ml. Pam₃CSK₄-stimulated microglia showed a more heterogeneous increase and a rather sigmoidal growth curve. Significant differences between the densities were observed till a concentration of 10 ng/ml.

Furthermore, I wanted to investigate the interplay between subpopulation size and the amount of secreted TNF α upon a cellular threat. I hypothesized that all secreting microglia secrete the same amount of TNF α and that microglia regardless of the density reach the same amount of total TNF α when facing the same threat. By assuming so, a higher microglia density should have a lower proportion of TNF α -secreting cells than lower microglia densities. However, analysis of the TNF α -secretion per cell revealed a density dependent secretion as well but in a reversed pattern (see figure 3.8B, p.34). The results showed that TNF α secretion per cell decreased with

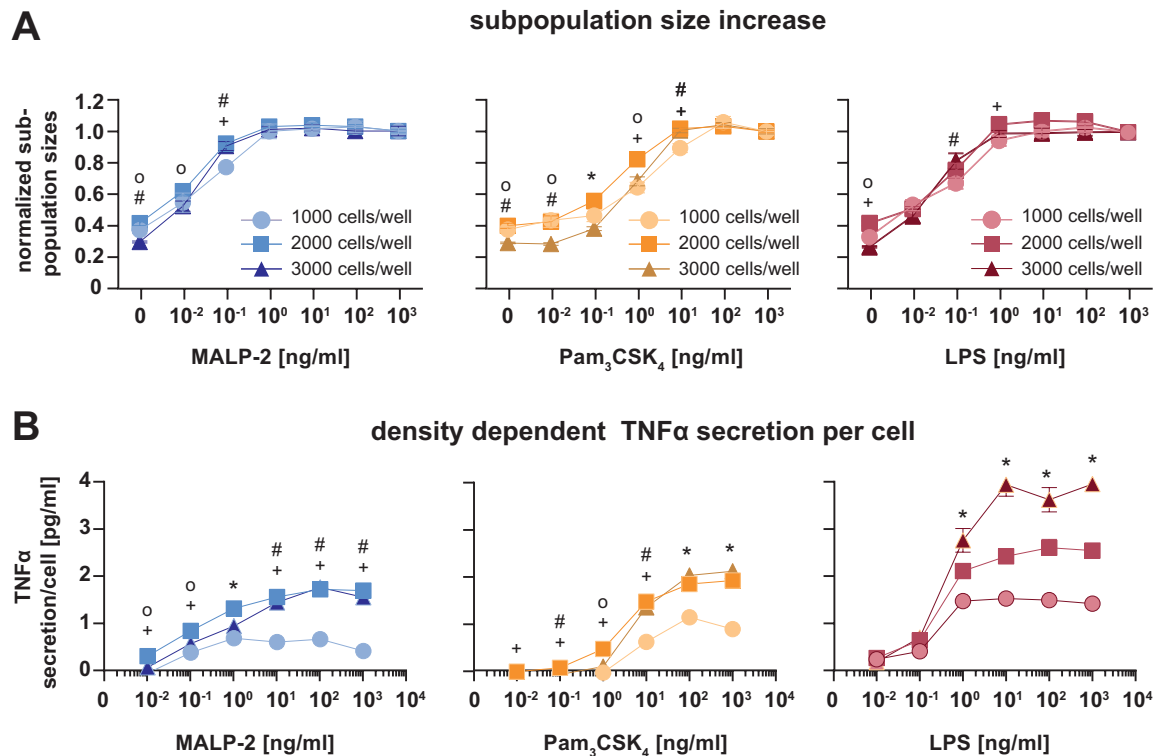

Figure 3.8 – Density dependent secretion per cell and subpopulation increase: A) Increase of the subpopulation sizes normalized to the highest value obtained for each stimuli and density. B) Density dependent TNF α secretion per cell. Significant differences obtained via ANOVA and Tukey's multiple comparison with P-values ≤ 0.05 were indicated as follows: * difference between all densities; + differences between 1000 and 2000 cells/well; # differences between 1000 and 3000 cells/well; o differences between 2000 and 3000 cells/well. Data are presented as mean \pm SEM. n=8

decreasing microglia density. This was demonstrated in LPS-stimulated microglia at concentrations above 0.1 ng/ml between all densities. For MALP-2 and Pam₃CSK₄ stimulations differences were mostly significant between at least two of the densities with a similar increase in secretion for microglia plated at 2000 and 3000 cells/well and a lower one for 1000 cells/well.

Alltogether, it was shown that TNF α and RANTES-producing microglia subpopulation sizes depend on the microglia density, as the secreting subpopulation sizes decreased with increasing microglia density. The general increase of the subpopulation sizes was barely affected by the density. Additionally, it was shown that microglia of higher densities produce less TNF α per cell than microglia of low densities. A corruption of the obtained data by increased cell death in higher densities could be excluded.

3.3 Microglia subpopulations overlap in their functions

After identification of the TNF α and RANTES producing subpopulations, I investigated their composition via FACS analysis. The results show that subpopulations positive for TNF α , RANTES and both are already existing in unstimulated cells, though in relatively small proportions (see figure 3.9A).

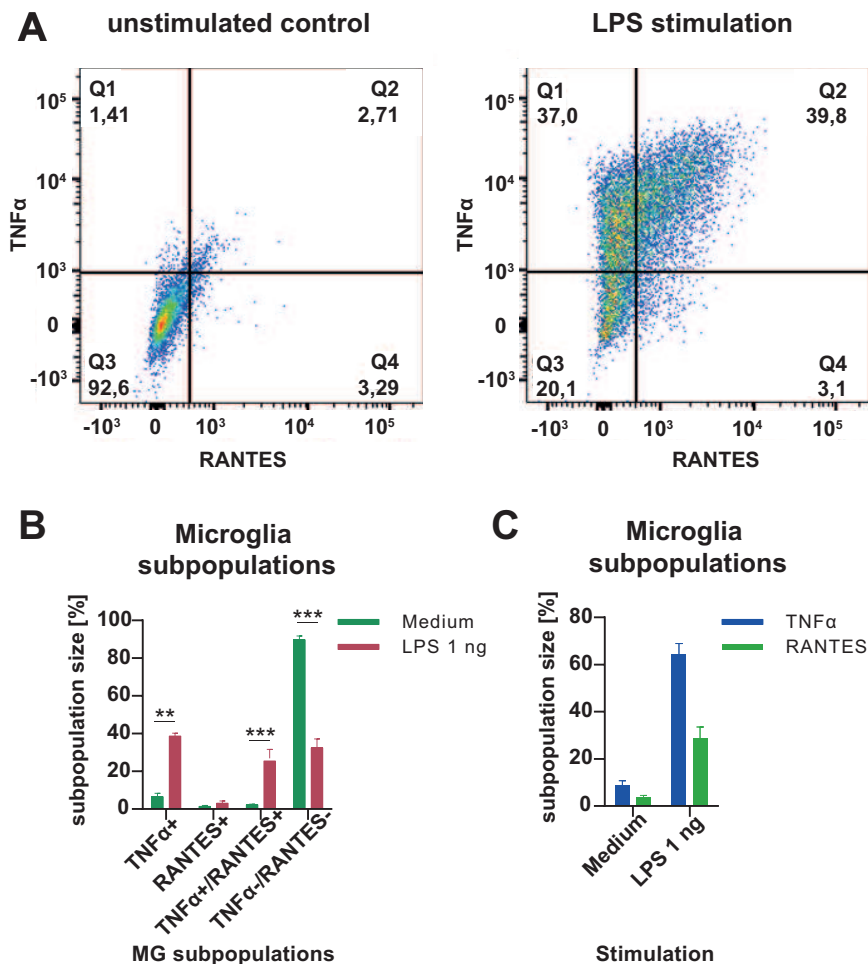

Figure 3.9 – Composition of TNF α - and RANTES-producing microglia subpopulation sizes analyzed via FACS: Microglia plated at 300000 cells/well were stimulated with medium or LPS (1 ng/ml) for 8 hours. TNF α - and RANTES-positive cells were analyzed via FACS. A) Representative FACS plots for unstimulated and stimulated microglia. B) Quantification of the individual subpopulations. C) Quantification of all TNF α - and RANTES-positive cells. Data was analyzed via multiple t-test (** ≤ 0.005 ; *** ≤ 0.0005). Data are presented as mean \pm SEM. n=6

Once microglia are stimulated with 1 ng/ml LPS, the cytokine producing microglia population rises massively. Thereby, I could detect that TNF α -positive microglia are assembled by a population that is just positive for TNF α , which increases upon stimulation significantly from 6.4 % to 38.8 % and a subpopulation that is able to produce TNF α as well as RANTES, which is also increasing significantly upon stimulation from 2.3 % to 25.5 % (see figure 3.9B, p.35). The RANTES-positive microglia population is also composed of a single and a double producing subpopulation of microglia. However, for RANTES the single positive microglia population stays more or less stable upon stimulation (increases insignificantly from 1.5 % to 3.2 %) while the subpopulation which is able to produce both cytokines increases. The total amount of TNF α - and RANTES-producing microglia rises after stimulation from about 8.7 % to 64.3 % and 3.7 % to nearly 28.7 %, respectively (see figure 3.9C, p.35).

Thus, I could demonstrate that cytokine producing microglia are composed of microglia that secrete the investigated cytokine only and those that secrete multiple cytokines at once. The increase in cytokine release upon LPS stimulation is thereby heterogeneously regulated, as up-regulation of RANTES is only conveyed by the subpopulation which secreted multiple cytokines while for TNF α the TNF α specific subpopulation increased as well.

3.4 Microglia proliferation and cytokine secretion

As I could demonstrate that microglia are able to secrete multiple cytokines as once, I investigated how microglia subpopulations are composed in case of diverse functions, i.e. TNF α secretion and proliferation.

