1 Introduction

1.1 Membrane trafficking

Compartmentalization into membrane-bound organelles is one of the fundamental principles of eucaryotic cells. Membrane boundaries distinguish eucaryotic organelles from each other. However, these organelles have to exchange proteins and lipids. Plasma membrane, early endosomes, late endosomes, recycling endosomes, lysosomes, Golgi apparatus, endoplasmatic reticulum communicate through membrane enclosed vesicles containing membrane impermeable cargo molecules. Membrane material is continuously in movement; it buds and fuses, transferring cargo from one cellular compartment to another. Transport vesicles are essential intermediates maintaining structural integrity and function of organelles.

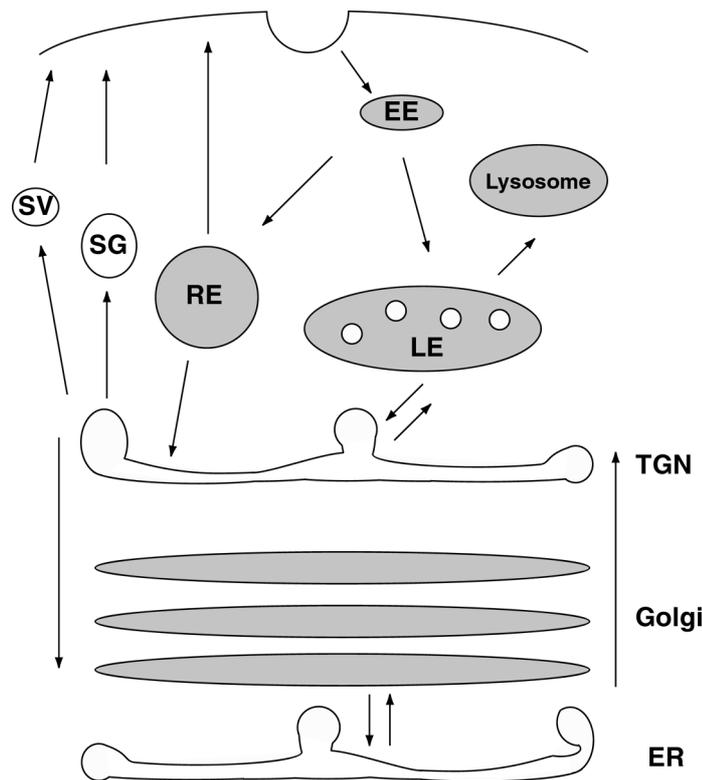

Figure 1: Schema of membrane trafficking pathways ER: endoplasmatic reticulum, TGN: trans-Golgi network, LE: late endosomes, EE: early endosomes, RE: recycling endosomes, SG: secretory granules, SV secretory vesicles

Several pathways can be distinguished in membrane trafficking. Proteins, which should be secreted from the cell and membrane proteins of the plasma membrane, are going through the secretory pathway (fig.1). During their synthesis on ribosomes these proteins are translocated into the endoplasmatic reticulum (ER) and glycosylated there. Such proteins will be moved via the Golgi to the trans Golgi network (TGN), where they receive further glycosylation. Sorting of proteins occurs in the TGN: they can be packaged for regulated secretion into secretory granules (SG) or into constitutive secretory vesicles (SV).

Lysosomal proteins are recognised in TGN and transported through late endosomes to lysosomes. Sorting signals for soluble lysosomal proteins are modifications with mannose-6-phosphate, which is recognised in the TGN by mannose-6-phosphate receptors, mainly MPR-46 (Kornfeld and Mellman 1989). The complex of lysosomal protein and mannose-6-phosphate receptor is transported to late endosome, where it dissociates. Mannose-6-phosphate receptor then is transported back to the TGN via specific interactions with the transport machinery.

The functional role of lysosomes is degradation of extracellular and intracellular material. Lysosomal enzymes are transported from late endosomes to lysosomes. Some lysosomal proteins fail to be transported to late endosomes. In this case they go through the secretory pathway to the plasma membrane, then are recaptured by another kind of mannose-6-phosphate receptor, MPR-300 and reach lysosomes via endocytosis. Sites for recognition and direction of membrane proteins to lysosomes are specific amino acid sequences in their cytoplasmic domains. Extracellular material reaches lysosomes through endocytosis via early endosomes (EE) and late endosomes (LE). Some of this material has to be returned back to the cell surface after being endocytosed. This takes place either directly from early endosomes or from recycling endosomes (RE). The best studied endocytic pathway involves clathrin, which forms coated membrane invaginations on the plasma membrane that recruit cell-surface receptors and then, through a series of highly regulated steps, pinch off to form clathrin-coated vesicles (Mukherjee et al. 1997; Kirchhausen 2000). Examples of receptor-mediated endocytic pathways are epidermal growth factor uptake mediated by its receptor EGF-R and asialoglycoprotein receptor (ASGR) mediated uptake of asialoglycoproteins. EGF-R is widely expressed by several cell types. The ASGR is galactose specific and plays an important role in endocytosis by hepatocytes. Clathrin

coated pit formation is impossible without adaptor complexes (APs). Adaptor complexes are important for clathrin binding to a membrane to build clathrin-cages and for cargo selection (Ahle and Ungewickell 1989; Robinson 1994). Until now four different APs were described. AP-1 is predominantly associated with the Golgi-apparatus and mediates sorting and transport of MPRs from the TGN to endosomes (Le_Borgne and Hoflack 1998; Molloy et al. 1999). AP-2 participates in internalisation of receptors from the cell surface (Schmid 1997). AP-3 is localised to the TGN and endosomes, its function is probably sorting of certain membrane proteins to lysosomes or related compartments like melanosomes. Mice lacking AP-3 complex subunits have pigmentation defects and storage pool deficiency (SPD). There are around 12 mouse mutants and several human diseases with similar phenotypes, which are probably all connected to that AP-3 dependent pathway. An example is the mouse *pearl* mutant, which is known to be a model for the rare case of Hermansky-Pudlak syndrome 2 (Huizing et al. 2000). AP-4 is associated with perinuclear compartments, possibly TGN. In experiments with MDCK cells AP-4 was shown to bind basolateral signals. This recent study connects its function to basolateral sorting in epithelial cells (Simmen et al. 2002). Less well characterised, but equally important, are non-clathrin endocytic pathways. These include phagocytosis, caveolae-mediated uptake, macropinocytosis and constitutive non-clathrin uptake. Phagocytosis is usually restricted to macrophages and other phagocytes that specialise in uptake and digestion of large particles. Other distinct non-clathrin pathways mediate the uptake of smaller cargoes. They utilise either caveolae, macropinosomes or a little-understood constitutive process of plasma membrane internalization. A diverse array of molecular machinery is involved, including caveolin, ARF6, dynamin, ankyrin/spectrin, actin (Nichols and Lippincott_Schwartz 2001).

Autophagosomes are characterised by double membranes enclosing intracellular material. They fuse with lysosomes. Autophagy is a complex cellular process that involves dynamic membrane rearrangements under a range of physiological conditions for example amino acid starvation. It is a highly regulated process that plays a role in cellular maintenance and development, and has been implicated in a number of genetic diseases. Upon induction of autophagy, cytoplasm and organelles are sequestered into vesicles and delivered to a degradative organelle, the lysosome in mammalian cells. The process is unique in that it converts topologically intracellular material into topologically extracellular. A trait

distinguishing autophagosomes from endocytic organelles is the almost complete lack of transmembrane proteins (Baba et al. 1995; Fengsrud et al. 2000). Autophagy is probably the main mechanism for degradation of long-lived proteins and the only mechanism for turnover of organelles including mitochondria and peroxisomes (Stromhaug and Klionsky 2001).

1.2 Molecular mechanisms of membrane transport

Membrane transport can be divided into different steps (see fig. 2) In the donor organelle special proteins are responsible for sorting of cargo proteins into certain areas of the membrane. Coat proteins are recruited via small GTPases of the Arf or Sar-family. They allow construction of transport vesicles (Bednarek et al. 1996; Hirst and Robinson 1998).

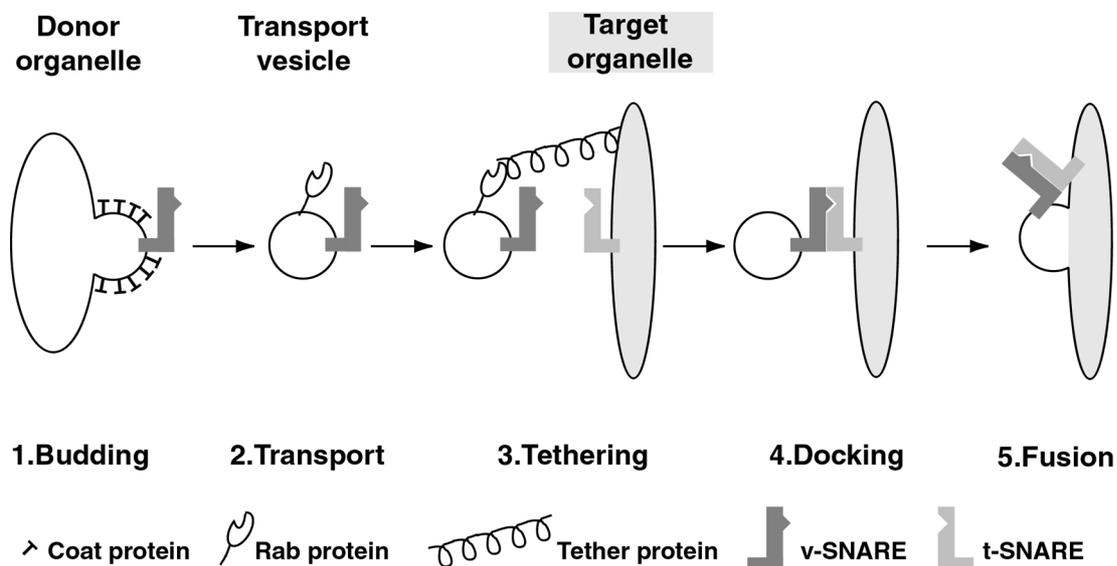

Figure 2: Schema of membrane transport through transport vesicles

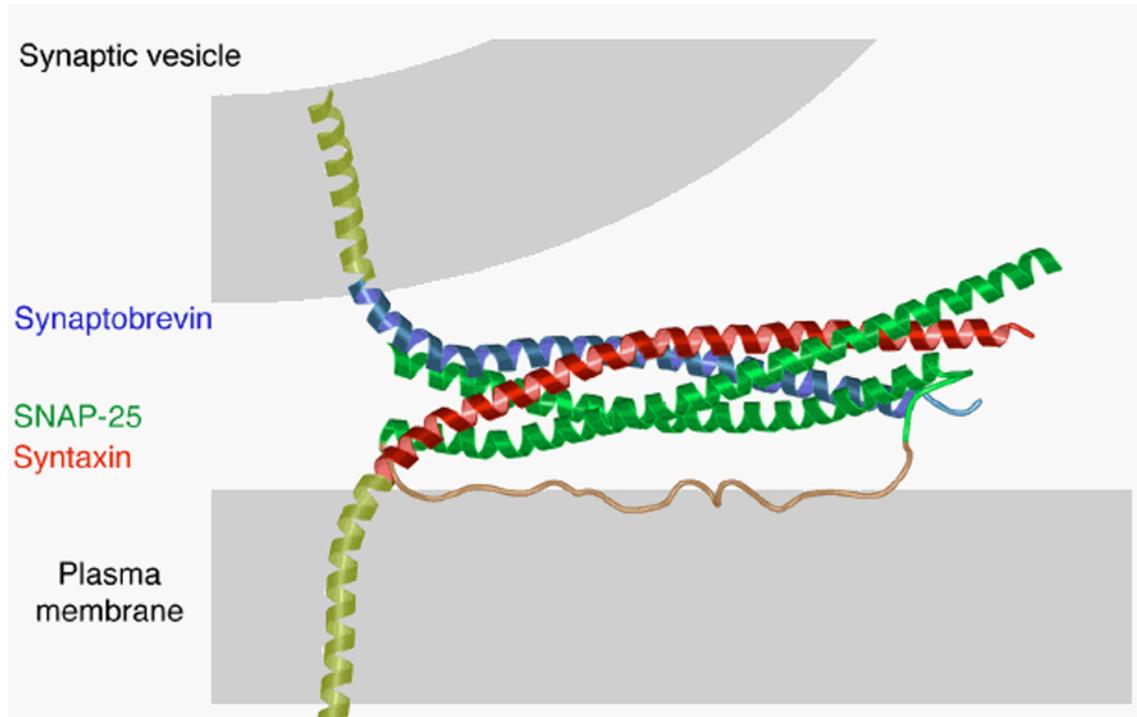

Depending on the donor organelle different proteins are responsible for construction of transport vesicles. These vesicles will then be transported to the acceptor organelle through interactions of cytoskeleton and motor proteins (Govindan et al. 1995). Vesicles need to be recognised specifically by the acceptor organelle. This is mediated by an interaction of tethering proteins on a surface of an acceptor organelle with Rab proteins on the vesicle leading to a loose tethering. After membranes became attached, fusion is initiated in a step that involves SNAREs on both transport vesicle (v-SNARE) and target membrane (t-SNARE) which assemble into a SNARE complex. Merging of both the proximal and the distal leaflets of the fusing membranes opens the fusion pore and

completes the fusion reaction. Finally, the fusion pore expands which is called fusion pore dilation (Jahn and Sudhof 1999). The specificity of membrane fusion is achieved by over 50 known rab-proteins and tethering proteins with specific membrane localisation (Martinez and Goud 1998). Tethering proteins form complexes with many subunits. Some of them can activate certain rab-proteins. It is thought that a signal arises due to the interaction of tether and Rab proteins which is then conducted to SNARE proteins (SNARE = SNAP receptor, SNAP = soluble NSF attachment protein, NSF = N-ethylmaleimide sensitive fusion protein). More than 40 known SNARE proteins have specific membrane localisation as well and thereby can contribute to specificity in membrane transport (Jahn and Sudhof 1999). NSF is an ATPase which dissociates SNARE complexes with the help of SNAP proteins after fusion allowing SNAREs to be transported to the donor organelle and to enter a new cycle of transport and fusion reaction (Grote et al. 2000).