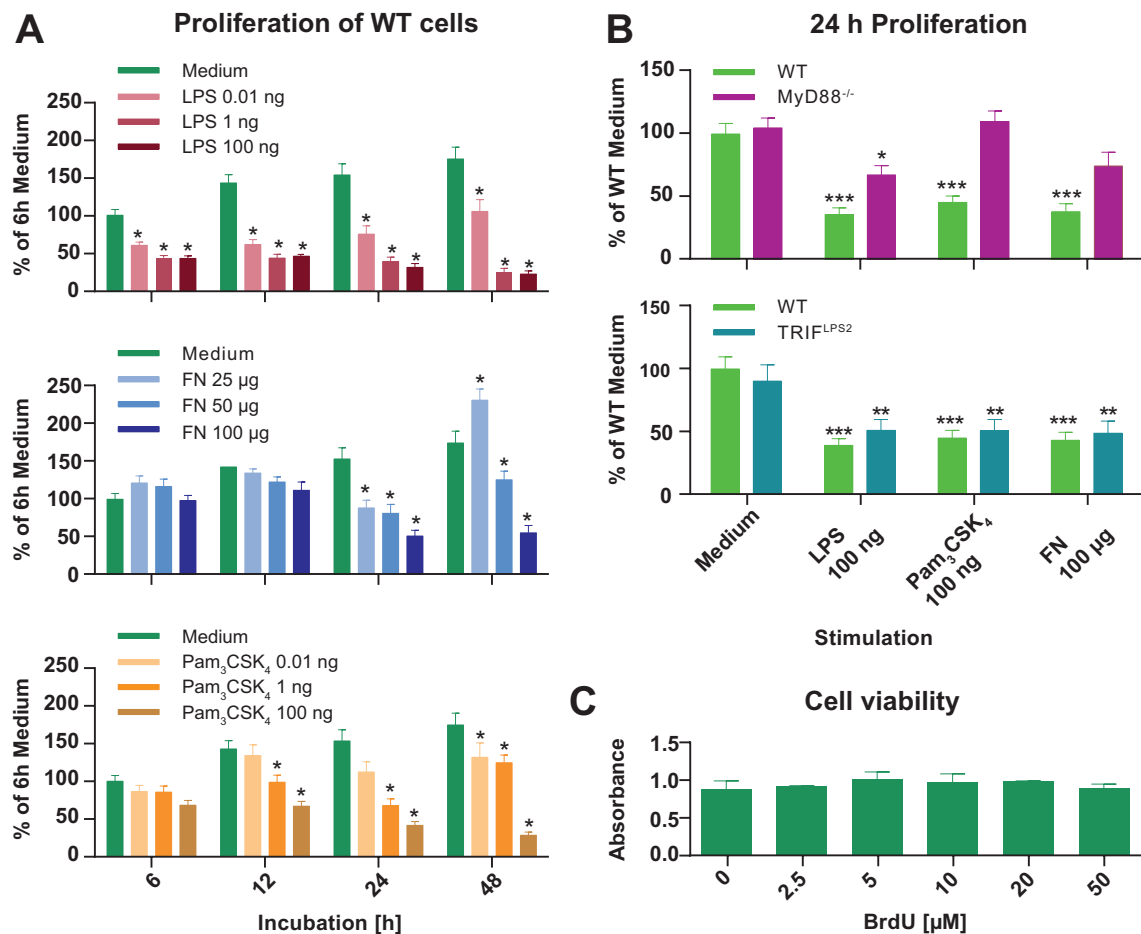

Figure 3.10 – Proliferation rate of challenged microglia isolated from WT and transgenic mice. A) Proliferation rate of WT microglia stimulated with 0.01 ng/ml, 1 ng/ml or 100 ng/ml of LPS or Pam₃CSK₄ or 25 μ g/ml, 50 μ g/ml and 100 μ g/ml of Fibronectin (FN); n= 14-20. B) Proliferation rate of myd88^{-/-} and trif^{LPS2} cells stimulated with 100 ng/ml of LPS and Pam₃CSK₄ or 100 μ g/ml of FN for 24 hours. n=30-48. The difference to WT medium levels was analyzed via 2-way ANOVA and Tukey's multiple comparison with asterisks indicating p-values * \leq 0.05; ** \leq 0.005; *** \leq 0.0005. C) Viability assessment via the WST-1 assay of Microglia treated with increasing concentrations of BrdU for 24 hours. n=6. Data was analyzed via multiple t-test. Data are presented as mean \pm SEM.

Since previous studies reported very controversial results on microglia proliferation upon challenges such as LPS stimulation (Gebicke-Haerter et al., 1989; Chen et al., 2012; Fukushima et al., 2015; George et al., 2015), I first examined the effect of any challenge on microglia proliferation, before investigating the temporal orchestration of proliferation and cytokine secretion. Therefore, I stimulated microglia with increasing concentrations of LPS, Pam₃CSK₄ (both 0.01 ng/ml; 1 ng/ml; 100 ng/ml), and Fibronectin (FN) (25 µg; 50 µg; 100 µg) for up to 48 hours and performed subsequently an ELISA based BrdU cell proliferation assay.

Analysis revealed that challenged microglia proliferate significantly less compared to untreated controls, and that this reduction becomes more pronounced the longer the challenge lasts (see figure 3.10A, p.37). Microglia stimulated with LPS showed a significant reduction in the proliferation rate for all tested incubation times and concentrations, ranging to a minimum of 22.1% compared to medium control. The FN-stimulated microglia showed a first impairment of proliferation after 24 hours for all used concentrations. At 48 hours, the decreasing effect seems to be reversed for low levels of FN (25 µg/ml) but stayed consistent for the other concentrations. Here, the minimum proliferation rate reached 51.6 % of the medium control. Microglia stimulated with Pam₃CSK₄ showed first reductions in the proliferation rate after 12 hours of incubation with 1 ng/ml and 100 ng/ml. After 24 hours, the proliferation rate was significantly reduced for all used concentrations with a minimum of 28.6 %.

After demonstrating this reduction in the proliferation rate, I wanted to identify the responsible signaling pathway. Thus, I performed additional proliferation assays in myd88^{-/-} and trif^{flps2} KO cells. For this purpose, I stimulated WT and KO microglia with high concentrations of the previously used stimuli for 24 hours (see figure 3.10B, p.37). A comparison between WT and myd88^{-/-} cells showed that, in contrary to stimulated WT cells, stimulation of myd88^{-/-} cells with Pam₃CSK₄ and Fibronectin did not reduce the proliferation rate significantly as it was observed in stimulated WT cells. Only LPS-stimulated KO cells showed a significant reduction compared to unstimulated WT cells. This reduction, however, was much weaker than in LPS-treated WT cells. In contrast to MyD88^{-/-} cells, trif^{flps2} cells behaved similar to WT cells. The significant reduction after stimulation was demonstrated for all used stimuli.

Additionally, I performed an WST-1 viability experiment with increasing concentrations of BrdU to exclude toxic effects of BrdU, which could bias the obtained proliferation data (see figure 3.10C, p.37). Microglia incubated with increasing concentrations of BrdU for 24 hours showed no differences in their viability compared to untreated control cells.

After assessment of the general proliferative behavior of challenged microglia, I tested if microglia proliferation and TNF α secretion occur simultaneously in the same cell once they are stimulated.

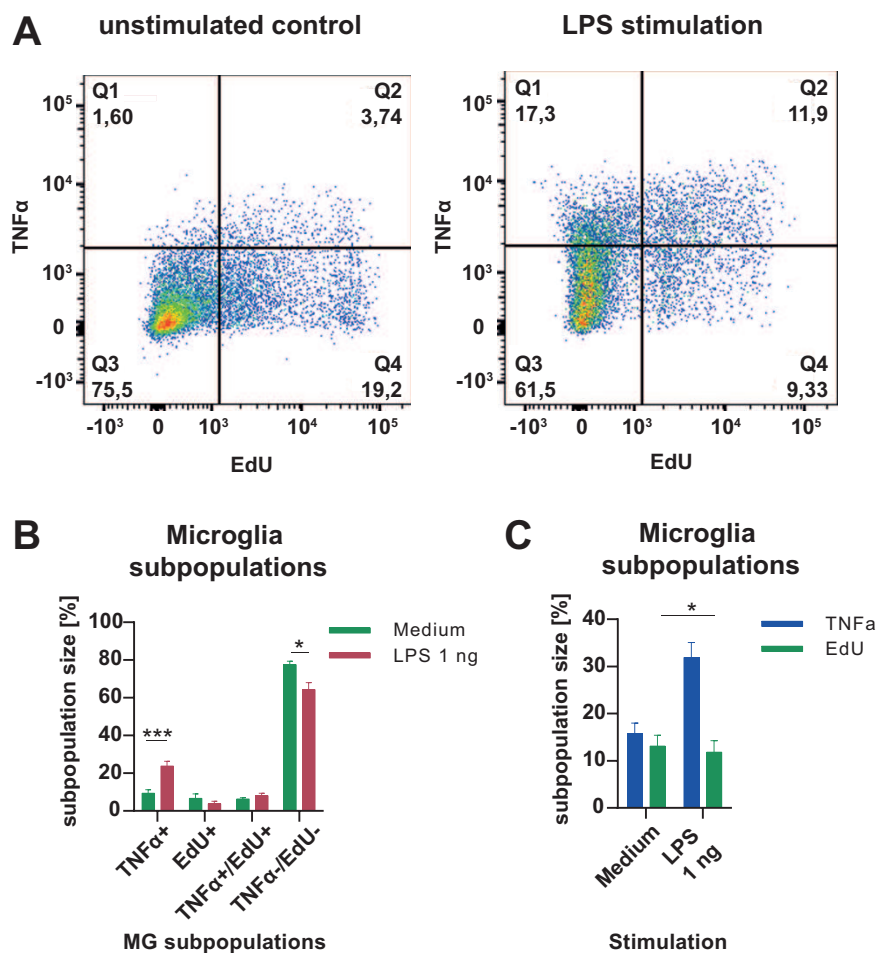

Figure 3.11 – Determination of TNF α -producing and proliferating microglia subpopulation sizes via FACS analysis: Microglia plated at 300000 cells/well were stimulated with medium or LPS (1 ng/ml) containing 5 μ M EdU for 8 hours. TNF α and EdU positive cells were analyzed via FACS. A) Representative FACS plots for unstimulated and stimulated microglia. B) Quantification of the individual subpopulations. C) Quantification of all TNF α and EdU positive cells. Data was analyzed via multiple t-test (* ≤ 0.05 ; *** ≤ 0.0005). Data are presented as mean \pm SEM. n=7-8

Hence, I performed combined FACS stainings for TNF α and EdU, a marker for proliferating cells. To do so, I stimulated microglia with 1 ng/ml LPS mixed with 5 μ M EdU for 8 hours. The obtained results of this double staining behaved quite similar to the previously performed one for TNF α and RANTES (see figure 3.11A, p.39). Unstimulated, TNF α -positive microglia are composed of a small population of TNF α secreting microglia (10.4 %) and a small population that is positive for both, secretion and proliferation (6.4 %) (see figure 3.11B, p.39). This composition was also observed for the proliferating microglia subpopulation which included a subpopulation of dividing microglia with a size of 6.8 %.

LPS stimulation increased the TNF α producing subpopulation to 23.95 %, whereas the double positive microglia population was stable at a size of 8 %. The proliferating microglia subpopulation was not significantly affected by LPS stimulation but was slightly reduced to 3.8 %. However, the total percentage of proliferating microglia decreased significantly upon LPS stimulation from approximately 13.1 % to 11.8 % (see figure 3.11C, p.39), which confirms my data obtained from the BrdU proliferation assay. The viability of microglia remained unchanged after a stimulation with increasing concentrations of EdU (see figure 3.12).

In summary, the proliferation rates in LPS, Pam₃CSK₄ and FN challenged microglia were reduced, primarily driven by the Myd88 signaling pathway. In addition, microglia can multitask as some cells are able to perform proliferation and cytokine secretion simultaneously. A corruption of these results by a toxic effect of the used cell division markers could be excluded.

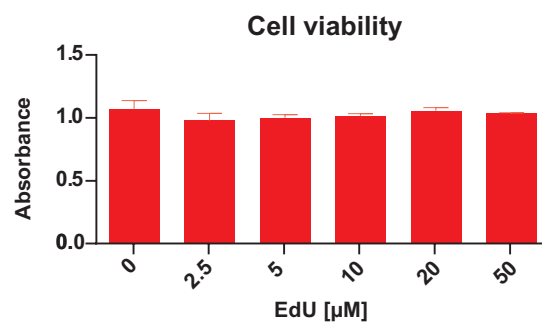

Figure 3.12 – Effect of EdU on microglia viability: microglia were treated with increasing concentrations of EdU for 24 hours. Viability was assessed via the WST-1 assay. Data was analyzed via multiple t-test. Data are presented as mean \pm SEM. n=6

3.5 Effect of environmental cues on microglia subpopulation sizes

Knowing that microglia subpopulation sizes are density dependent, the underlying mechanism conveying this effect is yet to be discovered. As microglia have mostly non-overlapping territories (Parkhurst and Gan, 2010) which excludes a contact-dependent organization, it is more likely that the secretion of certain substances could mediate the subpopulation sizes instead. As more microglia could produce higher amounts of a certain substance this increase in concentration could adjust the subpopulation sizes.

To test this hypothesis, I performed an insert experiment by plating 200000 microglia with or without transmembrane inserts containing additional 100000, 200000 or 300000 microglia cells. Stimulation with LPS results thus in supernatants produced by 200000-500000 cells. Investigation of the plated 200000 cells via FACS showed that the TNF α -positive microglia proportion was not affected by the supernatants of increasing microglia densities (see figure 3.13). Since an absent effect could also be caused by an insufficient mixing of the supernatants, the cytokine production in- and outside of the inserts was compared as well. Significant differences for the tested factors were found for RANTES only. Here, supernatants from inside the inserts with 100000 and 200000 cells contained lower RANTES protein compared to supernatants from outside (see figure 3.14, p.42).

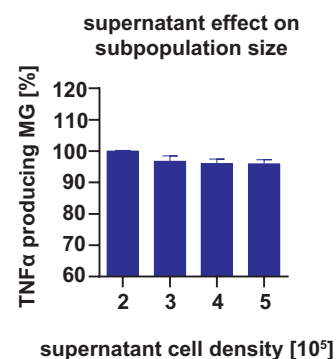

Figure 3.13 – Determination of supernatant effect on TNF α -producing microglia subpopulation size via FACS analysis: 200000 Microglia/well were plated with and without the presence of an insert containing additional 100000, 200000 or 300000 cells/insert and stimulated with 1 ng/ml LPS for 8 hours. The plated 200000 cells were subsequently analyzed for TNF α . FACS analysis of TNF α -producing microglia subpopulation size was normalized to values obtained from 200000 cells without inserts. Data was analyzed via multiple t-test. Data are presented as mean \pm SEM. n=8

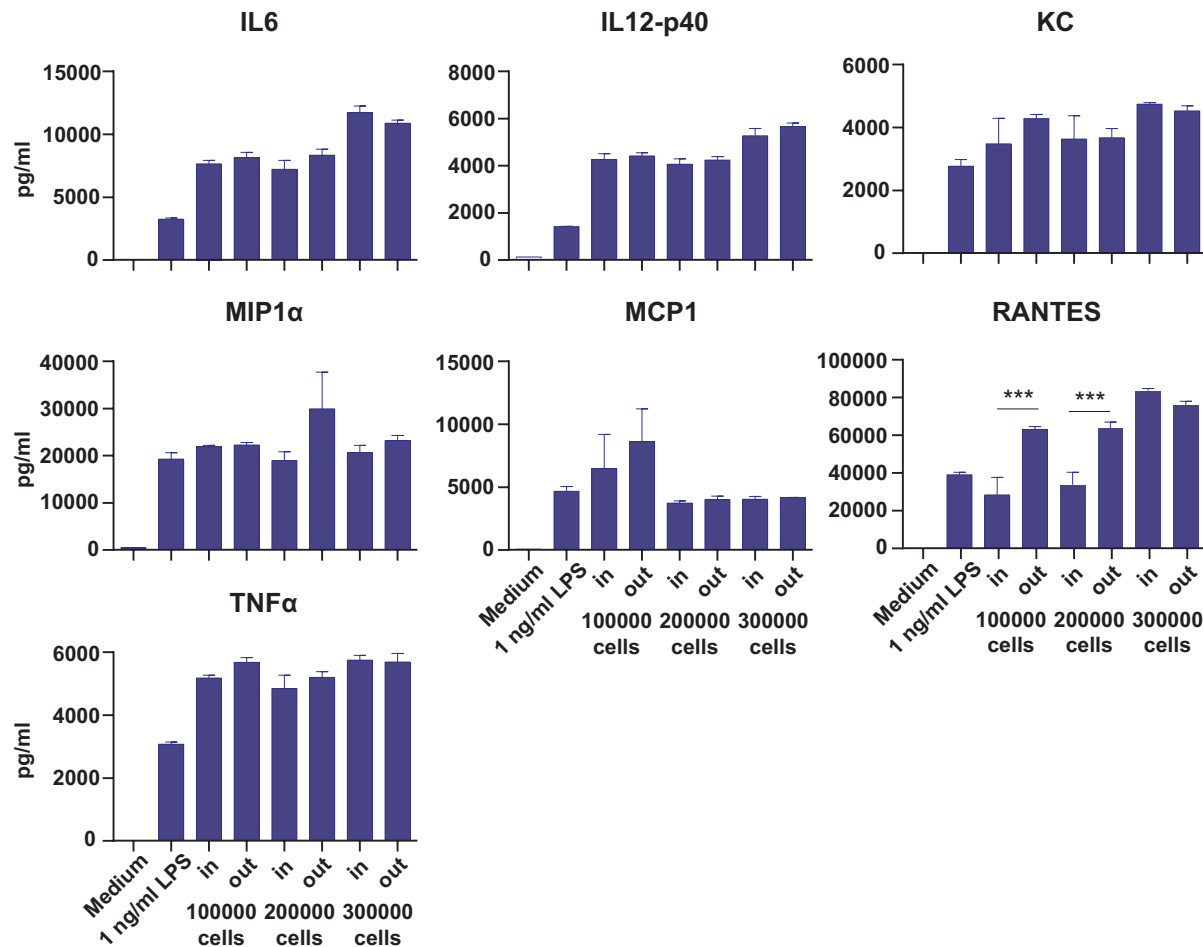

Figure 3.14 – Cytokine levels inside and outside of inserts: Supernatant from inside and outside the insert of the insert experiment were analysed via ELISA to determine the cytokine secretion of IL6, IL12-p40, KC, MIP1 α , MCP-1, RANTES and TNF α . Data was analyzed via ANOVA and Tukey's multiple comparison with asterisks indicating p-values *** ≤ 0.0005 . Data are presented as mean \pm SEM. n=4

To avoid the limitations caused by the insert experiment, an supernatant transfer experiment with supernatants from different densities with different treatments was performed. The first experiment revealed no differences in the TNF α -producing subpopulation size between the conditions but a significant difference between the LPS-treated groups (see figure 3.15A, p.43). The subpopulation sizes were significantly smaller in the groups that received supernatant from the cells that were already stimulated for 8 hours with LPS compared to the groups that received LPS after the supernatant transfer. A comparison of the supernatants from 200000 and 500000 cells for each group shows no effect on the subpopulation size.

To exclude that this decline is caused by a possible exhaustion of the LPS amount in the pre-stimulated condition, the experiment was repeated with a higher LPS concentration (10 ng/ml) and subpopulation sizes of TNF α -and RANTES-producing microglia were investigated. These repetitions were performed together with the master student Robin Hindmarsh. Again, the subpopulation size regarding TNF α did not change between the 200000 cells and the 200000 cells that received supernatant from 500000 cells, independent of the stimulation paradigm (see figure 3.15B), which also holds true for RANTES (see figure 3.15C). The TNF α -producing subpopulation sizes of microglia that were stimulated with LPS after the supernatant transfer (approximately 77 %) differed significantly from the sizes of microglia supplemented with already stimulated supernatant (approximately 55 %). This effect of the pre-stimulation could not be observed for RANTES.

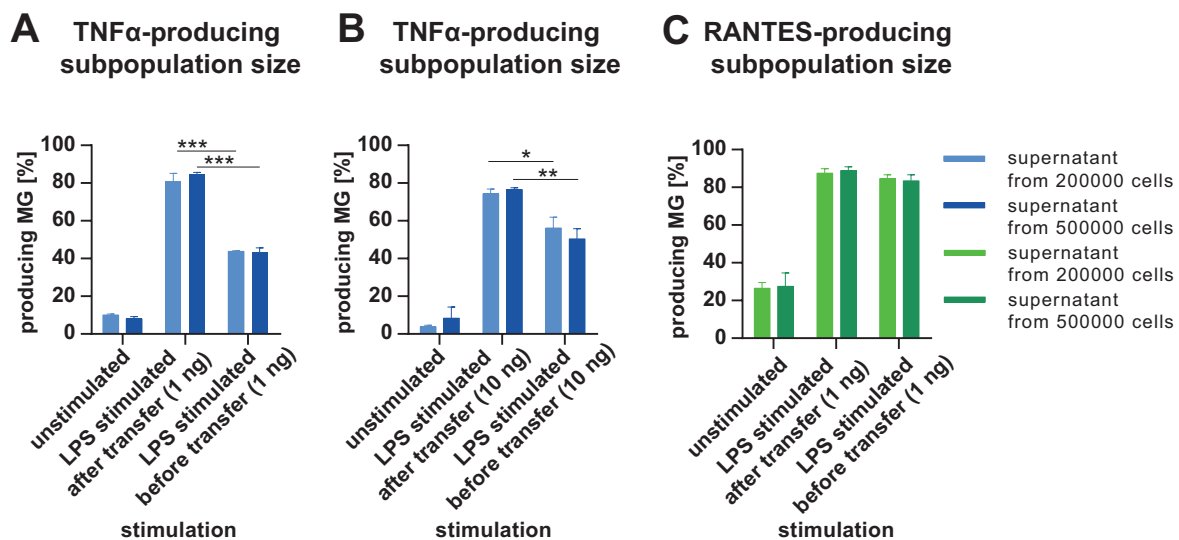

Figure 3.15 – Supernatant transfer experiment: 200000 or 5000000 microglia cells plated in 12-well plates were treated as the following: 200000 cells and 200000 cells that received the supernatant of 500000 unstimulated cells for 8 hours served as unstimulated controls. 200000 cells and 200000 cells with the supernatant of 500000 unstimulated cells were stimulated with LPS for 8 hours. 200000 cells were supplemented for 8 hours with the supernatants of 200000 or 500000 cells that were already stimulated with LPS for 8 hours beforehand. A) Microglia were stimulated with 1 ng/ml LPS and analyzed for the TNF α -producing subpopulation size. n=2. B) Microglia were stimulated with 10 ng/ml LPS and analyzed for the TNF α -producing subpopulation and C) the RANTES-producing subpopulation size. n=8. Data was analyzed via ANOVA and Tukey's multiple comparison with asterisks indicating significant differences between LPS stimulated groups with p-values * ≤ 0.05 ; ** ≤ 0.005 ; *** ≤ 0.0005 . Data are presented as mean \pm SEM. These experiments were partially performed together with the master student Robin Hindmarsh.

In conclusion, it was demonstrated that the supernatant of LPS stimulated microglia can but doesn't have to affect the microglia subpopulation sizes, while supernatants of different densities seems to have no effect.