1.3 SNARE proteins

Most SNARE proteins are attached to membranes through their C-terminal membrane anchor, a transmembrane domain or lipid modification. The SNARE superfamily is characterised by the presence of SNARE motif which is about 60 amino acid residues long (Jahn and Sudhof 1999). The SNARE motif is placed close to the membrane anchor and is responsible for SNARE-SNARE interactions and complex formations. SNARE proteins can contain one or two SNARE motifs. Criteria for the division of SNAREs into subfamilies are the sequences of the SNARE motifs. Up to now crystal structures of only two SNARE complexes have been solved. Well known now is the structure of the SNARE-complex, which takes part in fusion of synaptic vesicles with the plasma membrane. It is composed of the v-SNARE synaptobrevin 1 or synaptobrevin 2, which is localised on synaptic vesicles and the plasma membrane t-SNARE proteins syntaxin 1 and SNAP-25 (Sutton et al. 1998). The crystal structure was obtained from recombinant SNARE motifs without transmembrane domains and corresponds probably to the stage after fusion (cis-SNARE-complex). The crystal structure showed a parallel bundle of four α -helices formed by one helix of synaptobrevin 2, one of syntaxin 1 and two of SNAP-25 (fig.3a).

A

Sutton, Fasshauer, Jahn, Brunger (1998) Nature 395, 347-353

B

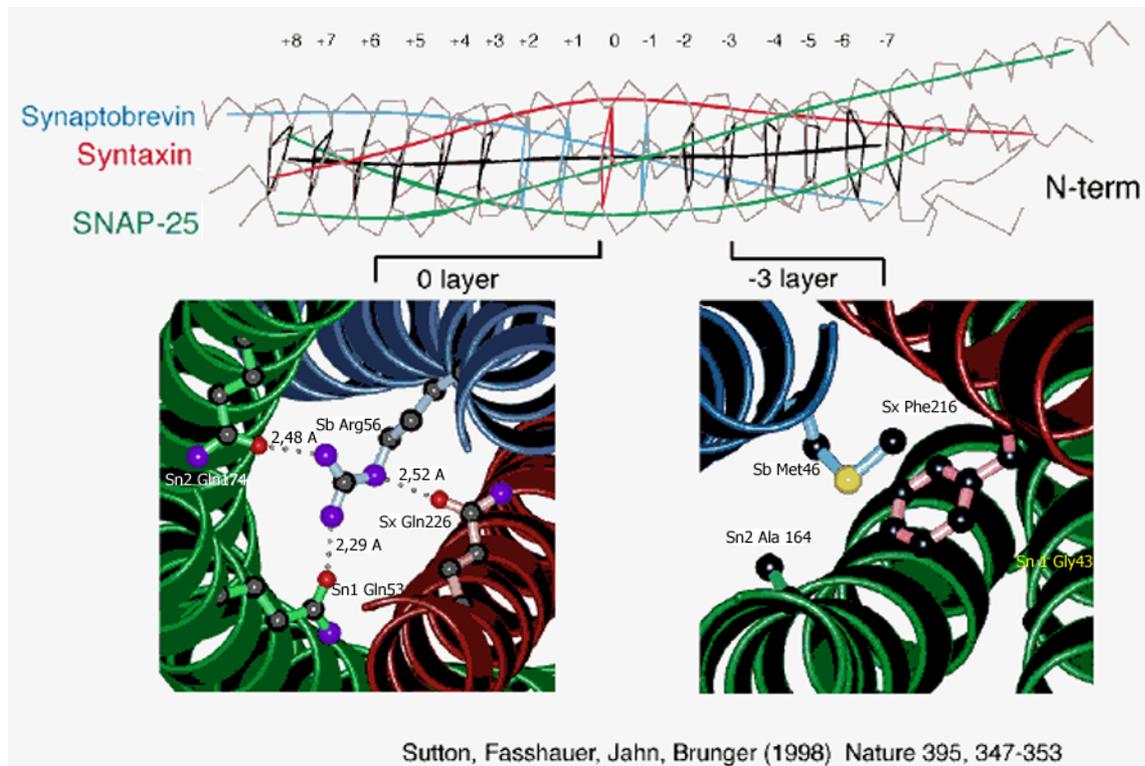

Figure 3: Modell of neuronal SNARE complex consisting of synaptobrevin, syntaxin, and SNAP-25 based on crystal structure

In the SNARE complex 16 layers can be identified, in which amino acid residues from all four helices are oriented into the inside of the bundle and interact with each other (Fig.3b). In the layers most amino acid residues are hydrophobic, but one arginine (R) residue of synaptobrevin interacts with three glutamine (Q) residues of other helices in the middle of the bundle, in the so called 0 layer. The surface of the synaptic fusion complex is highly grooved and possesses distinct hydrophilic, hydrophobic and charged regions. These characteristics may be important for membrane fusion and for the binding of regulatory factors affecting neurotransmission (Sutton et al. 1998). Amino acid residues predicted to form all 16 layers of the bundle are highly conserved in different SNAREs. The highest degree of conservation is found in the ionic 0 layer. The (-3) layer is highly asymmetric, composed of two big and two small amino acid residues, which are methionine in the R-SNARE synaptobrevin and phenylalanine in syntaxin 1, and glycine and alanine in SNAP-25. The -3 layer of other SNARE complexes is also composed of two big and two small amino acid residues. Both big amino acid residues are contributed by syntaxin 1- and synaptobrevin- related SNAREs, the small ones come from SNAP-25 homologues, to which a subgroup of syntaxins and Vti1 proteins belong. Mutations in these layers reduce complex stability and cause defects in membrane traffic even in distantly related SNAREs. When syntaxin 4 is modelled into the synaptic fusion complex as a replacement of syntaxin 1, no major steric clashes arise and the most variable amino acids localize to the outer surface of the complex. Therefore the main structural features of the neuronal complex are highly conserved during evolution (Fasshauer et al. 1998b). Very recently a crystal structure of the late endosomal fusion complex has been solved at a resolution of 1,9Å. Despite limited sequence homology, the helix alignment and the layer structure of the endosomal SNARE complex are remarkably similar to those of the neuronal complex (Antonin et al. 2002). More evidence supporting the four-helix bundle model is derived from other well characterised SNARE complex. Membrin, r-bet1, syntaxin5 and msec22b form a SNARE complex that operates in ER to Golgi transport in mammals and is equivalent to the yeast complex consisting of Bos1p, Bet1p, Sed5p and Sec22p (Xu et al. 2000). In contrast with the four-helix-bundle model of SNARE complexes, there are data supporting existence of pentameric SNARE complex (Ungermann et al. 1999). Five SNAREs Vam3p, Vam7p, Nyv1p, Vti1p and Ykt6p are required for vacuolar homotypic fusion and were coimmunoprecipitated. However, another group demonstrated that the five

vacuolar SNAREs can assemble into either of two alternative quaternary complexes, in which Nyv1p and Ykt6p competed for the same position. A pentameric complex was never detected (Fukuda et al. 2000).

1.4 Classification of SNARE proteins

In mammals more than 40 SNAREs were identified within the last years. Well known is the classification of SNAREs into v- and t- SNAREs, where v- stands for vesicular and t- for target membrane SNAREs. The division of SNAREs into only two groups according to localisation is problematic and does not allow to assign a functional role to each SNARE and to predict SNARE complexes. On one hand, there is no distinction between the membranes in homotypic fusion. On the other hand SNAREs are constantly transported with membranes and a single SNARE can be found in several membrane compartments. So localisation itself cannot determine in which transport step a certain SNARE protein functions and whether it is a v- or t- SNARE. There are sequence homologies between SNAREs supporting a new classification (Weimbs et al. 1998). The crystal structure of the neuronal complex gave a functional relevance for this novel classification of SNAREs. These proteins were divided into R- and Q- SNAREs on the basis of having an arginine or glutamine residue in the position predicted to form the 0 layer of the complex (Fasshauer et al. 1998a). In this case all t-SNAREs are Q-SNAREs, however v-SNAREs can be R- or Q-SNAREs. The conserved asymmetric -3 layer allows for further division of Q-SNAREs into syntaxin-related and SNAP-25 related Q-SNAREs: syntaxin 1 has here a big amino acid residue, phenylalanine, both SNAP-25 helices a small amino acid residues (glycine and alanine). Furthermore, a distinction can be made between SNAREs, more related to the N-terminal helix of SNAP-25 (SNAP-25N) and to the C-terminal helix of SNAP-25 (SNAP-25C).

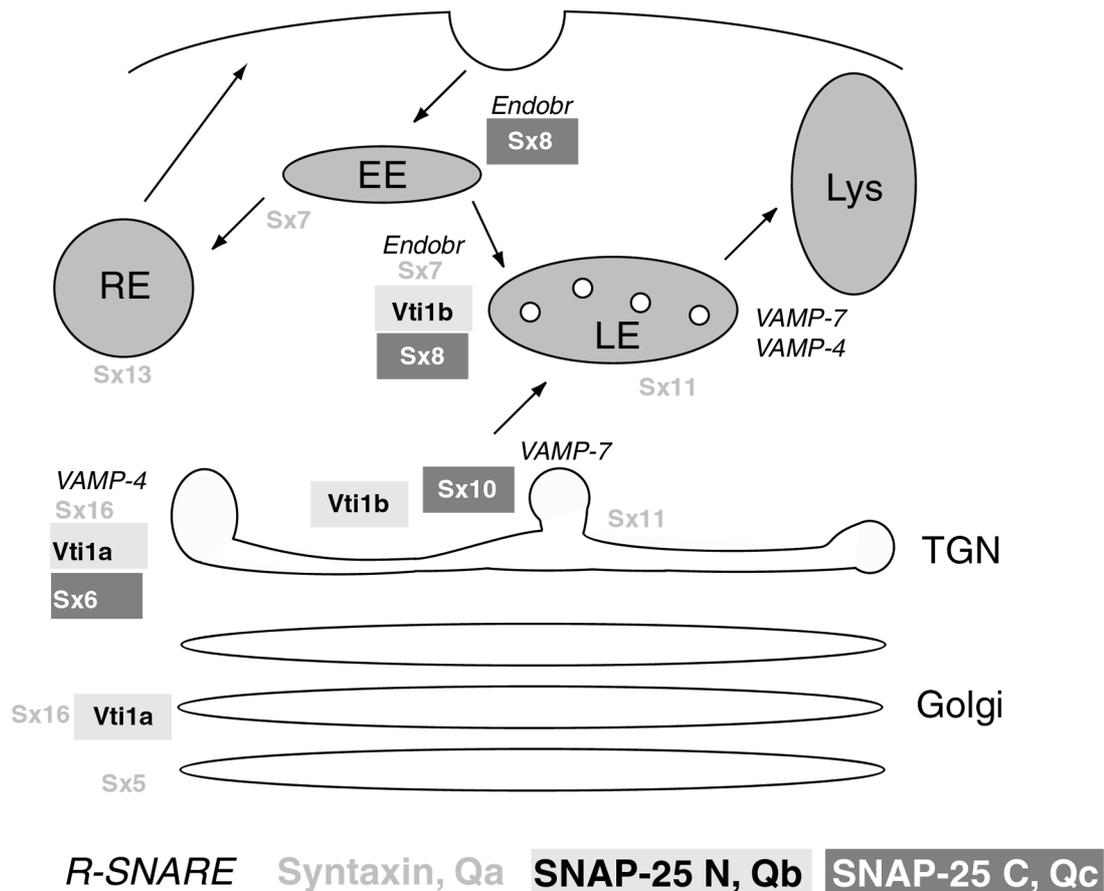

Figure 4: SNAREs of TGN and endosomal membrane system of mammals

This classification is consistent with a division of SNAREs into Qa, Qb, Qc -SNAREs and R-SNAREs (Bock et al. 2001). That classification was done using a genomic approach, where similarities and differences in primary amino acid sequences were examined within the SNARE superfamily. Syntaxin 7 and 16 for example were placed into the Qa group (syntaxins), Vti1 proteins into the Qb group (homologs of the N-terminal helix of SNAP-25) and syntaxin 6 and 8 into the Qc group (SNAP-25 C terminal helix homologs). VAMPs (4,5,7 and 8) are R-SNAREs. This reclassification is of great functional importance because it is predicted that each SNARE complex contains one helix of each of the four subgroups.