3.6 TNF α effect on TNF α secretion

As the secreted cytokines themselves could affect their own secretion or secretion of other cytokines in a feedback loop, leading to a reduction or increase in production over time I examined this possible effect as well. To test this, ELISA experiments of microglia pre-stimulated with TNF α for different durations, ranging from 5 minutes to 24 hours with a subsequent LPS stimulation were performed. Pre-stimulated microglia that received medium instead of LPS served as controls. The analysis of the amounts of secreted cytokines revealed that TNF α pre-incubation alone was not able to induce significant cytokine secretion. However, with a successive LPS stimulation, TNF α affected the production of most measured cytokines after a pre-incubation period of more than 6 hours (see figure 3.16, p.46). The cytokines RANTES, IL12-p40, TNF α and IL6 are significantly reduced after a pre-incubation period of 6 hours or longer. A significant reduction for KC emerges at 12 hours. MCP-1 was the only measured cytokine which was unaffected by the TNF α pre-stimulation. Only a single cytokine showed a significant increase in release after incubation periods of 6 hours and higher, namely MIP1 α . After observing this effect of TNF α pre-incubation on cytokine secretion, the experiment was repeated with pre-incubations of RANTES, MCP-1 and MIP1 α . These repetitions were carried out together with the bachelor student Timo Pauw.

As seen in figure 3.17, pre-incubation with RANTES showed no effect on the cytokine secretion. While the pre-incubation alone was not able to induce cytokine secretion, the combination with LPS also had no effect on the amount of secreted cytokines.

Pre-incubation with MCP-1 showed minor effects on all cytokines except RANTES (see figure 3.18, p.48). A pre-incubation with MCP-1 alone induced no cytokine production, but the combination with LPS stimulation induced various changes. IL6, IL12-p40 and KC showed a significant reduction in their secretion after 24 hours of pre-incubation time. For KC an additional increase was observed after 3 hours which was absent again at longer incubation periods. TNF α and MIP1 α showed significant increases after 3h and 6 h, respectively. MCP-1 levels showed differences at 10 minutes, 25 minutes and 6 hours and RANTES secretion was not affected by any pre-incubation period.

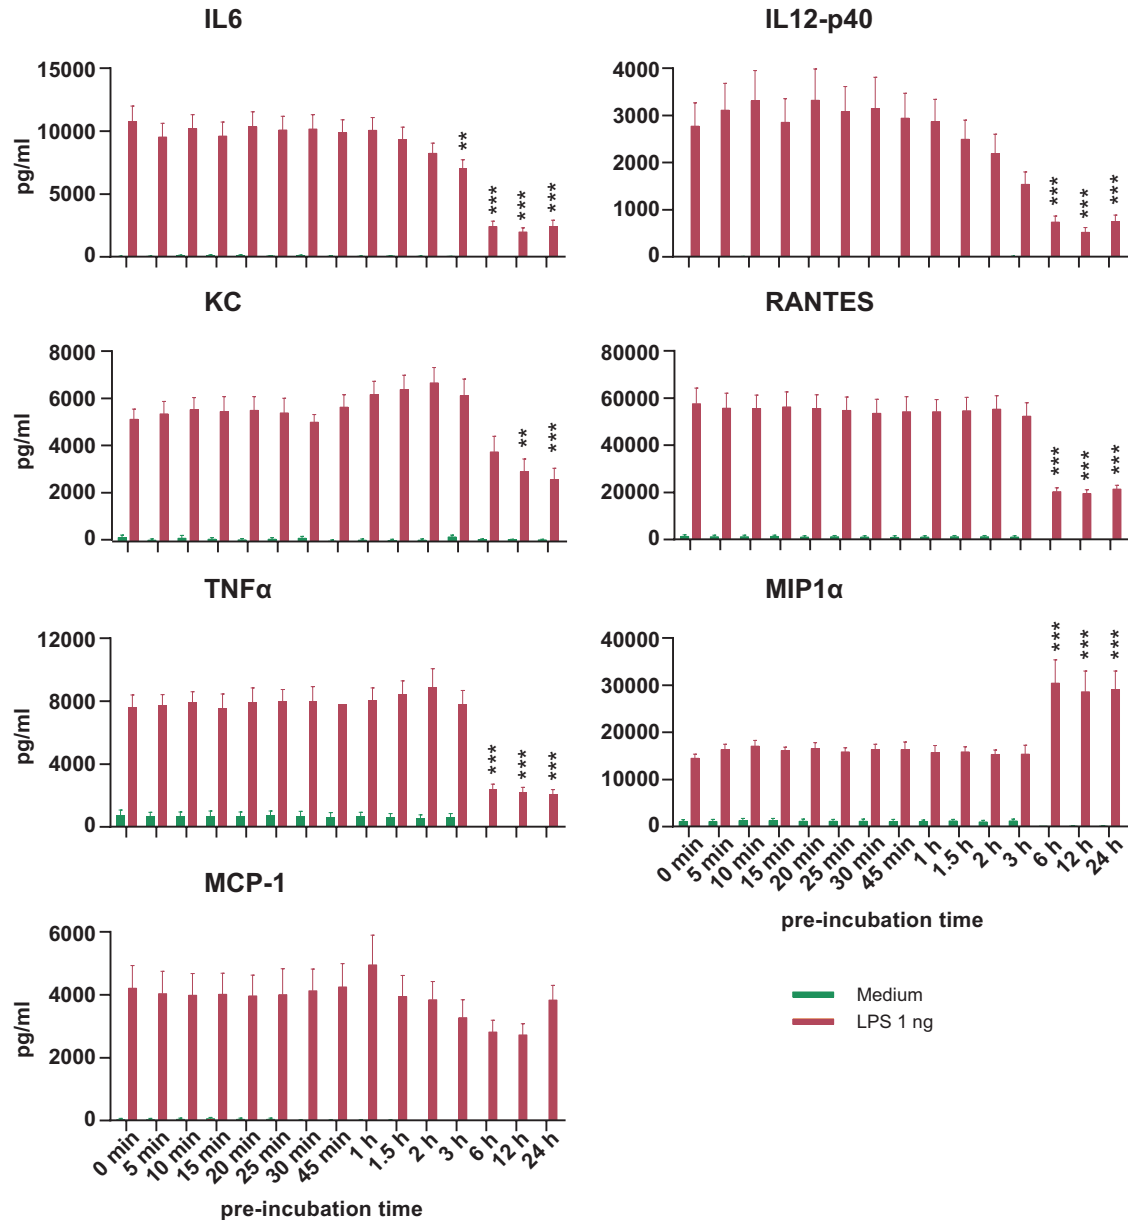

Figure 3.16 – Time dependent effect of TNF α pre-incubation on microglial cytokine and chemokine production in general and upon LPS stimulation: Microglia were pre-incubated with 10 ng/ml TNF α for the indicated time points. After removing TNF α cells were subsequently incubated with fresh medium or stimulated with LPS (1 ng/ml) for 18 hours. Chemokine and Cytokine production was assessed using ELISA. Data was analyzed via Two Way ANOVA and Tukey's multiple comparison with asterisks indicating significant differences between LPS stimulated groups with p-values ** ≤ 0.005 ; *** ≤ 0.0005 . Data are presented as mean \pm SEM. n=16

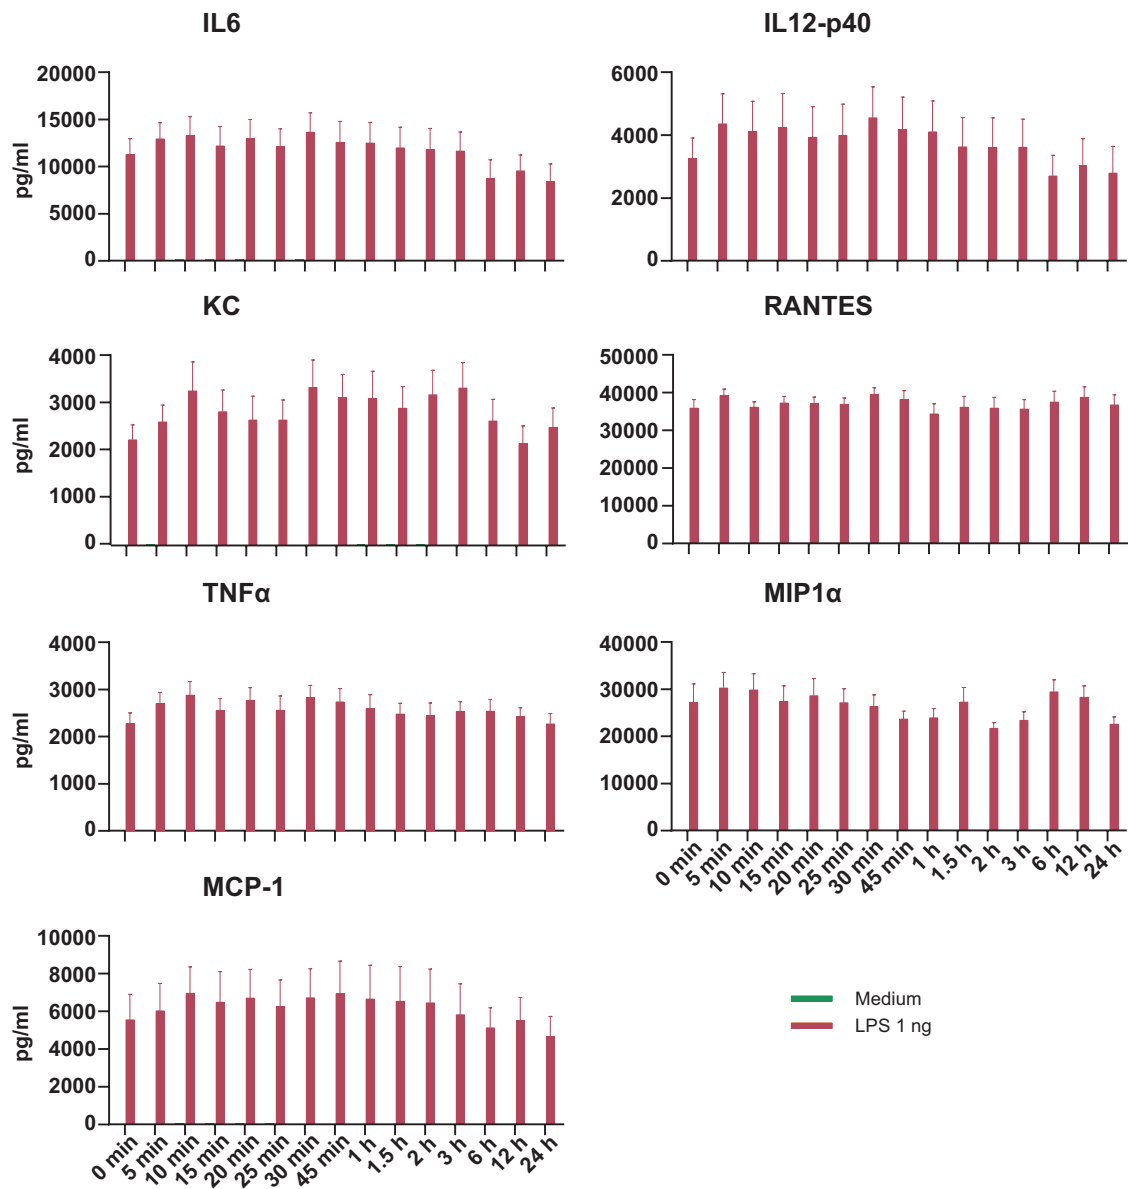

Figure 3.17 – Time dependent effect of RANTES pre-incubation on microglial cytokine and chemokine production in general and upon LPS stimulation: Microglia were pre-incubated with 0.1 ng/ml RANTES for the indicated time points. After removing RANTES cells were subsequently incubated with fresh medium or stimulated with LPS (1 ng/ml) for 18 hours. Chemokine and Cytokine production was assessed using ELISA. Data was analyzed via Two Way ANOVA. Data are presented as mean \pm SEM. n=16. This experiment was carried out together with the bachelor student Timo Pauw.

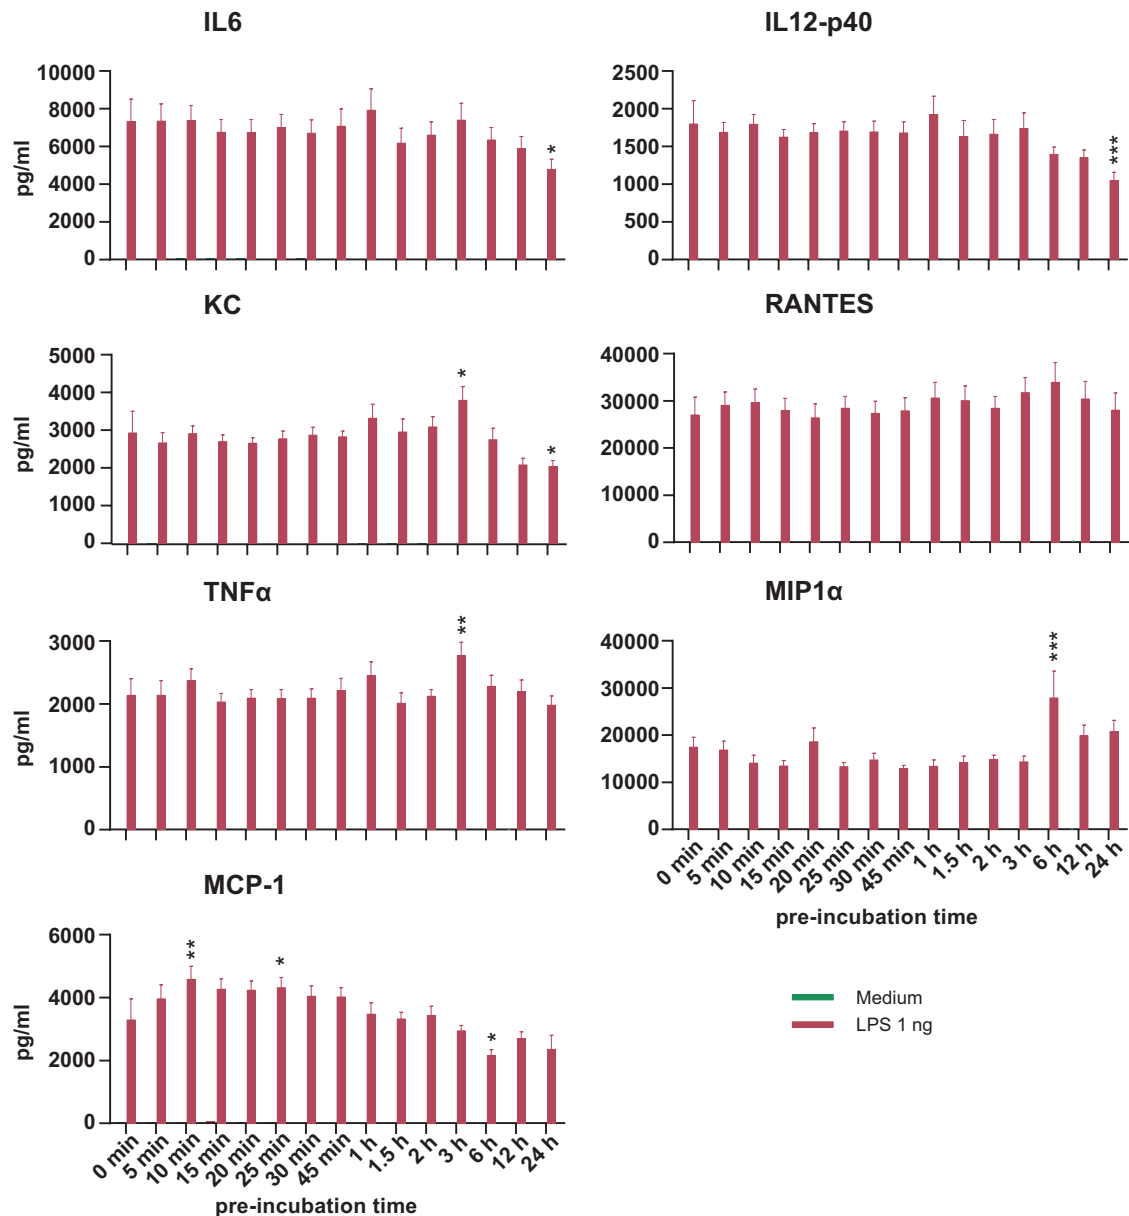

Figure 3.18 – Time dependent effect of MCP-1 pre-incubation on microglial cytokine and chemokine production in general and upon LPS stimulation: Microglia were pre-incubated with 0.1 ng/ml MCP-1 for the indicated time points. After removing MCP-1 cells were subsequently incubated with fresh medium or stimulated with LPS (1 ng/ml) for 18 hours. Chemokine and Cytokine production was assessed using ELISA. Data was analyzed via Two Way ANOVA and Tukey's multiple comparison with asterisks indicating significant differences between LPS stimulated groups with p-values $** \leq 0.005$; $*** \leq 0.0005$. Data are presented as mean \pm SEM. n=16. This experiment was carried out together with the bachelor student Timo Pauw

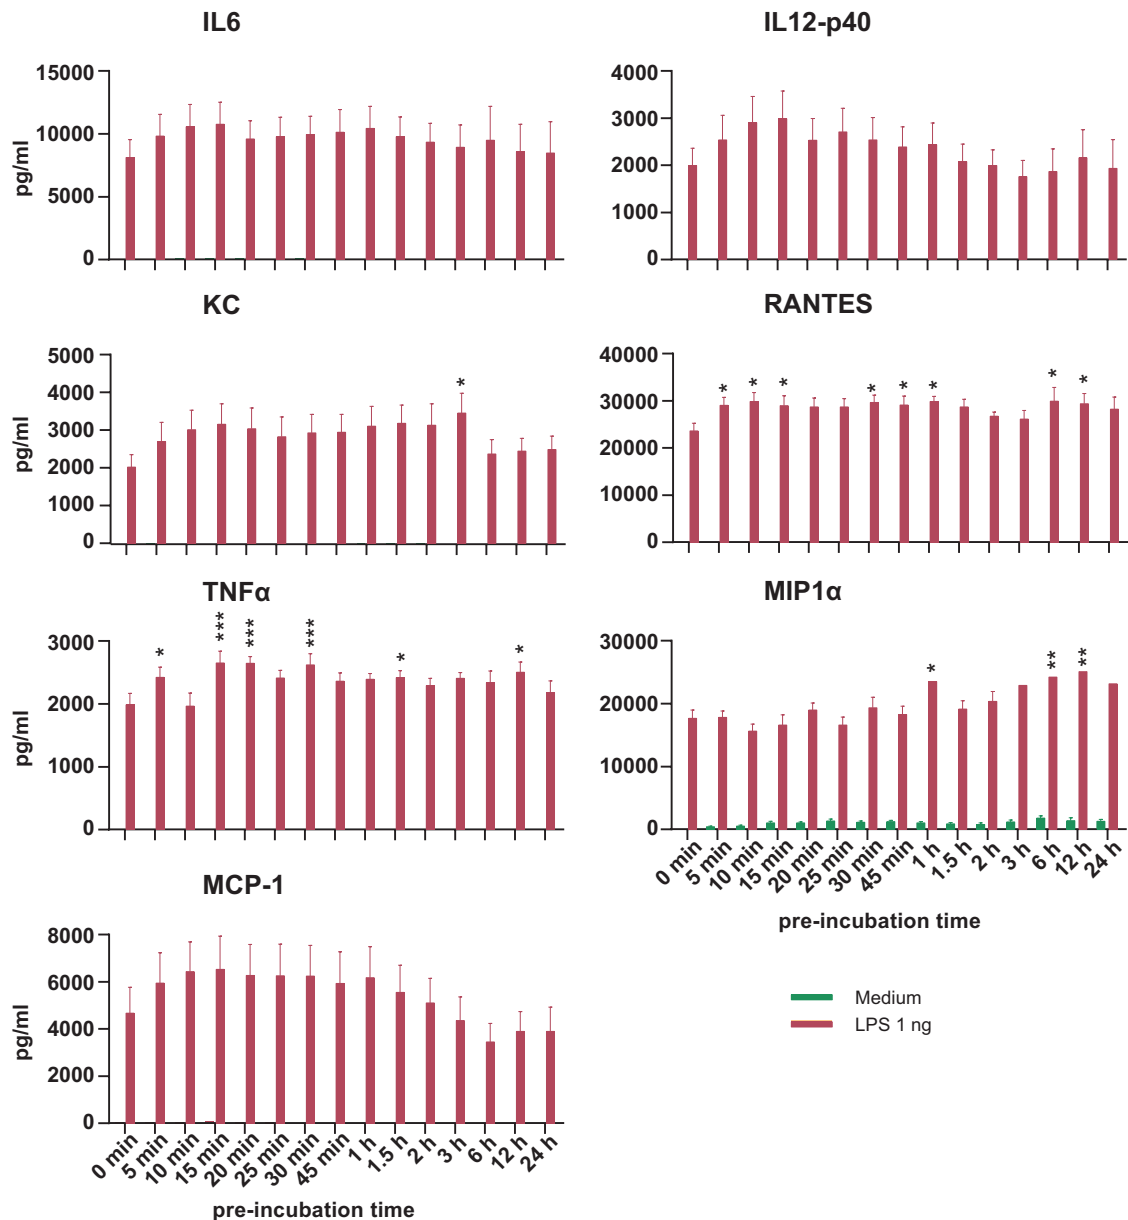

Figure 3.19 – Time dependent effect of MCP-1 pre-incubation on microglial cytokine and chemokine production in general and upon LPS stimulation: Microglia were pre-incubated with 100 ng/ml MIP1α for the indicated time points. After removing MIP1α cells were subsequently incubated with fresh medium or stimulated with LPS (1 ng/ml) for 18 hours. Chemokine and Cytokine production was assessed using ELISA. Data was analyzed via Two Way ANOVA and Tukey's multiple comparison with asterisks indicating significant differences between LPS stimulated groups with p-values $** \leq 0.005$; $*** \leq 0.0005$. Data are presented as mean \pm SEM. n=16. together with the bachelor student Timo Pauw.

A pre-incubation with MIP1 α in combination with LPS stimulation affected the secretion of KC, RANTES, TNF α and MIP1 α (see figure 3.19, p.49). While IL6, IL12-p40 and MCP-1 secretions were unaffected, the secretion of the other cytokines was elevated. KC levels were increased at 3 hours of pre-incubation time. RANTES levels increased significantly after 5 minutes and stayed relatively stable afterwards. TNF α showed a significant increase at 5, 15, 20 and 30 minutes as well as 1.5 and 12 hours of pre-incubation time. MIP1 α pre-incubation enhanced its own secretion after 1h, 6h and 12 hours of pre-incubation time. Cells pre-incubated with MIP1 α that received medium instead of LPS had no significant effect on the tested cytokines.