1.5 Subcellular distribution of SNAREs

SNARE proteins can be found on all intracellular compartments. Figure 4 shows the localisation of several SNAREs important for this work. As mentioned earlier, SNAREs are constantly moved from donor to acceptor compartment on the surface of transport

vesicles. After membrane fusion a SNARE protein should be recycled back to the donor compartment. Therefore localisation of a SNARE is not sufficient to predict its function (Jahn and Sudhof 1999). Endobrevin (VAMP 8) is localised to early and late endosomes (Antonin et al. 2000b). Syntaxin 8 is preferentially associated with early endosomes, indicated by its co-labelling with Rab5 according to one study (Subramaniam et al. 2000) and with the TGN in another one (Prekeris et al. 1999). Functional studies and electronic microscopy data show syntaxin 7 localisation to late endosomes (Mullock et al. 2000) and to the early endosomes (Prekeris et al. 1999). Electron microscopy and fluorescent confocal microscopy allowed the localisation of Vti1b to endosomal structures and the TGN (Kreykenbohm et al. 2002). These data are all coherent with *in vitro* studies of late endosomal fusion and solving of the crystal structure of the endosomal SNARE complex (endobrevin /syntaxin 7/syntaxin 8/ Vti1b) (Antonin et al. 2002). Vti1a is found predominantly in the Golgi and TGN and has therefore a localisation distinct from that of Vti1b (Kreykenbohm et al. 2002). A brain-specific splice variant of Vti1a, Vti1- β is localised to small synaptic vesicles (Antonin et al. 2000c). Mechanisms of sorting of SNARE proteins to certain compartments are still unknown. It is likely that adaptor complexes play a role. It is intriguing that VAMP-7 contains a potential adaptor protein binding motif, D/EXXXLL (aa 162-167), within the SNARE coil domain. Perhaps each of the SNAREs contains specific sequences that direct binding to particular adaptor proteins. The small number of amino acid residues that are so far defined to be important for adaptor binding interactions makes it difficult to understand their significance simply by inspection of amino acid sequences of the SNAREs (Advani et al. 1999). Only VAMP-4 and VAMP-7 contain recognizable di-leucine motifs, suggesting that alternative or additional motifs may regulate adaptor binding to SNARE or cargo molecules. Some experiments to clarify these issues were done recently. AP-1 specifically binds to VAMP-4, and this binding is dependent on the di-leucine motif of VAMP-4. Transfection of cells with VAMP-4 constructs lacking the di-leucine motif results in VAMP-4 mislocalisation. This shows that AP-1 and VAMP-4 interaction is required for proper sorting of VAMP-4 suggesting that other SNAREs may interact with adaptor complexes (Peden et al. 2001).

1.6 Function of SNAREs

A link between SNAREs and exocytosis was established by the discovery that botulinum and tetanus toxins – a group of eight related paralytic neurotoxins produced by *Clostridia* – block neuronal exocytosis by selectively proteolyzing individual SNARE proteins (Niemann et al. 1994; Montecucco and Schiavo 1995). Although the core complex itself is resistant to proteolysis, single SNAREs remain available to toxins and that prevents formation of new complexes and blocks membrane fusion in this way. Mutations in yeast SNAREs and in vitro transport assays confirmed that SNARE complexes are essential for fusion but not for membrane tethering (Mayer and Wickner 1997; Cao et al. 1998). Mutations affecting the core complex resulted in more or less severe loss-of-function phenotypes, supporting the key role of SNARE assembly in fusion (Jahn and Sudhof 1999). Nowadays, several steps in membrane fusion are distinguished: priming, tethering, docking, hemifusion (stalk formation), fusion pore formation, and fusion pore dilation. The “zipper” model of SNARE function in membrane fusion hypothesizes that SNARE proteins “zip” from their membrane distant amino terminal ends toward the membrane-proximal carboxy termini. SNARE complex assembly may drive the establishment of a hemifusion stalk (Jahn and Sudhof 1999). Once the amino termini have found each other, they may partially zip together, probably establishing a stalk-like membrane merger that reflects the fusion of proximal, but continuity of distal, leaflets resulting in hemifusion state (Zimmerberg and Chernomordik 1999; Lentz et al. 2000; Bruns and Jahn 2002). In viral fusion events hemifusion is viewed as a bona fide state that can progress to full merger of membranes (Razinkov et al. 1999; Melikyan et al. 2000). Since a lot of SNAREs are already known and their localisation is specific, there are assumptions about their role in specificity of membrane transport. This complex problem now is a subject of discussion for several research groups. Liposome-based *in-vitro* fusion assay support the hypothesis that only cognate SNAREs can form a complex and that indeed plays a role in specificity of membrane trafficking (Fukuda et al. 2000; McNew et al. 2000; Parlati et al. 2000). The idea is that for example, the SNAREs on the ER-derived vesicle can form a complex only with those on the Golgi, ensuring specificity. Such SNAREs are said to be “cognate”. Cognate SNAREs belong to four families: A designates Q-SNARE syntaxin, B and C the Q-SNAREs of the SNAP-25 family, and D the R-SNARE of the VAMP family (Sutton et al. 1998; Yang et al. 1999). However in vitro SNARE complex assembly from purified

proteins showed that these four different types of helices are needed for complex formation but it did not matter from which SNARE protein these coils originated (Fasshauer et al. 1999; Yang et al. 1999). In contrast, another study showed that in cracked PC12 cells only cognate SNAREs when added in solution could compete with membrane-bound SNAREs. They inhibit vesicle fusion – with a couple of exceptions, non-cognate SNAREs in solution could not. It was then supposed that the information for SNARE pairing specificity is not completely determined by the ability to form stable complexes, but is probably determined through interactions with other proteins. Additional proteins may be required for formation of the core fusion complex *in vitro* and Rabs, rab effector proteins and sec1 family members are potential candidates for that (Scales et al. 2000). There are examples in which non-cognate A, B, C and D SNARE motifs result in fusion *in vitro*. With the plasma membrane A, B, and C helices, fusion can occur when any D helix with a transmembrane domain is used (McNew et al. 2000). So isolated SNAREs cannot solely account for the specificity observed in vesicle trafficking (Scales et al. 2000). Studies in yeast showed that the SNARE proteins Vti1p and Ykt6p can participate in three different transport steps. Functional data indicate that the R-SNARE Ykt6p together with the Q-SNARE Vti1p form three different SNARE complexes with the syntaxin-related Q-SNAREs Sed5p, Pep12p and Vam3p localised to the Golgi apparatus, the prevacuole and the vacuole respectively. Authors conclude that Ykt6p or Ykt6p and Vti1p on the transport vesicle are not sufficient to ensure specificity in membrane traffic (Dilcher et al. 2001). This would support participation of additional proteins in vesicular targeting (Fischer von Mollard et al. 1997; Lazar et al. 1997; Lupashin et al. 1997; Dilcher et al. 2001). It seems that the accuracy of vesicle targeting is safeguarded not through a single lock-and-key interaction between SNAREs, but rather through several layers of constraints – a situation common to many biological processes (Scales et al. 2000). The most fundamental question remains, namely whether SNARE proteins indeed operate in “zipper” mechanism as fusogenic motors or simply serve as workhorses to pull membranes together thus transferring them into a readily releasable state. Completion of fusion is then performed by an unknown downstream protein (Bruns and Jahn 2002). A very different point of view on the role of SNARE complex formation is suggested by Ungermann et al., 1998. Whereas in the “zipper” model of membrane fusion SNARE complex assembly is considered as driving force, these authors consider the transition from cis-SNARE complex to trans-SNARE

complex as only a transient state, which precedes fusion, and as a signal to downstream factors, which are the fusion machinery. In *in vitro* experiments on homotypic yeast vacuolar fusion it was shown that trans-SNARE complexes can be dissociated by excess Sec17(SNAP-homolog) and Sec18 (NSF-like ATPase). That had only a small effect on overall fusion, indicating that other factors may be required for the fusion reaction (Ungermann et al. 1998).

In the second class of hypotheses, the gap between the fusing membranes is bridged by a hypothetical protein complex whose opposite ends enter and/or span both bilayers. That model which is quite an old has an experimental backing. Several assumptions come from experiments on vacuolar fusion (Peters and Mayer 1998; Peters et al. 1999; Peters et al. 2001). A central point of this alternative mechanism of membrane fusion is the V-ATPase. The V-ATPase is a proton pump that acidifies various compartments. It can undergo regulated disassembly, shedding its peripheral V1 sector into the cytosol and silencing its ATPase activity (Kane and Parra 2000). The membrane integral V0 sector consists of several subunits and includes a multimeric (probably hexameric) cylinder of proteolipids – small tetraspanning membrane proteins. Purified reconstituted proteolipids can form Ca^{2+} -inducible pores, which can expand to mediate passage of even large ions such as acetylcholine (Dunant and Israel 1998). After vacuoles have docked and trans-SNARE complexes have formed, but before fusion has occurred, V0 sectors from apposed membranes form trans-complexes (Peters et al. 2001). These trans complexes do not contain V1 sectors and are strongly enriched in calmodulin and the vacuolar Q-SNARE Vam3. It appears that interaction with the Q-SNARE Vam3 and calmodulin might recruit a subset of V0 sectors for the formation of trans complexes during fusion (Mayer 2001). Supportive for this hypothesis is that V0 is present on all compartments of the secretory and endocytic pathways, including the plasma membrane (Harvey and Wieczorek 1997). Ca^{2+} and calmodulin, which binds V0, is also required for intra-Golgi transport and endosome fusion (Colombo et al. 1997; Porat and Elazar 2000). Endosome-lysosome fusion is Ca^{2+} dependent (Pryor et al. 2000). Two apposed V0 sectors might establish a continuous proteinaceous channel with a central pore between the two membranes. Radial opening of this pore could initiate fusion, whereas lateral separation of the subunits could create amphiphilic clefts that could be invaded by lipids and thereby initiating fusion pore formation. However, strong functional evidence for involvement of V0 sectors in the late

reaction stage remains to be established (Mayer 2001). Up to now it is not clear if one or another model of membrane fusion is true. It is possible that elements of the contradictory models are present in the real situation. Trans SNARE complex might initiate merging of the membrane leaflets and lipid transfer and only the completion of fusion pore formation or its expansion might be independent of trans-SNARE complexes. On this stage a pore-mediated fusion could act (Mayer 2001). It is also possible that there is no universal mechanism of membrane fusion and some reactions like exocytosis are mediated by trans-SNARE complexes machinery whereas vacuole fusion involves other mechanisms. There is novel evidence that vacuolar fusion is more complicated than vesicle exocytosis and may therefore require proteins after the action of SNAREs. Proteins involved in docking and fusion accumulate as a vertex ring in large contact zones between vacuoles. Membrane fusion is then coordinated around the vertex ring and needs vacuolar transporter chaperone complex (VTC) and Vac8p protein. Several fusion pores connect and leave an internal membrane which is located inside of fused vacuoles (Wickner 2002).