Since TNF α was the only tested cytokine which was able to induce a strong and consistent effect on the cytokine levels, I investigated the effect of TNF α in more detail. First, an LDH assay was performed to exclude a toxicity effect of TNF α on the microglial cells due to an excessive incubation. Upon tissue damage or toxicity, cells release LDH which leads to an increase in its concentration. No significant increases between the 0-minute control and the other pre-incubation times for the LPS stimulated microglia could be detected (see figure 3.20A). Pre-stimulated microglia that received medium instead of LPS afterwards also showed no changes in their viability.

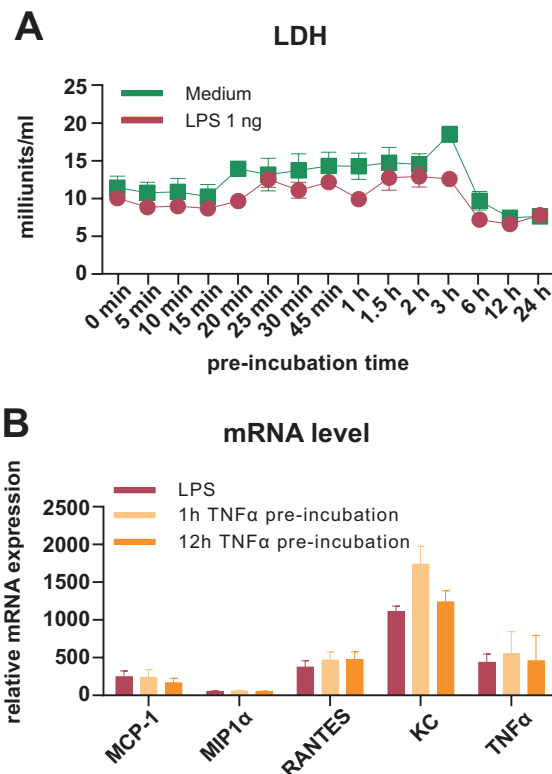

Figure 3.20 – Effect of TNF α on microglia viability and RNA levels of cytokines: A) Supernatants from the TNF α pre-incubation experiments were used to determine the viability of microglia via the LDH assay. B) RNA was extracted from microglia pre-stimulated with 10 ng/ml TNF α for 0 h, 1 h and 12 h and stimulated with 1 ng/ml LPS for 3 hours. mRNA levels were measured by RT-PCR, relative mRNA expression for MCP-1, MIP1 α , RANTES, KC and TNF α was calculated by $2^{-\Delta\Delta CT}$ to medium controls with Gapdh as the control gene. Data was analyzed via ANOVA. Data are presented as mean \pm SEM. n=4

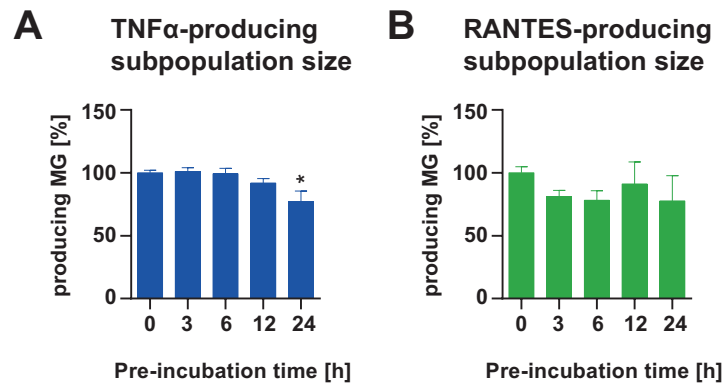

Figure 3.21 – FACS analysis of TNFα pre-incubation effect on TNFα- and RANTES-producing microglia subpopulation sizes: Microglia were pre-stimulated with 10 ng/ml TNFα for 0 h, 1 h, 3 h, 6 h, 12 h and stimulated with 1ng/ml LPS for 8 hours. Data was normalized to values obtained from 0 h control cells and analyzed via ANOVA and Tukey's multiple comparison with asterisks indicating significant differences between LPS stimulated groups with p-values ≤ 0.05 . Data are presented as mean \pm SEM. n=8

Next, I investigated if the observed TNFα effect on cytokine secretion is also detectable on the level of transcription using qPCR. Therefore, microglia were pre-incubated with 10 ng/ml TNFα for 0, 1 and 12 hours and subsequently stimulated with LPS for 3 hours. The mRNA levels of the tested cytokines relative to the levels obtained from the negative control revealed no differences between the three treatment groups of all tested cytokines (see figure 3.20B, p.50). I also wanted to see if the observed effect of TNFα could affect the cytokine secretion by changing the size of the producing subpopulation. Thus, I repeated the pre-incubation experiment in a FACS approach for up to 24 hours of pre-incubation time and 8 h LPS stimulation. The data revealed a reduction in the TNFα-producing subpopulation size to 77.1 % of the control after a pre-incubation period of 24 hours (see figure 3.21A). The RANTES-producing subpopulation size was not affected by the TNFα pre-incubation (see figure 3.21B). Since ELISA and FACS experiments were performed with different incubation times for LPS (18 and 8 hours, respectively), the observed insignificant change might be caused by an insufficient incubation time with LPS. Thus, a control ELISA experiment was performed with TNFα pre-stimulated microglia, stimulated with LPS for 8 hours. As it is shown in figure 3.22, 8 hours of LPS incubation is insufficient to elicit the same effect that was observed with 18 hours of LPS stimulation on TNFα and RANTES secretion (see figure 3.22, p.52). While IL6, IL12-p40 and MCP-1 showed a reduction in secretion after 12 hours of pre-incubation time, the levels of KC, MIP1α, RANTES and TNFα were not affected at any pre-incubation duration.

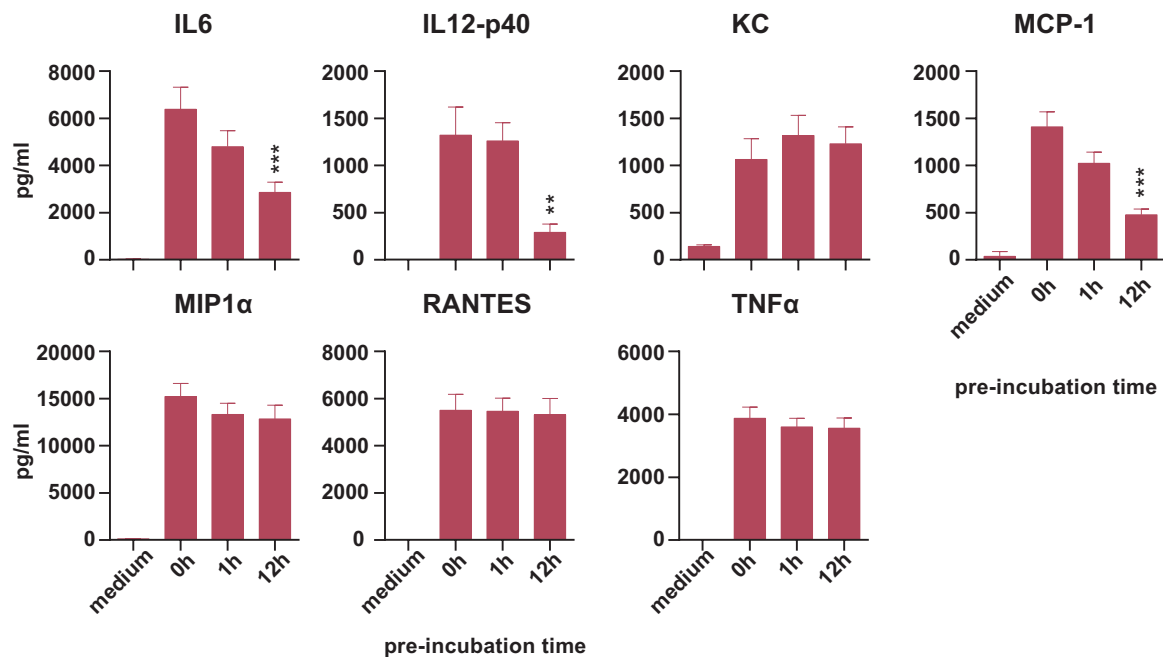

Figure 3.22 – Effect of TNFα pre-incubation on microglial cytokine and chemokine production after 8 hours of LPS stimulation: Microglia plated at a density of 15000 cells in a 96-well format were pre-incubated with 10 ng/ml TNFα for 0 h, 1 h and 12 hours and subsequently stimulated with LPS (1 ng/ml) for 8 hours. Microglia without pre-stimulation that received fresh medium instead of LPS served as medium controls. Chemokine and Cytokine production was assessed using ELISA. Data was analyzed via ANOVA and Tukey's multiple comparison with asterisks indicating p-values ** ≤ 0.005; *** ≤ 0.0005. Data are presented as mean ± SEM. n=16

Taken together, only a fraction of cytokines was able to regulate and self-adjust cytokine secretion levels. TNFα had the strongest effect of all tested cytokines even though this effect was absent on mRNA level. FACS analysis demonstrated an influence of TNFα pre-incubation on the TNFα-producing microglial subpopulations exclusively. A possible cause for the variations in the effect of the ELISA and FACS experiments could be the incubation time for LPS, as the effect of TNFα pre-incubation on some cytokines could be only observed after 18 hours but not after 8 hours of LPS stimulation.

4. Discussion

Microglia are known to be implicated in neurodevelopmental, neuroinflammatory, neurodegenerative and neuropsychiatric diseases ((reviewed in Block and Hong, 2005). Immune dysregulation caused by the diseased environment leads to over-activation, exaggerated and/ or inhibited functions of microglia, which are in most cases associated with neuroinflammation, worsening the diseases (Maezawa and Jin, 2010; Suzuki K et al., 2013). Treatments aiming to control this neuroinflammation as therapeutic approaches to oppose the diseases are thus under extensive investigation. And indeed, antipsychotics, for instance ones used for schizophrenia, are known to decrease the secretion of several pro-inflammatory factors like TNF α or nitric oxide, suggesting a potentially useful therapeutic effect (Kato et al., 2008, 2007; Kowalski et al., 2003; Sugino et al., 2009). However, some antipsychotics increase the amount of other pro-inflammatory cytokines as well (Himmerich et al., 2011; Kluge et al., 2009). This phenomenon and the fact that microglia also display beneficial, immune-resolving functions, questions the usefulness of unspecific anti-inflammatory drugs (Biber et al., 2016). Thus, with the emerging awareness of microglia subpopulations, it would be of utmost importance to identify drugs which specifically target the aversive microglia while leaving the protective ones unaffected or even supported (Kamigaki et al., 2016; London et al., 2013). An understanding of microglia subpopulations and their organization would be the requirement to accomplish the identification of specific drugs. Though, research addressing this issue is scarcely existing so far. This study investigated the behavior and organization of different microglia subpopulations to shed some light on this so far unknown but highly important subject.

4.1 Microglia subpopulation sizes are dynamically adapted in response to different challenges

Microglia are able to respond to specific stimuli in a dose dependent manner. This was shown for LPS, Pam₃CSK₄, *staphylococcus aureus*, *escherichia coli*, fibronectin and Lipid A conducted in in vivo and/or in vitro studies for a broad range of cytokines like TNF α (Janova et al., 2016; Kielian et al., 2002; Lund et al., 2006; Mildner et al., 2007; Regen et al., 2011). Even though, the underlying signaling mechanisms are known in most cases, the organizational principle of the change in the secreted amount was not investigated so far. The lack of investigation can be explained by the former assumption that microglia are a homogenous population of immune cells (reviewed by Hanisch, 2013). This assumption would allow just one explanation for the change in the cytokine levels – the secretion per cell has to be altered. However, research from the recent decade strongly suggests a rather heterogeneous character of microglia, offering another hypothesis which might explain the change in cytokine quantities: Alterations in the relative portion of secreting cells (Baalman et al., 2015; Butovsky et al., 2006; Chen et al., 2010; Clausen et al., 2008; Fang et al., 2014; Färber et al., 2005; Gertig and Hanisch, 2014; Kawahara et al., 2009; Kobayashi et al., 2013; Kocur et al., 2015; Kuhn et al., 2004; Marshall et al., 2014; Noda et al., 2000; Pannell et al., 2014b; Pepe et al., 2014; Schmid et al., 2002; Shinjo et al., 2014; Trias et al., 2013; Venkatesan et al., 2010; Wlodarczyk et al., 2015). In the present study, I addressed this question of how the change in cytokine secretion is organized by investigating TNF α , a cytokine which was already demonstrated to be produced by a subpopulation of microglia only, and RANTES, a cytokine that was not investigated regarding subpopulations so far (Scheffel et al., 2012).

By testing the effect of increasing concentrations of LPS, Pam₃CSK₄ and MALP-2 on TNF α - and RANTES-producing microglia I was able to demonstrate a variety of important features. Both TNF α - and RANTES were secreted by microglia subpopulations, which confirms the findings from Scheffel et al. and adds RANTES production to the list of subpopulational features. As both randomly chosen cytokines characterize subpopulations of microglia, this characterization might be a general feature of all cytokines, as it was shown for Interleukin 1 beta as well (Clausen et al., 2008). Thus, at the first glance, the development of drugs specifically targeting cytokine producing subpopulations would be feasible.

In addition, I showed that subpopulation sizes can be modulated in response to a challenge, for instance by LPS, MALP-2 and Pam₃CSK₄. In regard to LPS, this phenomenon was already confirmed in the context of microglial neurotransmitters and neurohormone responsiveness (Pannell et al., 2014b). There, LPS stimulation lead to an up- or downregulation of the responding microglia subpopulation sizes.

The effect on subpopulation size, however, experiences a ceiling effect at a certain point of concentration, depending on the respective cytokine. This ceiling effect might resemble a physiological limitation of the immune reaction in regard to LPS and other immunoreactive substances. In an intact central nervous immune system, this limitation could prevent an overproduction of cytokines, which would result in a disruption of homeostasis and finally neurodegeneration. As dysregulation of microglial cells is considered as part of the pathology in neurodegenerative diseases, this physiological limitation might be affected as well leading to exacerbated inflammatory responses (von Bernhardt et al., 2015).

Furthermore, I have shown that the increase in subpopulation size correlates with cytokine secretion. Hereby, the degree of influence strongly depends on the respective cytokine and might be limited to certain stimuli. Thus, the increases in cytokine release upon stronger challenges are caused by an increase in the amount of secreting microglia cells. Though studies in that field of research are sparse, a single study demonstrated a similar effect in mouse fibroblasts (Tay et al., 2010). There, single cell analysis of TNF α induced activation revealed that higher doses activate more cells than lower ones which supports the here demonstrated correlation. The authors were even able to develop a stochastic mathematical model which reproduces the demonstrated dynamics quite precisely. As microglia subpopulations behave similarly, it is likely that their dynamics can be fitted to a model as well, which would be a big step forward in understanding how this biological system operates.

Though I demonstrated a correlation between microglia subpopulation sizes and cytokine secretion, calculation of the cytokine secretion per cell revealed an increase as well, which seems to be cytokine- as well as stimuli-dependent. While the TNF α secretion per cell increased with increasing stimuli concentrations, the RANTES secretion rate altered upon LPS stimulation only. Interestingly, these findings are in line with macrophage research, showing that the transcription factor Gli-3 is expressed by a subpopulation of macrophages only (Ravasi et al., 2002). This

subpopulation as well as the expression level per cell increased significantly upon LPS stimulation. Even though, these experiments were performed on mRNA and not on protein level, they endorse the previously described results.

In conclusion, the relationship between the subpopulation size and stimuli strength might be uniform while the cytokine secretion per cell is cytokine as well as stimuli specific. Thus, a general conclusion answering the initial question if an increase in the amount of cytokines is caused by an increase in secreting cells and/ or an increase in secretion per cell cannot be made. It is possible that there is just an increase in the number of microglia but it is also possible that there is an additional increase in the amount of secretion per cell. These results highlight the complex organization behind microglia subpopulations which seems to be stimulus as well as cytokine dependent. Of course, it cannot be excluded that there are also subpopulations that vary just in the secreted cytokine amount per cell, but to elucidate this additional research on other subpopulations is needed. Though, the results imply that microglia subpopulations are very plastic which would exclude the small possibility that microglia subsets are arising during a late step in development after tissue invasion. Of course, this origin would make it quite easy to identify subsets and subset-specific properties which could be targeted by a drug, but reality seems to be more complicated.

4.2 Microglia subpopulation sizes and behavior are density dependent

Different brain regions are known to vary highly in their microglia numbers, which was demonstrated for mice as well as for humans (Lawson et al., 1990; Mittelbronn et al., 2001). Microglia numbers differ from 5 % to 12 % of all cells in the murine brain and from 0.5 % to 16 % in human. The distinct brain regions are known to display highly diverse characteristics, ranging from microglial gene expression profiles to receptor abundance (Crain and Watters, 2015; Grabert et al., 2016). Important factors that play a role in shaping these interregional differences, thereby affecting the microglia, are the microenvironment and the expression of immunoregulatory markers (de Haas et al., 2008; Ren et al., 1999; Schmid et al., 2009; Smith et al., 2013; Wu et al., 1997). Whether the density of microglia by itself contributes to this variation is yet unknown. Though there is evidence for a density dependent effect of microglia, as differences in their abundance affect LPS-induced neurotoxicity of neurons in vitro (Kim et al., 2000).

Thus, I hypothesized that microglia densities play a role in shaping microglia subpopulations as well. By investigating the TNF α - and RANTES- producing microglia subpopulation sizes in microglia of increasing densities, I demonstrated a negative correlation between subpopulation size and density upon LPS, MALP-2 or Pam₃CSK₄ stimulation.

I assumed that this dampening in microglia subpopulation size increase might be caused by a self-regulatory mechanism, preventing the microglia from TNF α overproduction. However, analysis revealed a positive correlation between density and secretion per cell as well. It can thus be concluded that denser microglia have a smaller proportion of TNF α producing cells, though, with a significantly higher relative TNF α production. As a result, denser microglia populations produce significantly more TNF α than populations of lower density when facing an equal threat. The potential inflammatory consequences of this phenomenon are intense as a shift in cell density by a factor of 3 might result in a fourfold higher cytokine concentration.

The relationship between microglia abundance and cytokine secretion, which likely applies for cytokines in general, has therefore a very strong impact on the force of the immune reaction, which appears to be more aggressive in higher densities. As microglia densities vary within

brain regions, it could be hypothesized that the different susceptibilities to an immune challenge between the regions are caused by this density dependent intensity of the immune reaction. This hypothesis would fit to an observation made by Kim et al. (2000) as they described an increased LPS-induced neurotoxicity for increasing microglia:neuron ratios. An overproduction of cytokines is at certain concentrations toxic to neurons. The correlation between the microglia abundance and the increase in TNF α secretion might be a reasonable explanation. This hypothesis is supported by the fact, that microglia expand their number during chronic neurodegenerative disease progression, which is linked to an increased neuronal degeneration (Gómez-Nicola et al., 2013).

Interestingly, the described density dependence had no effect on the relative increase of the subpopulation size, which was similar between all tested densities. This observation would fit to a hypothesis made by Ravasi and Hume, who claimed that macrophage heterogeneity arises from transcriptional probability (Ravasi et al., 2002). Each gene would thus have a specific activation probability which rises upon challenges like LPS stimulation. Assuming that this hypothesis applies for microglia as well the uniform increase in subpopulation sizes regarding different cell densities might be caused by a static expression probability of the TNF α gene, regardless of the relative cell abundance.

It can thus be concluded that the microglia density has a huge effect on shaping microglia subpopulations in size and effect intensity, though not on the stimuli induced progression, which instead might be organized in a probabilistic manner. The blockage of microglia expansion could serve as a useful therapeutic approach, by limiting the microglia density, thereby delaying disease progression. Indeed, pharmacological treatment which inhibits microglial proliferation was just recently shown to prevent the progression of Alzheimer's-like pathology in mice (Olmos-Alonso et al., 2016).

4.3 Microglia subpopulations are highly complex organized

Microglia perform a whole set of different functions. Recent research could demonstrate that they are organized in functional subpopulations to achieve this diversity (Marshall et al., 2014; Venkatesan et al., 2010). As demonstrated here and elsewhere, secretion of cytokines is performed by microglia subsets as well (Scheffel et al., 2012). However, how the secretion of multiple cytokines is organized is largely unknown. Only a single study gave evidence that TNF α and interleukin 1 beta are produced by largely non-overlapping microglia subpopulations after ischemic stroke in mice (Clausen et al., 2008). However, no further research addressing this topic has been conducted ever since. Thus and to gain further insight into that topic, I investigated the organization of TNF α and RANTES secreting subpopulations. Since both substances can be secreted by more than half of the microglia population, I hypothesized that specific subpopulations are likely to overlap. Analysis of unstimulated and LPS stimulated microglia subpopulations showed that, indeed, a microglia subset producing both TNF α and RANTES simultaneously exists. Cytokine-specific microglia were present as well, though behaved rather heterogeneous in response to a challenge, indicating an organization of those cells in even further subsets. While the proportion of TNF α positive and double positive microglia rose significantly upon stimulation, the RANTES positive population remained stable. Thus, it appears that there exists a more general microglia population, able to produce multiple cytokines and to adapt their size in response to challenges. In addition, there are more specialized subpopulations producing one cytokine only. Those subpopulations can, depending on the cytokine they produce, also adapt their size.

This complex organization of microglia subpopulations was also demonstrated by other studies in regard to receptor expression. Investigation of microglial CXCR4 and CXCR7 receptors revealed a subpopulation of 55 % which co-expressed those receptors and subpopulations of 20 % and 6 % expressing only CXCR4 or CXCR7 respectively (Lipfert et al., 2013). Consecutive application of galanin, somatostatin and angiotensin II to neonatal mouse microglia resulted in microglia subsets of 31 % responding to one stimulus, 8 % to two stimuli and 2 % that responded to all stimuli (Pannell et al., 2014b). They could also demonstrate a large number of microglia

subpopulations expressing different subsets of neurotransmitter receptors leading to a huge diversity in their sensitivity.