1.7 Vti1 proteins

1.7.1 Yeast Vti1p

Yeast Vti1p has been discovered in a 2-hybrid screen as a binding partner of the cytoplasmic domain of the CPY-receptor Vps10p but the relevance of this interaction is unclear. Vti1p has 217 amino acids, a C-terminal transmembrane domain and a luminal tail of four amino acids. The SNARE motif with a glutamine in the 0 layer is placed next to the transmembrane domain. Accordingly to its sequence homology Vti1p belongs to Q-SNAREs related to the N-terminal helix of SNAP-25. Vti1p is localised to the Golgi apparatus and endosomes using immunofluorescence microscopy and subcellular fractionation. *VTI1* is an essential gene; its deletion is lethal (Fischer von Mollard et al. 1997; Fischer von Mollard and Stevens 1999). Functional studies revealed the importance of Vti1p in several transport steps in yeast cells: from the Golgi to late endosomes, retrograde transport to the cis-Golgi; biosynthetic transport to the vacuole, the equivalent of mammalian lysosome; homotypic vacuolar fusion (fig.5) and TGN homotypic fusion. Thus Vti1p is a part of four distinct SNARE complexes.

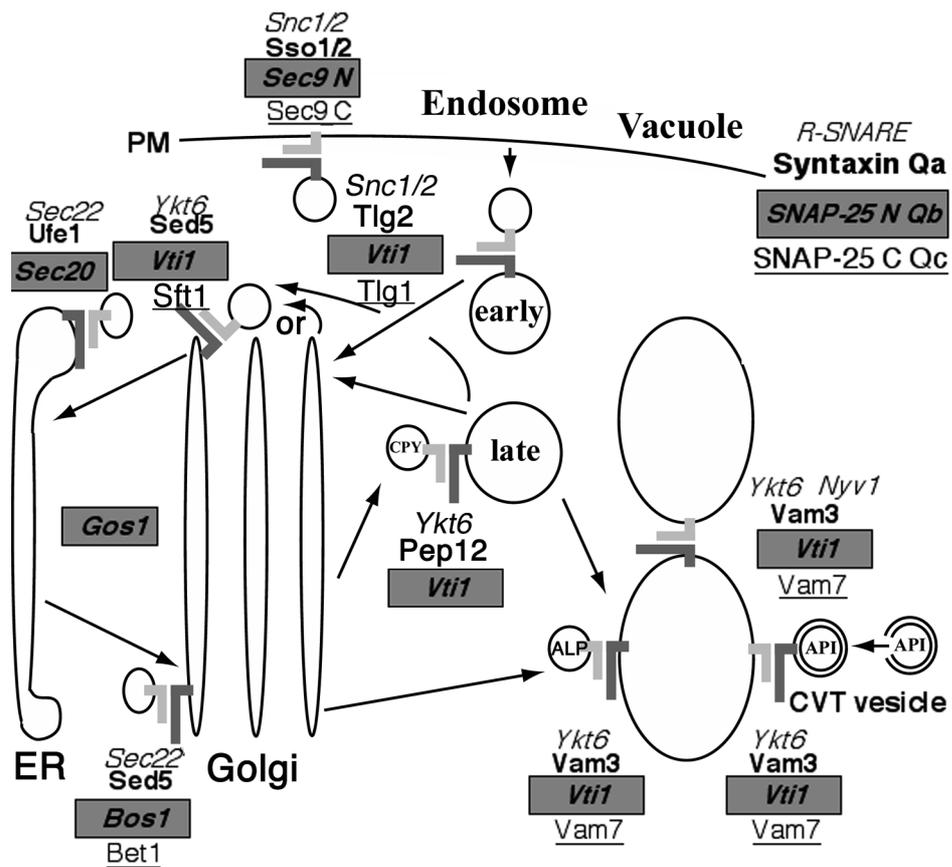

Figure 5: Transport pathways and SNARE complexes in yeast cells

1.7.2 Vti1 homologs

Database searches show homologs of Vti1p in model organisms such as *Arabidopsis*, *C.elegans*, and *Drosophila*. Mammals have two homologs of Vti1p, Vti1a (27kDa) and Vti1b (29kDa). Vti1p has 33% amino acid identity with Vti1a and 27% with Vti1b. Mouse Vti1a and Vti1b share only 30% amino acid identity, indicating that they are very divergent proteins. In brain a splice form of Vti1a, Vti1a- β was found (Antonin et al. 2000c). In contrast to other Q-SNAREs and all other Vti1 proteins mouse and rat Vti1a have an aspartate in place of the highly conserved glutamine. An aspartate residue should be able to make strong ionic interaction with an arginine residue of the ionic 0-layer (Antonin et al. 2000c). Are Vti1a and Vti1b redundant proteins or did they evolve into more specialised proteins than their yeast homolog? In the second case Vti1a and Vti1b should have distinct localisation, SNARE partners and function.

1.7.2.1 Mammalian Vti1b

Vti1b has 233 amino acid residues. Preliminary studies on Vti1-rp1 (Vti1b) suggested that it is preferentially associated with the TGN and/or endosomal compartment (Xu et al. 1998) or with the Golgi and TGN (Advani et al. 1998). A recent study showed Vti1b localization to the perinuclear area with extension of the staining further into the periphery of the cell. Little overlap was observed with the Golgi marker protein giantin. Also localization of Vti1b was unchanged after brefeldin A treatment. Vti1b was localized to early endosomes, multivesicular late endosomes, and tubules and vesicles not connected with the TGN by immuno electron microscopy. The study clearly shows distinct localisations of Vti1b and Vti1a (Kreykenbohm et al. 2002). hVti1b could functionally substitute for yeast v-SNARE Vti1p in two vesicle transport pathways in retrograde traffic to the cis-Golgi and in traffic from the Golgi via the late endosome to the vacuole (Fischer von Mollard and Stevens 1998). Vti1b is a member of a SNARE complex mediating fusion of late endosomes in vitro. In addition to Vti1b, the complex consists of syntaxin 7, syntaxin 8, and endobrevin/VAMP-8. Antibodies against each member of the complex inhibit late endosomal fusion in vitro and retard delivery of epidermal growth factor to lysosomes in vivo. By contrast, fusion of early endosomes was not inhibited by antibodies directed against Vti1b (Antonin et al. 2000a). Syntaxin 7 interacted with Vti1b and endobrevin in B16 melanoma cells (Wade et al. 2001). A coimmunoprecipitation of syntaxin 8 with Vti1b was also described by Subramaniam et al. (Subramaniam et al. 2000). A complex with the SNARE motifs of Vti1b, syntaxin 7, syntaxin 8 and endobrevin/VAMP-8 was recently crystallised and it was found that the structure is a four helix-bundle, very similar to the neuronal SNARE complex (Antonin et al. 2002). Vti1b takes the position of the N-terminal helix of SNAP-25, whereas syntaxin 8 is equivalent to the C-terminal helix of SNAP-25.

1.7.2.2 Mammalian Vti1a

The existence of a second mammalian Vti1p homologue first was discovered through database searches. The deduced amino acid sequence of Vti1-rp2 (Vti1a) has 217 residues with a COOH-terminal membrane anchor. Affinity purified antibodies raised against the cytoplasmic region of this protein specifically detect a 29-kilodalton integral membrane protein enriched in the Golgi membrane (Xu et al. 1998). By immunofluorescence and

immuno-electronmicroscopy Vti1a was localised to the Golgi and the TGN. (Kreykenbohm et al. 2002). Vti1a was coimmunoprecipitated with syntaxin 5 and syntaxin 6, but syntaxin 5 and syntaxin 6 were not part of the same complex, showing that Vti1a might be a member of two distinct SNARE complexes (Xu et al. 1998). Vti1a was coimmunoprecipitated with VAMP-4, syntaxin 6 and syntaxin 16 (Kreykenbohm et al. 2002). Vti1a, syntaxin 6, syntaxin 16 in a t-SNARE complex interacted with VAMP-4 or VAMP-3 in two different quaternary SNARE complexes (Mallard et al. 2002). Using a novel permeabilised cell system, it was shown that these complexes have a role in transport from early endosomes/recycling endosomes to the TGN. Antibodies directed against Vti1a inhibited fusion of early endosomes in vitro (Antonin et al. 2000a) as well as transport of VSV-G glycoprotein through the Golgi (Xu et al. 1998). Vti1a has a brain-specific splice form Vti1a- β , which is localised to small synaptic vesicles. Vti1a- β was enriched on small synaptic vesicles using subcellular fractionation. Vti1a- β has seven additional amino acids (LIKLR EE) directly N-terminal before the SNARE motif has in that can possibly play an important role for cellular distribution of that protein (Antonin et al. 2000c). Ultrathin cryosections obtained from mossy fiber synapses were stained with antibodies which recognise both Vti1a and Vti1a- β . Nerve terminals were mainly decorated with antibodies against Vti1a and protein A gold. Small synaptic vesicles stained with Vti1a antibodies are visible in presynaptic nerve terminals at higher resolution. VAMP-4, syntaxin 6 and syntaxin 16 coenriched with purified small synaptic vesicles. These data support the view that these four SNAREs form a complex that might be functional in the life cycle of synaptic vesicles (Kreykenbohm et al. 2002).

1.8 Targeted gene replacement as tool for studies of mammalian protein function

Mutants are the most important tools for assigning biological functions to genes. Targeted mutation can be generated in a selected cellular gene by inserting mutant copies of the gene into cells and screening for cells in which the mutant copy has taken place of the original, healthy gene on a chromosome by homologous recombination. Such altered cells are helping researchers to produce mice carrying specific genetic mutations. The currently available technologies for in vitro manipulation of mouse embryonic stem cells have opened up new areas in mammalian genetics. Mutations can be generated at will in defined

genes thought to be involved in any biological process, including those involved in human genetic diseases. A lot of examples can be named, where genetic “knock-out” in mice generated a model of severe human disease. Gene targeting technologies allow asking questions as to the in vivo functions of a specific gene in the context of the whole animal or its different cell types.

2 Aim of the work

An aim of this work was to isolate mouse genomic DNA for Vti1b and Vti1a, to characterise the chromosomal regions encoding Vti1b and Vti1a for targeted gene replacement and generation of null mutant mice to describe a role of mammalian Vti1b, a homolog of yeast Vti1p. Knockout mice have several important advantages compared to studies in vitro. The development of the organism can be analysed, defects in specific organs and cell types can be investigated. In case of success in Vti1b knock-out mice generation, special aims of this work were:

to describe phenotypic manifestation of Vti1b deficiency,

to study the role of Vti1b in membrane traffic,

to prove the proposed role of Vti1b in late endosomal fusion in vivo using endosomal tracer assays,

to study properties of Vti1b deficient cells and tissues using biochemical and cell biological methods,

to use Vti1b deficient cells as a tool for the identification of additional components of the fusion machinery.

A second general aim of this study was the deletion of mVti1a in mice. Vti1a deficiency in the whole organism can show the role of this protein in membrane traffic and define the function of its splice variant Vti1a- β in small synaptic vesicle biogenesis or recycling.

3 Materials and methods

3.1 Materials

3.1.1 Devices

Analytical balances type 1602 MP and M5P	Sartorius, Göttingen
Autoclave type Technoclav 50	Tecnomara, Zürich, Switzerland
Balances type 1264 MP and 1265	Sartorius, Göttingen
Chamber for agarose gel electrophoresis	Self-made, workshop of the institute
Chamber for polyacrylamide gel electrophoresis	Self-made, workshop of the institute
Centrifuges:	
Biofuge Fresco	Schütt, Göttingen
Cooling centrifuge, model J-21 C and J2-MC	Beckmann, München
Eppendorf centrifuges 5414 and 5415C	Schütt, Göttingen
Megafuge 1.0	Heraeus, Göttingen
Rotors for cooling centrifuge:	Beckmann, München
JA-10 rotor, till 17680 x g	
JA-20 rotor, till 48300 x g	
Laborfuge GL	Heraeus, Osterode
Ultracentrifuge TL-100	Beckmann, München
Rotor for TL-100: TLA-100.3, till 430000 x g	Beckmann, München
Electroporator 1000 Stratagene®	Cortland NY, USA
Film developer Curix 60, automatic	AGFA-Gevaert, Leverkusen
Flake ice machine	Ziegra, Isernhagen
Fluorescent spectrophotometer F1200	HITACHI, Tokyo, Japan
Freezer, -80C°	Colora Messtechnik, Lorch
Gel air dryer BioRad	Hercules, CA, USA
Gene Pulser™ and Capacitance extender (125-960 µF)	BioRad, München
Incubator type 2771	Heraeus, Osterode;Köttermann, Häningsen
Incubator, water surrounded, stable CO ₂ atmosphere	Forma Scientific, Marietta, USA
Laboratory “rugged” rotator	Self-made, workshop of the institute
Liquid nitrogen storage tank Biosafe Chronos	Messer Griesheim, Frankfurt/M.
Liquid scintillation counter model 1900TR	Packard, Frankfurt/M.
Luminescent image analyser LAS – 1000 CH	Fuji Film,
Microscopes:	
Axiovert 100 / CCD camera TILL Photonics	Zeiss, Oberkochen/Gräfelfing
Laser Scanning Microscope LSM 310	Zeiss, Oberkochen
ID 03 light microscope	Zeiss, Oberkochen
Microwave oven	Bosch, Stuttgart