In summary, cytokine secreting microglia subpopulations are composed of different subpopulations producing different cytokines or combinations, leading to heterogeneity within heterogeneity, finally resulting into an almost infinite organization complexity. My data support the possibility for transcriptional probability dependent heterogeneity. If LPS increases the possibility of certain genes to be expressed in each cell, a random landscape of microglia heterogeneity would emerge with each cell expressing different sets of genes. Giving our current knowledge on microglia heterogeneity, this complexity, however, makes a targeted drug development rather difficult, as specific cytokines are not exclusively produced by specific subsets but a combination of them. Investigating heterogeneity in microglia even further, identifying the whole variety within the “microgliome” is thus of utmost importance for future research.

4.4 Microglia are multitasking capable as they perform cytokine secretion and proliferation simultaneously

So far, the capability of microglia to perform various different functions was termed multitasking (Casano and Peri, 2015). Multitasking, however, would indicate that microglia are able to perform several functions simultaneously, a feature which was not demonstrated for microglia so far, as most of the investigations were performed via bulk measurement. Investigation of microglia on single-cell level would be necessary to validate or disprove their multitasking abilities. Thus, I decided to investigate this issue by addressing proliferating microglia. As proliferation is one of the cells' most important and thus tightly controlled functions, it would be of great interest to know whether dividing microglia perform other tasks besides proliferation itself simultaneously. Therefore, I examined whether microglia are able to perform proliferation and TNF α secretion upon a challenge with LPS at once.

The effect of LPS on microglia proliferation is controversially issued in the literature. Microglia proliferation was shown to be either unaffected, increased, decreased or even both upon LPS stimulation, depending on the brain region (Chen et al., 2012; Fukushima et al., 2015; Gebicke-Haerter et al., 1989; George et al., 2015).

To gain further insight on this debate, I investigated the effect of LPS on microglia proliferation beforehand. The obtained results showed a reduction in the proliferation rate of microglia upon LPS stimulation, which confirms the findings of Gebicke-Haerter et al. (1989). This reduction, which was observed for immune challenges with Pam₃CSK₄ and fibronectin as well, might be initiated to prevent an excessive immune response caused by higher microglia densities. As microglia proliferation increases in chronic neurodegenerative diseases, this preventive mechanism is likely to become disrupted in those disorders.

Next, I investigated un- and LPS stimulated microglia for TNF α -secreting and proliferating subpopulations. Analysis revealed that microglia are able to perform both tasks simultaneously. Again, subpopulations positive for just one of the investigated functions were discovered as well. LPS stimulation lead, as expected, to an increase of the TNF α producing subpopulation.

The subpopulations positive for both functions or proliferation only were not affected significantly. However, the previously observed reduction in microglia proliferation upon stimulation was confirmed in this approach as well.

Thus, it can be concluded that microglia are indeed capable of multitasking as some cells can proliferate and secrete cytokines at once. This capability might be a general feature, allowing the conduction of all possible functions simultaneously with at least a second one. This organization again supports the hypothesis that heterogeneity arises from transcriptional probability.

4.5 Microglia subpopulation size is influenced by environmental cues

As microglia subpopulation sizes are dependent on the microglia density, the question arises how this effect is mediated. Since microglia have mostly non-overlapping territories a contact-dependent organization is doubtful, leaving a substance-dependent organization as a possible alternative (Parkhurst and Gan, 2010). Since microglia functions are demonstrated to be influenced by the microenvironment, this explanation would be quite likely (Schmid et al., 2009; Wu et al., 1997).

Therefore, I hypothesized that microglia subpopulations are organized by one or more substances that are secreted by denser microglia in a heterogeneous manner. To proof this, I performed an insert experiment exposing microglia to supernatants from different microglia densities upon LPS stimulation. Unfortunately though, this method was not able to demonstrate any effect on the TNF α -producing microglia subpopulation size. Further research demonstrated that not all substances can pass through the insert membrane unhindered. Therefore, a more adequate experimental approach was needed for testing a supernatant induced effect.

To mimic a more accurate microenvironment, I thus performed a supernatant transfer experiment. Microglia, which were incubated with supernatants of increasing microglia densities, showed no density dependent differences in the TNF α - and RANTES-producing microglia subpopulation sizes. LPS stimulation which followed this supernatant transfer showed a similar outcome. These results indicate that the supernatant of unstimulated microglia has no effect, independent of the microglia density, suggesting a similar composition of the substances within the supernatants.

Microglia supplemented with supernatants of LPS stimulated microglia of increasing densities showed a reduced proportion of TNF α producing cells compared to microglia that were directly LPS stimulated. Thereby, the subpopulation sizes were independent from the density, presumably as the concentrations of signaling molecules already reached saturation. This effect was absent in RANTES-producing microglia, indicating a cytokine-specific regulation of subpopulations.

This regulation is likely caused by an immune challenge and is not necessarily defined beforehand. However, further studies investigating a time course of regulatory signals are necessary to unravel a differential effect by microenvironment compositions and to clarify the underlying mechanisms.

4.6 Organization of microglia subpopulation sizes is partially self-regulated

The demonstrated impact of the microenvironment on microglial subpopulations gave rise to new questions on the exact factors modulating this effect. Signaling of certain cytokines like IL6 leads to the suppression of its own production and/ or the production of other cytokines (Greenhalgh and Hilton, 2001). I hypothesized that cytokine signaling not only encompasses this negative feedback loop but also has an effect on the cytokine secreting subpopulation sizes.

To investigate this possibility, I examined the effect of TNF α on its own secretion and the secretion of other cytokines, namely IL6, IL12-p40, KC, RANTES, MIP1 α and MCP-1 induced by LPS exposure.

The analysis revealed a striking difference between cytokine levels of LPS stimulated microglia and LPS stimulated microglia that were pre-stimulated with TNF α for more than 6 hours. The pre-incubation caused a marked reduction in IL6-, IL12-p40-, KC-, RANTES- and TNF α secretion, while the secretion of MIP1 α was upregulated and the secretion of MCP-1 unaffected. As higher doses of TNF α were shown to induce increased productions of TNF α and IL6, suggesting a positive feedback loop, these results are quite contradicting (Kuno et al., 2005). One possible explanation might be the difference in initial TNF α concentrations and LPS stimulation, highlighting a dynamic self-regulation by TNF α rather than an unidirectional feedback loop.

Similar experiments using different cytokines were not able to induce a similar significant outcome. While RANTES had no effect at all, MCP-1 had just minor, non-stable effects on some cytokines. MIP1 α elicited an increased release of RANTES, TNF α and its own, though, the differences were marginal compared to the previously described TNF α pre-incubation.

This outcome indicates that some cytokines like TNF α have a special status as they are able to effectively regulate the secretion of other cytokines. Correspondingly, microglia activation upon LPS is partially mediated by the microglia-derived TNF α and in liver cells, TNF α regulates chemokine induction after infection with mycobacterium tuberculosis (Kuno et al., 2005; Roach et al., 2002). No evidence is given by the literature for regulatory effects of RANTES, MCP-1 or

MIP1 α on cytokine secretion, underlining the special status of TNF α .

Based on these results, TNF α seemed to be the most promising cytokine that could affect the cytokine secreting subpopulation size. Even though, the differences elicited by TNF α pre-incubation on the cytokine release could not be observed on mRNA level, a slight reduction in the TNF α producing subpopulation size was present at a pre-incubation time of 24 hours. The RANTES-producing subpopulation size was not affected by the pre-incubation. The quantitative difference between the secreted cytokines and subpopulation size regarding TNF α pre-incubation might be a consequence from a differential duration of LPS stimulation.

Nevertheless, a small effect of TNF α on the TNF α -producing microglia subpopulation size was demonstrated, indicating a self-regulating property of TNF α . This regulatory effect can likely be expanded to other cytokines as well as it is indicated by the ELISA data. To confirm this, further research is needed.

This self-regulation might explain the density caused differences in the TNF α -producing microglia subpopulation sizes. As microglia of a higher density produce much more TNF α than microglia of a lower density, the secreted TNF α could have a stronger effect on the microglia subpopulation size leading to a more pronounced reduction. Conclusively, the increased secretion would lead to a smaller subpopulation size in denser microglia than in less dense microglia which would fit to the observed density effect.

5. Summary and Conclusion

In this study, I investigated the functional heterogeneity of microglia using cytokine secretion as a hallmark for an immune response. I was able to show that not all microglia but mere subpopulations secrete cytokines upon an immune challenge. Thereby, increasing severity of the challenge correlated with the subpopulation size and the amount of the secreted cytokines. The immune response was strongly cytokine and stimuli dependent, indicating an enormous plasticity of the subsets. This plasticity was not only demonstrated regarding the population size but also the cytokine secretion per cell, which was cytokine specifically regulated as well. Furthermore, I identified the microglial density as an additional factor shaping microglia subpopulations in size and efficiency. An increase in microglia density lead to a lower proportion of subpopulations and simultaneously to a higher cytokine production per cell, which finally results in a much stronger immune response. Interestingly, cell density has no effect on the stimuli induced progression of the subpopulation size increase, which instead might be organized in a probabilistic manner. The general effect of microglia density on the subpopulation size is likely caused by an immune challenge and not necessarily defined beforehand. This effect is most probably conveyed via secreted substances, as I could identify TNF α as one of them. TNF α has a regulatory effect on its own secretion and the secretion of other cytokines, which affects the cytokine producing subpopulation size as well. As TNF α in most cases leads to a reduction of the cytokine secretion, it might be considered as a mechanism to resolve the immune response.

Additionally, I was able to demonstrate the complex organization of subpopulations and their ability to perform multitasking. Thus, microglia subsets perform a variety of functions that might partially be shared by different subpopulations. This organization was identified for similar functions like secretion of different cytokines but also for different functions like cytokine secretion and proliferation.

Altogether, I could demonstrate that microglia can be categorized in functional subpopulations, which can be adapted as a response to a challenge. This adaptation might be highly specific as it depends on function, stimuli and microenvironment. Additionally, function specific subpopulations are composed of even more specific “subsubpopulations”, which provides a small insight

into the high complexity and the infinite possibilities of microglia subsets. Further investigation of microglia heterogeneity to identify the whole variety within the “microgliome” is thus of utmost importance for future research.

7. Curriculum vitae

Ulla Gertig, née Haladyniak

date of birth December 02, 1988 in Burg

Education

- 10/2012 - 12/2016 Georg-August-University Göttingen
PhD in the graduate program "Molecular Medicine"
Constitutive heterogeneity and response diversity of microglia in pathological conditions
- 10/2010 - 09/2012 Georg-August-University Göttingen
M.Sc.: "Developmental, Neural, and Behavioral Biology"
Study focus: neurobiology
Effects of pharmacological inhibition of histone deacetylases in Drosophila olfactory memory (An age-dependent analysis)
- 10/2007 - 08/2010 Georg-August-University Göttingen
B.Sc.: Biology
The role of Igf2 signaling during the extinction of learned fear
- 08/2001 - 06/2007 Burger Roland-Gymnasium
Allgemeine Hochschulreife

Scientific experience

- 10/2012 - 12/2016 University Medical Center Göttingen
Institute of neuropathology
PhD student
- 03/2012 - 04/2012 Georg-August-University Göttingen
- 02/2011 - 03/2011 Institute for zoology and anthropology
- 04/2011 - 05/2011 Student assistant
- 02/2010 - 03/2010