Mortar and pestle	Schütt, Göttingen
Multichannel FinnpiPETTE® 50 -300 µl	Labsystems, Helsinki, Finland
Peristaltic pump P1	Pharmacia, Uppsala, Sweden
pH-meter CG 820	Schott, Göttingen
Phosphoimager, IPR1000	Fuji, Tokyo, Japan
Pipetman 20, 200, 1000µl	Gilson Medical Electronics, Villers-le-bel, France
Power supply Gibco BRL Electrophoresis	Gaitherburg, MD, USA
Platform rocker	Self-made, workshop of the institute
Semi-dry-blot-system	CTI GmbH, Idstein
Shaker incubator G 25	News Brunswick Sc., Edison/USA
Shaker waterbath GFL 1083	Köttermann, Häningsen
Spectrophotometer Uvikon 810	Kontron, Eching
Standard power pack P25 Biometra® Bio105 LVD	Biomed Analytic, Göttingen
Steri-kult-incubator, 3035/200	Forma Scientific, Marietta, USA
Sterile hood, A/B3 & SG 400	Baker Company, Inc., Stanford, USA
Surgical scissors; small, formed	Aesculap, Tuttlingen
Surgical scissors; small, straight	Aesculap, Tuttlingen
Thermocycler Master cycler gradient	Eppendorf, Hamburg
Thermocycler Gene Amp 9600	Perkin-Elmer Cetus, Norwalk, USA
Thermo mixer compact Eppendorf	Kottberg, Göttingen
Thermo printer	Intas, Göttingen
Thermostat 5320	Eppendorf, Hamburg
Transilluminator Modell IL-400-M	Bachofer, Reutlingen
Tweezers	Aesculap, Tuttlingen
Ultrasound-disintegrator Sonifier W-450	Branson Ultrasonic SA, Carouge- Geneve, USA
Ultra-Turrax T25	Janke&Kunkel, Staufen
Ultra low freezer -80°C	New Brunswick Scientific, USA
UV-hand lamp(312 nm and 254 nm)	Bachofer, Reutlingen
Video camera	Intas, Göttingen
Video printer	Intas, Göttingen
Vortex-Genie	Bender&Hobein AG, Zürich, Switzerland
Waterbath type HOR 7225	Köttermann, Häningsen

3.1.2 Materials

Catheter (for blood vessels) Jelco™	Criticon, Norderstedt
Cell culture flasks 25 and 75 cm ²	Greiner, Nürtingen
Cell culture pipettes for single use, 2 ml, 5 ml, 10 ml, 25 ml	Greiner, Nürtingen
Cell culture plates 35, 60, 100 and 150 mm Ø	Greiner, Nürtingen
Cellophane foil	Pütz-Folien, Taunusstein-Wehen

Centrifuge glass:	Nalgene, München
JA-10 polypropylene	
JA-20 polypropylene	
Corex®II centrifuge tubes 15ml	Corning Inc., NY, USA
Cryotubes 1,8 ml	Nunc, Wiesbaden
Disposable hypodermic needles for single use, Braun	Neoject, Gelnhausen
Glass beakers 25 ml, 50 ml, 100 ml, 250 ml, 1000 ml	Schott, Mainz
Glass fibres Assistent®	Schütt, Göttingen
Hybond-N™ filters	Amersham, Braunschweig
Hypodermic syringe for single use	Braun, Melsungen
Nitrocellulose blotting membranes 0,2µm	Sartorius, Göttingen
Parafilm®	American National Can™, Neenah, USA
Pasteur pipettes	Schütt, Göttingen
Pipette tips 10µl, 200µl, 1000µl	Sarstedt, Nümbrecht
Pipette tips filtered, sterile 10µl, 200µl / 1000µl M _β P™	Molecular Bioproducts inc., San Diego, USA / Eppendorf, Hamburg
Pipette tips Finntip 300µl	Labsystems, Helsinki, Finland
Polycarbonate centrifuge tubes for rotor TLA100.3	Beckmann, München
Polyvials®V	Zinsser Analytic, Frankfurt/M
PVDF blotting membranes	Roth, Karlsruhe
PVDF blotting membranes Westran®	Schleicher&Schuell, Dassel
Reaction tubes: 0,2 ml	Perkin-Elmer Cetus, Norwalk, USA
0,5 ml	
1,5 ml and 2,0 ml	Sarstedt, Braunschweig
Scalpels	Greiner, Nürtingen
Sephadex® G-50	Braun, Melsungen
Single use insulin syringe Omnican 40	Pharmacia, Uppsala, Sweden
Sterile filters 500 ml	Becton Dickinson, Heidelberg
Sterile filters Minisart NML, Ø 0,45µm and 0,2µm	Sarstedt, Braunschweig
Sterile tubes 10ml	Sartorius, Göttingen
Sterile tubes Falcon® 50ml	Greiner, Nürtingen
Tubes 5 ml, 75x13 mm Ø	Sarstedt, Braunschweig
Whatman GB0002 paper	Sarstedt, Braunschweig
Whatman GB0003 paper, extra thick	Sarstedt, Braunschweig
X-ray films, XAR-5	Schleicher&Schuell, Dassel Kodak, Stuttgart

3.1.3 Chemicals

If not otherwise indicated, chemicals of *per analysis* purity were purchased from following companies: Aldrich Chemical Company (Milwaukee, USA), Baker (Deventer, Netherlands), BioRad (München), Boeringer (Mannheim), Calbiochem (Frankfurt), Fluka

(Buchs, Switzerland), GIBCO/BRL (Eggenstein), Merck (Darmstadt), Pharmacia (Freiburg), Sigma (Deisenhofen), Serva (Heidelberg) and Roth (Karlsruhe).

Acetic acid	Merck
Acetone	Merck
Acetonitrile, HPLC	Baker
30% acrylamide / 0,8% bisacrylamide	Roth
Agar	Sigma
Agarose for electrophoresis	Roth
Ammonium acetate	Fluka
Bacto-tryptone	Difco
Bacto-yeast extract	Difco
Bromphenol blue	BioRad
Calcium chloride	Merck
Chloroform	Merck
DAKO® mounting media	Carpinteria, CA, USA
Dimethylsulfoxide (DMSO), ultra pure	Merck
Dithiotreitol (DTT), ultra pure	Serva
DL-lactate (disodium salt)	Sigma
Ethanol	Merck
Ethidiumbromide	Serva
Ethylendiamintetraacetic acid – disodium salt (EDTA)	Merck
FITC-dextran, MW=14000	Sigma
Formaldehyde (37%) solution	Merck
Formamide	Fluka
Glucose	Merck
Glycine	Roth
HEPES (N-2-Hydroxyethylpiperazine-N'-2-ethansulfon acid)	Serva
Liquid scintillation mix Lumasafe Plus	Packard Bioscience, Groningen, Netherlands
Magnesiumsulfate (MgSO ₄)	Merck
2-Mercaptoethanol (2-MSH)	Sigma
Methanol	Merck
Morpholinopropanesulfon acid (MOPS)	Serva
NZYDT powder	Difco
Paraform aldehyde	Sigma
Percoll®	Amersham Pharmacia
Ponceau S solution	Serva
Phenol	Fluka
Potassium chloride (KCl)	Merck
Rapid hyb buffer	Amersham
Sodium acetate (NaAc)	Merck
Sodium azide (NaN ₃)	Sigma
Sodium carbonate (Na ₂ CO ₃)	Merck
Sodium chloride (NaCl)	Roth

Sodium citrate	Merck
Sodium dodecylsulfate (SDS)	Sigma
Sodium hydrogen carbonate	Merck
Sodium hydroxide (NaOH)	Merck
Sodium pyruvate	Merck
Sucrose	Roth
TEMED N'N'N'N'Tetramethylethylenediamin	Sigma
Trichloroacetic acid (TCA)	Merck
Tris-(hydroxymethyl)-aminomethan (Tris)	Roth
Water, HPLC purity grade	Baker

3.1.4 Detergents

Nonidet – P40	Sigma, Deisenhofen
Saponin	Sigma, Deisenhofen
Triton X 100	Sigma, Deisenhofen
Tween 20	Sigma, Deisenhofen

3.1.5 Enzymes and nucleotides

Alkaline phosphatase type II: bacterial (from E.coli)	Boehringer, Deisenhofen
Proteinase K	Boehringer, Mannheim
Restriction endonucleases	New England Biolabs, Bad Schwalbach/ MPI Fermentas, St. Leon- Rot
RNAse A	Boehringer, Mannheim
T4 – DNA - ligase	New England Biolabs, Bad Schwalbach
Taq – DNA - polymerase	Pharmacia, Freiburg
Ultra pure dNTP set	Pharmacia, Freiburg

3.1.6 Kits for treating of DNA, RNA and proteins

HiSpeed™ Plasmid midi kit QIAGEN	Diagen, Hilden
Megaprime DNA labelling kit	Amersham, Braunschweig
QIAEX II gel extraction kit	Diagen, Hilden
QIAGEN Lambda maxi kit	Diagen, Hilden
QIAprep Spin™ miniprep kit	Diagen, Hilden
RNeasy® Protect mini kit	Diagen, Hilden
Super Signal® west pico chemiluminiscent substrate	PIERCE, Rockford, IL, USA

3.1.7 Proteins, protease inhibitors and protein standards

Albumin bovine Fr.V (BSA) standard grade	Serva, Heidelberg
Asialofetuin	Sigma, Deisenhofen
BODIPY®-LDL	Molecular probes, USA

EGF, murine	Calbiochem, Frankfurt
Gelatine, research grade	Serva, Heidelberg
Jodacetamide (JAA)	Serva, Heidelberg
Leupeptin	Sigma, Deisenhofen
Pansorbin – cells (heat – inactivated <i>Staphylococcus aureus</i> cells suspension)	Calbiochem, Frankfurt
Pepstatin A	Sigma, Deisenhofen
Phenylmethylsulfonylfluoride (PMSF)	Serva, Heidelberg
Prestained protein MW - standard	Calbiochem, Frankfurt

3.1.8 Antibodies

3.1.8.1 Primary antibodies

Antigen	Immunised species	Preparation	Reference
γ -adaptin	Mouse, monoclonal	Affinity purified (AP)	Transduction laboratories
Cathepsin D, murine	Rabbit, polyclonal KIIS3	Serum	(Pohlmann et al. 1995)
Lamp1, murine	Rat, monoclonal 1D4B	Hybridoma medium	Hybridoma Bank, Iowa, USA;(Kasper et al. 1996)
Lamp2, murine	Rat, monoclonal ABL93	Hybridoma medium	Hybridoma Bank, Iowa, USA;(Kasper et al. 1996)
LimpII, rat, luminal domane	Rabbit, polyclonal, Igp85	Serum	Tanaka, unpublished
MPR46, cytoplasmic domain	Rabbit, polyclonal	Affinity purified (AP)	(Klumperman et al. 1993)
mVti1a	Rabbit, polyclonal	Serum and affinity purified (AP)	(Antonin et al. 2000c)
mVti1b	Rabbit, polyclonal	Serum and affinity purified (AP)	(Antonin et al. 2000c)
SNAP - 29	Rabbit, polyclonal	Serum	(Antonin et al. 2000a)
Syntaxin 7	Rabbit, polyclonal	Serum	(Antonin et al. 2000a)
Syntaxin 8	Rabbit, polyclonal	Serum	(Antonin et al. 2000a)
Transferrin receptor, human	Mouse, monoclonal	Affinity purified (AP)	ZYMED
EGF-R	Rabbit, polyclonal	(AP)	Santa Cruz Biotech.
Adipophilin	Guinea pig, polyclonal	(AP)	PROGEN

3.1.8.2 Secondary antibodies

FITC – conjugated: goat anti mouse, goat anti rabbit, goat anti rat and goat anti guinea pig.

Texas Red conjugated: goat anti mouse, goat anti rabbit and goat anti rat. Cy2 – conjugated goat anti mouse and anti rabbit.

HRP – conjugated: goat anti mouse, goat anti rabbit, goat anti rat and goat anti guinea pig.

All these antibodies were purchased through Dianova, Hamburg.

3.1.9 Radioactive substances

α - [^{32}P] – dCTP, Redivue 3000 Ci/mmol	Amersham- Buchler, Braunschweig
L – [^{35}S] – methionine / cystein, aqueous solution 14 mCi/mmol	Amersham- Buchler, Braunschweig
L – [^{14}C] – valine, aqueous solution 263 mCi/mmol	Amersham- Buchler, Braunschweig
Na[^{125}I] in NaOH solution 105 mCi/ml	Amersham- Buchler, Braunschweig

3.1.10 Vectors and DNA standard

pBluescript SK ⁺	Stratagene
pCMV – SPORT2, containing mVt11b coding sequence	AA105524, ATCC, USA
pT7T3D – Pac, containing mVt11a coding sequence	AA16379, ATCC, USA
Phage λ - 2FixII DNA library of sv129 mouse type DNA ladder	A gift of Dr. Nils Brose Gibco/BRL, Eggenstein

3.1.11 Bacterial strains and embryonic stem cells

E-14 mouse embryonic stem cell line (type sv129 Ola)	Work group of Dr. K. Rajewsky, Köln (Hooper et al. 1987)

Geneticin G418 (Neomycin)	Gibco/BRL, Eggenstein
Kanamycin disulfate	Merck
Mitomycin C	Sigma
Penicillin/Streptomycin (100x) 10000U/10000µg per ml	Gibco/BRL, Eggenstein

3.1.13 Mouse strains

C57BL/6J female mice were used as surrogate mothers and for crossing with chimerical males (Source: BRL, Basel, Switzerland).

3.1.14 Frequently used buffers and stock solutions

50x TAE:	2M Tris-base 0,1M EDTA adjust pH 8,0 with acetic acid
TE:	10mM Tris/HCl pH 8,0 1mM EDTA
TBS:	150mM NaCl 50mM Tris/HCl pH 7,4
1M Tris/HCl	12,1g Tris – base were dissolved in 80 ml bidistilled H ₂ O, pH – value (7,4 ; 7,5 ; 8,0 ; 8,5 or 9,0) was adjusted and volume was enlarged till 100 ml
10% SDS:	100g Sodium dodecylsulfate were dissolved in 1000ml bidistilled H ₂ O at 65 ⁰ C
0,5M EDTA:	18,1g Disodiummethylenediaminetetraacetate x 2 H ₂ O were in 80 ml bidistilled H ₂ O upon addition of several drops of concentrated NaOH, pH 8,0 was adjusted with concentrated NaOH and volume enlarged till 100 ml
3M NaAc:	40,8 g Sodium acetate x 3 H ₂ O were dissolved in 80 ml H ₂ O, pH 5,2 was adjusted with ice acetic acid and volume enlarged till 100 ml
20 x SSC:	175,3 g NaCl 88,2 g Na – Citrate were dissolved in 800 ml H ₂ O, pH 7,0 was adjusted with concentrated HCl and volume enlarged till 1000 ml
10X PBS:	80 g NaCl 1,6 g Na ₂ HPO ₄ were dissolved in 800 ml bidistilled H ₂ O, pH 7,4 was adjusted and volume enlarged till 1000 ml
CI:	Chloroform and isoamylalcohol were mixed in proportion of 24:1

3.1.15 Media for cultivation of bacteria and phage λ

LB - medium:	10 g bactotrypton 5 g bacto yeast extract 5 g NaCl were dissolved in 800 ml bidistilled H ₂ O, pH 7,5 was adjusted and volume enlarged till 1000 ml, autoclaved
LB – medium for host bacteria	10 g bactotrypton 5 g bacto yeast extract 5 g NaCl were dissolved in 800 ml bidistilled H ₂ O, pH 7,5 was adjusted and volume enlarged till 1000 ml, autoclaved. The mixture was stored at 4 ⁰ C. MgSO ₄ x 7 H ₂ O solution sterile (till 10 mM) and x ml sterile Maltose solutions (till 0,2%) were added before use
LB – ampicillin and kanamycin agar plates:	For cultivation of bacterial transformants, the LB – medium was supplemented by agar (end concentration 1,5%) and then autoclaved. The liquid was chilled till approx. 50 ⁰ C and ampicillin or kanamycin was added (end concentration 200 µg/ml). The mixture was transferred into 10cm plates, cooled at RT and stored at 4 ⁰ C.
NZYDT agar plates:	21,1 g NZYDT powder 15 g agar were mixed in 1000 ml bidistilled H ₂ O and autoclaved. The mixture was transferred into 10cm and 15cm plates, cooled at RT and stored at 4 ⁰ C.
NZYDT top - agarose for NZYDT agar plates:	21,1 g NZYDT powder 7 g agarose for electrophoresis were mixed in 1000 ml bidistilled H ₂ O and autoclaved. The mixture was stored at 4 ⁰ C.
SM – buffer:	5,8 g NaCl 2 g MgSO ₄ x 7 H ₂ O 50 ml 1M Tris – HCl pH 7,5 were mixed in 1000 ml bidistilled H ₂ O and autoclaved, afterwards 5 ml 2% gelatine were added.

3.1.16 Media for eucaryotic cell culture and solutions for treating of these cells

Cryogenic conservation medium for ES cells	60% DMEM 20% FKS (Boehringer) 20% DMSO
Dulbeccos Modified Eagles Medium (DMEM)	Gibco BRL , Eggenstein
Electroporation buffer for ES cells	20mM HEPES pH 7,0 137mM NaCl

	0,7mM Na ₂ HPO ₄ 6mM glucose 0,1mM β-mercaptoethanol Sterile filtered and stored at – 20 ⁰ C
Fetal calf serum (FKS)	Gibco BRL , Eggenstein Boehringer, Mannheim
L – glutamine (200 mM)	Gibco BRL , Eggenstein
LIF – factor ESGRO™	Chemicon International, Inc., CA, USA
Medium for “DNA”- mouse embryonic stem cells (E – 14) culture	DMEM 15% FKS Gibco 2mM L – glutamine 100 U/ml Penicilline/Streptomycin 1x sodium pyruvate 1x non essential aminoacids 0,5ml β-mercaptoethanol 335µg/ml G 418
Medium for mouse embryonic fibroblasts (MEF) culture	DMEM 10% FKS Gibco BRL 2mM L – glutamine 100 U/ml Penicilline/Streptomycin
Medium for mouse embryonic stem cells (E – 14) culture	DMEM 15% FKS Boehringer 2mM L – glutamine 100 U/ml Penicilline/Streptomycin 1x sodium pyruvate 1x non essential aminoacids 0,5 ml β-mercaptoethanol 5 x 10 ⁵ Units LIF-factor
Non essential aminoacids (100x)	Gibco BRL , Eggenstein
PBS (for ES cell culture)	Gibco BRL , Eggenstein
PBS (for fibroblast cell culture)	150 mM NaCl 120 mM KCl 10 mM Na ₂ HPO ₄ /KH ₂ PO ₄ , pH 7,4 0, 002% (w/v) phenol red
Sodium pyruvate(100x)	Gibco BRL , Eggenstein
β-mercaptoethanol	35 µl diluted in 5 ml PBS were sterile filtered to obtain 1000x solution

Trypsin/EDTA solution	0,05% (w/v) trypsin 0,02% (w/v) EDTA in Puck's modified salt solution Gibco BRL , Eggenstein

3.2 Methods of molecular biology

3.2.1 Methods of DNA treatment

If not otherwise indicated, all following methods were taken from laboratory manual “Molecular cloning” of (Sambrook et al. 1989).

3.2.1.1 Precipitation of DNA with ethanol

A volume of DNA was determined and concentration of Na – Acetate was adjusted till 0,3 M , then 2 volumes of ethanol were added and mixed. The precipitation proceeds 20 minutes at -70°C , 10 minutes on dry ice or overnight at -20°C . DNA was pelleted for 10 minutes at $12000 \times g$, then washed in 70% ethanol and centrifuged again for 5 minutes. The DNA precipitate was dried on air for 5 – 15 minutes.

3.2.1.2 Phenol/chloroform/isoamylalcohol extraction of DNA

This is a standard method of treating DNA. An equal volume of Phenol/ chloroform/ isoamylalcohol (25/24/1 mixture) was added to DNA solution, shaken till emulsion was formed and centrifuged for 3-5 minutes. Upper phase was removed and kept for downstream preparations.

3.2.1.3 Determination of DNA concentration

A photometric estimation of DNA concentration was done at 260 nm in quartz cuvette against H_2O . One OD corresponds a concentration of 50 $\mu\text{g/ml}$ of double-stranded DNA and 31 $\mu\text{g/ml}$ of oligonucleotides.

3.2.1.4 Purification of DNA using Sephadex® G50

Sephadex® G50: 5g Sephadex G50 were mixed with 50 ml TE and autoclaved.

Gelfiltration through Sephadex G50 was done for removing of unbound radioactive nucleotides and salts from DNA labelled probes.

A blue pipette tip was plugged with siliconised glas fibres and filled with Sephadex suspension (ca. 1 ml). The tip was put in a 5 ml plastic tube and centrifuged in a 10ml cell culture tube for 2 minutes at 3000 rpm. A new portion of Sephadex was filled in the same

tip and centrifuged again. Eluates were thrown away. DNA probe (200 μ l) labelled by Ready Prime™ was transferred onto the Sephadex column and again centrifuged for 4 minutes at 3000 rpm. The flow-through was transferred in an eppendorf tube, the volume determined and incorporation of radioactive nucleotides in DNA probe was determined in a β -counter using Cerenkov coefficient (Berger 1984).

3.2.1.5 Restriction digestion of DNA with endonucleases

An activity of restriction endonucleases is estimated in units (U). One unit corresponds to an amount of enzyme, which is enough for digestion of 1 μ g of lambda phage DNA completely in one hour on all available sites. To be sure that restriction digestion proceed quantitatively, the amount of enzyme and the incubation time will be increased by factor of two.

Reaction mix for digestion of plasmid DNA:

x μ g	DNA
2 μ l	corresponding 10x buffer (for ex. N1 – N4)
2x x U	restriction endonuclease
adjust to	double distilled H ₂ O
20 μ l	

The mixture was incubated for 2 hours at 37⁰C and then analysed in an agarose gel.

Preparative restriction digestions were done in bigger volumes and with increased amounts of enzymes.

7-25 μ l	DNA solution (15 μ g DNA)
5 μ l	corresponding 10x buffer (for ex. N1 – N4)
50 U	restriction endonuclease
adjust to	double distilled H ₂ O
50 μ l	

Reaction mix for digestion of genomic DNA:

The mixture was incubated overnight at 37⁰C and then used completely to separate fragments in an agarose gel for southern blot analysis.

As reaction buffers , New England Biolabs buffers were used (NEB). These buffers were 10x concentrated by supplier and purchased together with enzymes.

3.2.1.6 DNA ligation

Plasmid vector pBluescript SK⁺ was cut at an appropriate polylinker site. A desired fragment was cut out from the DNA of interest. Both, the vector and the desired fragment were extracted from agarose gels using the QIAEXII kit (QIAGEN). The amounts of DNA in the eluates were estimated on agarose gels (ethidium bromide staining is proportional to the amount of base pairs). 1,5 µl of 10x ligase buffer were mixed with the vector and fragment eluates, the volume was adjusted with double distilled H₂O to 14µl and 1µl of T4 DNA ligase was added. The mixture was incubated at 14⁰C overnight and then used for *E.coli* transformation.

3.2.1.7 Phosphatase treatment of digested plasmid DNA

To prevent re-ligation of single digested plasmids, they were treated with alkaline phosphatase. 5µg plasmid DNA was digested with the desired endonuclease for 2 – 3 hours in 50 µl reaction volume. 2 µl of alkaline phosphatase (Boehringer) were added (if digestion was done in the buffer N1, 5 µl of 10x buffer N3 were added simultaneously) and the reaction mix was incubated for 1 hour at 37⁰C. Then 0,5 µl of 500 mM EDTA (final concentration should be 5 mM) were added and heated for 20 minutes at 75⁰C. A preparative agarose gel was run and a plasmid extracted accordingly to QIAEXII (QIAGEN) kit protocol.

3.2.1.8 Site-directed mutagenesis

For introduction of new restriction sites into cloned genomic fragments of interest an oligonucleotide directed mutagenesis was used.

Primer construction

A pair of PCR primers was constructed to amplify plasmid completely so that on the 5' end and on the complimentary on 3' end they would introduce a new or destroy an existing restriction site. The mutation in a plasmid can be monitored in comparison with native one by restriction digestion.

Phosphorylation of primers

To allow ligation at the end of the procedure primers were phosphorylated:

1 μ l	200 pmol of the primer 1 (same for primer 2)
1 μ l	10x T4 kinase buffer
1 μ l	10 mM ATP
6 μ l	dd water
1 μ l	T4 kinase
The reaction mix was incubated for 30 minutes at 37°C	

PCR

Pfu DNA polymerase was used because it has low rate of mistakes. The Pfu DNA polymerase needs 2 minutes to amplify 1 kb.

1 μ l	1:10 or 1:50 diluted plasmid	PCR cycles, example:	
5 μ l	10x Pfu buffer		
5 μ l	dNTP		
1,5 μ l	primer 1 – PO ₄		1min 95°C
1,5 μ l	primer 2 – PO ₄		1min 52°C
35 μ l	H ₂ O		10 min 72°C
The reaction mix was incubated 4 minutes at 95°C, then 1 μ l Pfu was added		10 cycles total (max 12)	

DpnI restriction digestion

To eliminate native unchanged plasmid, the restriction enzyme DpnI was used, which digests only methylated DNA. 1 μ l of DpnI was added after the PCR reaction indicated above and the reaction incubated for 1 hour at 37°C. For inactivation of the enzyme the tube was heated for 30 minutes at 80°C. 12,5 μ l of the reaction were used directly for ligation or the mixture was loaded on preparative agarose gel and a fragment of interest was extracted using the QIAEXII method.

Ligation

12,5 μ l	DNA
1,5 μ l	10x ligase buffer
1 μ l	concentrated T4 ligase
The mixture was incubated at 16°C overnight and used for <i>E.coli</i> transformation	

3.2.2 DNA isolation

3.2.2.1 Mini preparation of plasmid DNA

Lysozyme solution	NaOH / SDS solution
50mM glucose 10mM EDTA 25mM Tris-HCl pH 8.0 (store at 4 °C)	0,2M NaOH 1% SDS (prepare fresh)

Two ml of LB medium containing 200 µg/ml ampicilline were inoculated with a single bacterial colony from a LB – plate and an overnight culture was obtained. 1,5 ml of the suspension was transferred into an eppendorf tube and centrifuged for 2 minutes at 13000 rpm. The liquid phase was removed and the pellet was resuspended in 100 µl of lysozyme solution. The mixture was incubated for 5 minutes on ice, then 200 µl of NaOH / SDS solution were added and mixed gently by inversion. A viscous lysate was incubated at RT for 10 minutes and 150 µl of 3M NaAc (pH 5,2) pipetted into a tube, followed by incubation on ice for 10 minutes. The obtained fluffy solution was centrifuged 10 minutes in microfuge on high at RT. The supernatant was transferred into a new tube. If nessesary, the DNA was purified by a phenol/chlorophorm extraction. 1 ml (2,5 volumes) cold 100% ethanol were added to the supernatant and then centrifuged 15 minutes in microfuge at 4⁰C on high. The supernatant was then aspirated off and 0,5 ml of cold 70% ethanol were added and span for 5 minutes. The liquid phase was removed and pellet was dried at 37⁰C for 30 minutes. The dry pellets were dissolved in 40 µl of TE containing 100µg /ml RNase A and used for restriction digestion analysis.

3.2.2.2 Mini preparation of plasmid DNA (QIAGEN method)

Plasmid preparations for later preparative usage were done accordingly to protocols and using the original mini prep QIAGEN reagents (QIAGEN handbook, April 1997). 2 – 5, or 10 ml of LB medium (depending on copy number of the plasmid used for transformation) with 200 µg /ml ampicilline were inoculated with a single *E.coli* bacterial colony from LB – plate and an overnight culture was obtained. The whole amount of the overnight culture was centrifuged in a Megafuge 1.0 for 5 minutes at 5000 rpm. The cell

pellets were resuspended in 250 µl of P1 buffer (4⁰C), mixed with 250 µl of buffer P2 and incubated for 5 minute at RT. After addition of 350 µl buffer P3 and mixing, a cloudy solution was centrifuged for 10 minutes at 13000 rpm at RT. The supernatant was loaded onto mini-column and centrifuged for 1 minute at 13000 rpm. The flow-through was thrown away and 750 µl of PE buffer were loaded onto column followed by a centrifugation for 1 minute again. The flow-through was again thrown away and the column was centrifuged for 1 minute to remove traces of ethanol. To elute DNA, 50 µl of 10 mM Tris-HCl, pH=8,5 were added and the column left for 5 minutes. The column was centrifuged and the DNA concentration was determined in the eluate.

3.2.2.3 Midi preparation of plasmid DNA (QIAGEN method)

Plasmid preparations for preparative usage were done accordingly to protocols and using original midi prep QIAGEN reagents (QIAGEN handbook, April 1997).

Using a sterile toothpick, a bit of a culture frozen in 7% DMSO was transferred into 5 ml LB-ampicilline medium and incubated at 37⁰C for 6 - 8 hours.

100 or 500 ml of LB medium (depending on copy number of the plasmid used for transformation) with 200 µg /ml ampicilline were inoculated with 100 or 500 µl *E.coli* bacterial suspension and an overnight culture was obtained. The whole volume was centrifuged at 8000 rpm for 10 minutes in a JA-10 rotor. The pellet was resuspended in 4 ml of P1 buffer and transferred into JA-20 centrifuge tubes. 4 ml of P2 buffer were added to the suspension and mixed followed by incubation for 5 minutes at RT. The mixture was neutralised by addition of 4 ml of P3 buffer and incubated then for 20 minutes on ice. After that the lysate was centrifuged 30 minutes at 18000 rpm in JA-20 rotor at 4⁰C and a supernatant loaded onto a type 100 column equilibrated by QBT-buffer. The plasmid DNA binds to the QIAGEN resin in these columns. The column was washed with 10 ml QC-buffer and the DNA eluted in 5 ml of QF-buffer and collected in a Corex® tube. The DNA was precipitated with 0,7 volumes of isopropanol and centrifuged at 18000 rpm for 30 minutes at 4⁰C. The pellet was washed with 70% ethanol twice, air-dried and resuspended in 300-500 µl of 10 mM Tris-HCl, pH 8,5. Finally, the concentration of the DNA was determined at OD 260 nm.

3.2.2.4 Maxi preparation of phage λ DNA (QIAGEN method)

An *E. coli* LE392 culture was grown overnight in 5 ml NZYDT supplemented with 10 mM Mg_2SO_4 and 0,2% maltose. The culture was diluted with 45 ml of the same medium and grown for more than 1 hour upon measuring of OD 600 nm (should be below 2, one OD is 8×10^8 cells). To reach a ratio of bacteria / phages of 30 / 1, 10^{10} cells were infected with $3,3 \times 10^8$ pfu λ phages for 30 minutes at 37°C without shaking. The mix was added to 250 ml of NZYDT supplemented with 10 mM Mg_2SO_4 and 0,2% maltose and grown till complete lysis (6 - 8 hours) at 37°C in a shaking incubator. 5 ml of chloroform (2%) were added to the lysate and incubated for 15 minutes at 37°C. The lysate was spun down for 15 minutes at 8000 rpm in a JA 10 rotor and the supernatant treated accordingly to QIAGEN lambda handbook. To 250 ml supernatant 400 μ l of buffer L1 were added and incubated for 30 minutes at 37°C. During this time all bacterial RNA and chromosomal DNA are digested. 50 ml of ice-cold buffer L2 were added to the lysate and incubated on ice for 60 minutes. Buffer L2 contains PEG for precipitation of the phage particles. The mixture was centrifuged at 18000 rpm for 10 minutes and the supernatant was discarded. The pellet was resuspended in 9 ml of buffer L3 by pipetting up and down and 9 ml of buffer L4 were added. The mixture was incubated at 70°C for 20 minutes and then cooled on ice. Buffer L4 contains SDS which denatures phage proteins and releases the DNA. 9 ml of buffer L5 were added to the liquid and immediately but gently mixed by inverting the tube 6 times and then centrifuged for 30 minutes, 4°C at 18000 rpm. The supernatant was transferred promptly to a fresh tube and the step repeated for 10 minutes. The obtained clear liquid was loaded onto a QIAGEN tip 500 equilibrated by QBT buffer and allowed it to enter the resin by gravity flow. The tip was washed with 30 ml of buffer QC and the DNA was eluted in 15 ml of buffer QF. The DNA was precipitated by adding of 10,5 ml of room-temperature isopropanol and centrifuged at 18000rpm for 30 minutes at 4°C. The obtained pellet was washed twice with room temperature 70% ethanol and centrifuged each time for 5 minutes at 18000 rpm for 10 minutes. The supernatant was removed and the pellet air-dried for 15 minutes followed by redissolving it in 300 μ l of 10 mM tris-HCl, pH 8,5. Finally, a concentration of the DNA was determined at OD 260 nm.

3.2.2.5 Genomic DNA isolation from mouse tissues

Digestion buffer	for 50 ml:
100 mM NaCl 10 mM Tris-HCl pH 8.0 25 mM EDTA 0,5% SDS	1ml 5 M NaCl 500 μ l 1 M 2,5 ml 0,5 M 2,5 ml 10%
directly before use add 0,1 mg / ml proteinase K	

Mouse liver or kidney was cut into small pieces, put into a mortar filled with liquid nitrogen and grind with a pestle. Obtained powder was filled into a 15 ml tube weighted before and weight of it was determined. For every 100 mg tissue 1,2 ml of digestion buffer were added and the mixture was incubated for 12 – 18 hours at 56⁰C in a water bath. A sample was extracted twice with equal amounts of phenol / chloroform and spun for 5 minutes at 3000 rpm in a cold room. A blue pipette tip was cut off and the viscous supernatant was transferred into a new tube. Two volumes of cold 100% ethanol were added, after that DNA pellet was seen. The DNA pellet was fished out of the tube with a glass hook molten from a pasteur pipette and washed twice in 500 μ l of 70% ethanol. The pellet was air-dried for 15 minutes and dissolved in 500 μ l of 10 mM Tris-HCl pH 8,5 during an incubation of 3 hours at 37⁰C. The concentration of the DNA was determined at OD 260 nm and 15 μ g were used for a restriction digestion.

3.2.2.6 DNA isolation from embryonic stem cells

NET - buffer	for 50 ml:
100 mM NaCl 10 mM Tris-HCl pH 8.0 25 mM EDTA	1ml 5 M NaCl 500 μ l 1 M 2,5 ml 0,5 M

Proteinase K solution 2 mg / ml in NET -
buffer, store at - 20⁰C

Frozen cell pellet were resuspended in 700 μ l of NET-buffer using a vortex. 70 μ l of proteinase K solution were added and vortexed, then 70 μ l of 10% SDS were added and

vortexed again. The mixture was incubated for 3 – 4 hours at 56⁰C followed by a new addition of proteinase K solution. The obtained lysate was incubated overnight at 56⁰C, extracted with phenol / chloroform / isoamylalcohol, with chloroform / isoamylalcohol and the DNA was precipitated upon addition of 3 volumes of 100% ethanol. The DNA pellet was fished out with a glass hook molten from a pasteur pipette, washed twice with 70% ethanol and air – dried for 15 minutes. Depending on amount of the pellet, it was redissolved in 50 – 150 µl of 10 mM tris – HCl pH 8,5 during 3 hours at 37⁰C in a water bath. The concentration of the DNA was determined at OD 260 nm and 15 µg were used for a restriction digestion.

3.2.2.7 DNA isolation from mouse tail biopsy

Proteinase K solution 10 mg / ml in NET –
buffer, store at - 20⁰C

Fresh 1 cm pieces of mouse tails were put each into a 1,5 ml eppendorf tube, 500 µl of NET-buffer were added and vortexed. 50 µl of proteinase K solution were added and vortexed, then 50 µl of 10% SDS were added and vortexed again. The mixture was incubated with vigorous shaking at 56⁰C overnight. Hairs and other insoluble rests were spun down for 5 minutes at 13000 rpm and the supernatant transferred into a new tube. DNA was precipitated upon addition of 500 µl of isopropanol. The DNA pellet was fished out with a glass hook molten from a pasteur pipette, washed twice with 70% ethanol and air – dried for 15 minutes. The pellet was dissolved in 100 µl of 10 mM Tris – HCl pH 8,5 during 20 minutes and 1 µl or 0,6 µl used for PCR.

3.2.3 Agarose gel electrophoresis for DNA separation

For separation of DNA fragments of different length agarose gels were used. Suitable agarose concentration was chosen depending on the size of separating the DNA fragments:

Concentration of agarose (% w/v)	DNA size (kb)
0,7	20 - 1
1,0	7 - 0,5
1,5	4 - 0,2
2,0	3 - 0,1

Sample buffer 6x:	for 50ml:
0,15% bromphenolblue	75 mg
0,15% xylenecyanate FF	75 mg
40% (w/v) Sucrose	20 g

The necessary amount of agarose was boiled in 500 ml of 1x TAE buffer (40 mM Tris – HCl, 2mM EDTA, pH 8,0) using a microwave oven and stored at 65⁰C. For small analytical gels, 30 ml (for small preparative gels, 50 - 60 ml) of agarose was put into a chamber for electrophoresis directly and chilled at RT till the gel was solidified. The chamber was then filled with 1x TAE buffer, DNA probes were mixed with sample buffer (end concentration 1x) and put into gel pockets. The left gel pocket was always filled with 10µl of 1kb - DNA – ladder as standard. After electrophoresis, the gel was soaked in ethidium bromide solution for 15 –20 minutes and pictures were taken.

For big preparative gels, 200 - 400 ml agarose were used for a gel. After boiling of the appropriate amount of agarose in 1x TAE buffer, the liquid was chilled till 55⁰C, ethidium bromide was added (final concentration 0,5 µg / ml) and put on a gel rack. The rack was immersed into a chamber for electrophoresis filled with 1x TAE. DNA probes were mixed with sample buffer (end concentration 1x) and put into gel pockets. The left gel pocket was always filled with 30µl of 1kb - DNA – ladder. Electrophoresis was done at a voltage of 3

– 4 V /cm. Due to intercalation of ethidium bromide, DNA fragments are visible as stripes under UV – light. Photo pictures of gels were taken together with a ruler for later adjustment of fragment lengths on southern blots.

3.2.4 Extraction of DNA fragments from agarose gels

The QIAEXII DNA extraction kit was used for extraction of DNA from agarose gels. All solutions and protocols were taken from QIAGEN – supplier. The desired DNA fragment was cut out from a gel under UV – light (hand lamp, 312 nm) and weighted. For each 100 mg of gel 300 µl of QX1-buffer were added and, in dependence on DNA amount, 10 – 30 µl of QIAEXII glass milk pipetted to a probe. The mixture was incubated 5 times for 2 minutes at 50⁰C with mixing each time to keep the glass milk in suspension. The glass milk was spun down for 30 seconds at 13000 rpm, resuspended in 500 µl of QX1-buffer and centrifuged again. The supernatant was removed, the pellet was resuspended in 500 µl of PE- buffer followed by a new centrifugation step. The liquid was completely removed with a pipette and the pellet was air-dried till it became white. The DNA was eluted in 20 – 25 µl of 10 mM tris-HCl pH 8,5 during 5 minutes at RT or if the length of the DNA fragment was more then 3000 bp at 50⁰C. Elution efficiency was controlled on agarose gels.

3.2.5 Transformation of *E.coli* via electroporation with plasmid DNA

40 µl of competent *E.coli* (strain XL1 blue) cells frozen in 10% sterile glycerol were thawed on ice, immediately mixed with 1,2 µl DNA ligation mix and placed into an ice-cold sterile electoporation cuvette (Stratagene). Cells were transformed by an impulse of 1800 V at a constant capacitance of 10 µF. Immediately after electroporation cells were resuspended in 500 µl of room temperature SOC medium, transferred into a sterile eppendorf tube and incubated for 30 minutes at 37⁰C. Finally the whole suspension was put onto 10 cm LB – ampicilline (or kanamycine) agar plate, distributed homogeneously with a spatula, dried for 10 minutes and the plate left overnight in an incubator at 37⁰C. The colonies obtained were analysed by plasmid miniprep method.

3.2.6 Cryoconservation of *E.coli* clones using DMSO solution

Positive *E.coli* transformants were plated from liquid culture onto LB – ampicilline (or kanamycine) agar plate using a wolfram loop and grown overnight at 37⁰C. Obtained *E.coli* layer was harvested by a sterile toothpick, resuspended in 1 ml of sterile 7% DMSO in water and immediately frozen at – 80⁰C.

3.2.7 DNA hybridisation techniques

3.2.7.1 DNA transfer to Hybond N membranes

This method is famous as southern-blotting (Southern 1975; Alwine et al. 1977).

The presence of a fragment of interest in a mixture of DNA fragments after enzymatic restriction digestion was determined using southern blotting followed by DNA hybridisation.

Denaturation solution	1,5 M NaCl 0,5 M NaOH
Neutralisation solution	1,5 M NaCl 0,5 M tris-HCl, pH 7,2 1 mM EDTA
Transfer buffer (20x SSC)	3 M NaCl 0,3 M trisodium citrate, pH 7,0

DNA after electrophoresis was denatured in the gel. To do that, the gel was incubated in the denaturation solution (a volume was taken so that the gel was completely immersed in it) twice for 15 minutes. Neutralisation was done twice for 15 minutes in the appropriate solution and the gel was then equilibrated for 20 minutes in 20x SSC. After these pre-incubation steps the capillary transfer were assembled as indicated in figure 6.

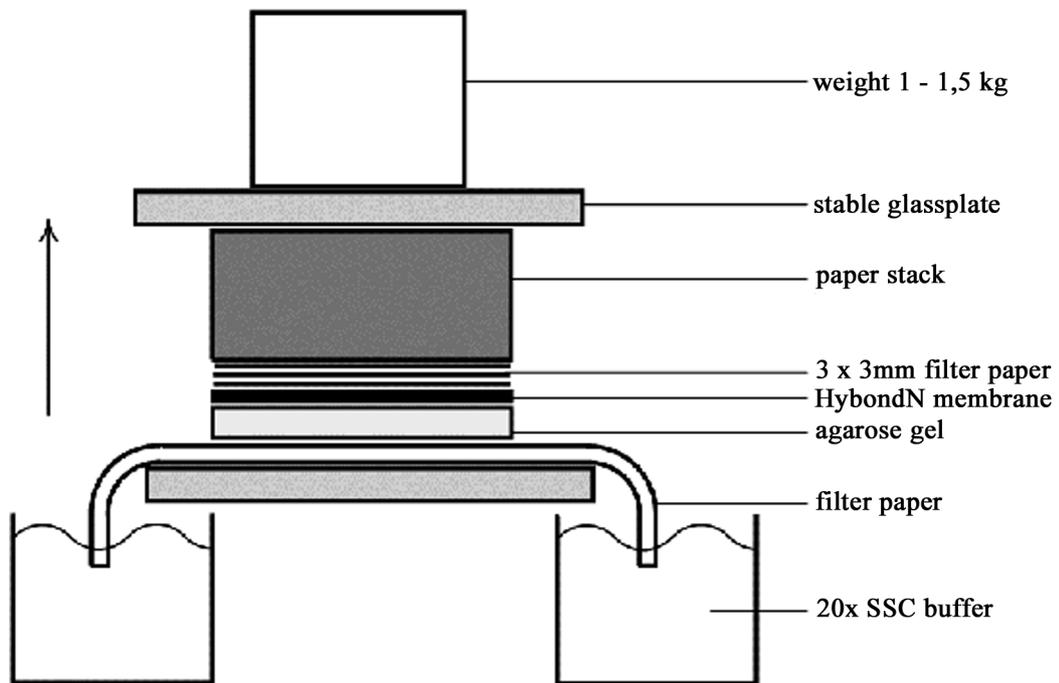

Figure 6: A schema of capillary transfer of DNA to nylon membrane (southern blotting)

A nylon (HybondN) membrane was soaked for 3 minutes in dd H₂O and then for 10 minutes in 20x SSC before placing it onto a gel. An arrow shows the direction of liquid movement, which transfers DNA from agarose onto membrane. The transfer was always done overnight (16 – 24 hours). Then the membrane was air-dried for 1- 2 hours and the DNA cross-linked to the membrane with UV light (15-30 seconds on the transilluminator). To remove rests of SSC the membrane was washed in dd H₂O for 1 minute and dried at 65⁰C for at least 30 minutes.

3.2.7.2 DNA labelling with α - [³²P] – dCTP (making of DNA probes)

This method is adopted from Feinberg and Vogelstein (Feinberg and Vogelstein 1983). A random priming procedure was used to get radioactive single stranded DNA of the desired sequence (a probe). Rediprime™II DNA labelling kit (Amersham Pharmacia Biotech) was used for that.

Denaturation of DNA: approximately 25 ng of DNA fragment were mixed in 45 –47,5 μ l H₂O (HPLC), denatured for 5 minutes at 95⁰C and centrifuged shortly

Labelling: 45 – 47,5 μ l of denatured DNA
 1 tube of labelling pre-mix (contains dATP, dGTP, dTTP, Klenow-fragment of DNA polymeraseI, random primers)
 50 – 25 μ Ci α - [³²P] – dCTP (Redivue, Amersham)
 were mixed together and incubated at 37⁰C for 15 minutes
 After that the reaction was stopped upon addition of 150 μ l TE buffer and kept on ice till further usage.

For separation of non-incorporated α - [³²P] – dCTP the reaction volume was gel filtered on a Sephadex®G50 column (see under 3.2.1.4). The incorporated radioactivity in the flow through was counted according to the Cerenkov procedure (Berger 1984) in a β -counter. The percentage of incorporated radioactivity was calculated from the fact that 50 μ Ci corresponds to 111 x 10⁶ cpm (Cooper 1981). Specific radioactivity usually was 10⁹ cpm/ μ g DNA.

The following probes were used for λ -phage mouse genomic library screenings and for genotyping of embryonic stem cell transformants:

mVt1a:

λ -phage library

“probe 237”
 contained 100bp upstream from ATG codon and 60bp downstream from stop codon from pT7T3D– Pac (AA016379) were cut out with XhoI + NotI; contains 900 bp mVt1a cDNA sequence
 “EST probe”
 contained 100bp 5` untranslated region, first exon and 750 bp intron sequence of Vt1a; cut out from pT7T3D (AA097517) with XhoI/NotI

ES cell clones	
NdeI screening	“pVA45 derived probe” 900 bp from pVA45 were cut out by XbaI + EcoRI
XbaI screening	“pVA42 derived probe” 1300 bp from pVA42 were cut out by XbaI + EcoRI
mVti1b:	
λ-phage library	“probe 235”
Nothern blot	1000 bp from pCMV – SPORT2 (AA105524) were cut out by SalI + NotI; contains mVti1b cDNA sequence
ES cell clones	
EcoRI screening	“EcoRI 400bp probe” 400 bp from pVA12 were cut out by EcoRI
XbaI screening	“XbaI PCR probe” 490 bp were PCR amplified with using of primer 1 (CCATGEATTGTCCTGTCC, pos 3598 – 3616) and primer 2 (CATGTATAACATTAATAGCTTG, pos 4069 – 4089) on pVA7 template

3.2.7.3 Screening of phage λ mouse genomic DNA libraries

Preparation of host bacteria

E. coli strain LE392 was grown ON in LB medium as host bacteria (see 3.1.15). 10 ml of stationary culture were diluted 1:10 with the same medium and the bacteria were grown to an OD₆₀₀ of 0,5 – 0,8. The bacteria were pelleted for 10 min at 2800 rpm and resuspended in 50 ml of 10 mM MgSO₄. Obtained bacterial suspension was incubated for 1h at 37⁰C with rotation and then kept at 4⁰C till use.

Plating of the library

The prepared bacteria were incubated with phage library diluted in SM-buffer (see 3.1.15) 1:1000. The amount of bacteria and phage solution for infection was always tested experimentally on one small plate before plating of large number of plates. For optimal was taken the amount of phage suspension added resulting in total lysis of the bacteria on plates. In our case 1 ml of prepared bacteria was infected with 40μl of phage suspension and left standing without shaking at 37⁰C for 20 min. After that 14 ml of top-agarose (see 3.1.15) of 60⁰C were added and immediately poured onto 15 cm agar-plate (see 3.1.15). Plates were dried opened for 20 min in a sterile hood and incubated upside down at 37⁰C for about 6 h till plaques were visible. Afterwards “lysed” plates were kept at 4⁰C to increase solidity of the top-agarose for making of filter replicas.

Generating HybondN replica filters

Denaturation solution	1,5 M NaCl 0,5 M NaOH
Neutralisation solution	0,5 M NaCl 1 M tris-HCl, pH 7,2 1 mM EDTA
Equilibration solution (2x SSC)	0,3 M NaCl 0,03 M trisodium citrate, pH 7,0

A HybondN filter was placed onto the cooled top of the plate lysed by phage and left there for 30 sec. The plate and filter were marked with pencil and 5 holes (through the filter and agar) during that time for orientation of the filter later. A second filter was put onto the same plate for 1 min and the procedure was repeated completely. Filters were put upside down onto filter paper soaked with denaturation solution for 5 min. Then filters were placed with DNA facing up for 2x10 min on filter paper soaked with neutralisation solution. Filters were submerged for about 5 min in a tray filled with 2x SSC solution and then air-dried for about 2h. To cross-link the DNA, filters were put onto a clean UV-transilluminator and exposed to UV light for 15 sec. Fully treated filters were dried at 60°C for 30 min and used for DNA hybridisation with an appropriate probe (see 3.2.7.2 and 3.2.7.4).

3.2.7.4 Hybridisation of HybondN membranes with radioactive labelled DNA probes (Amersham procedure)

Washing solution 1:	2x SSC (see under 3.2.7.1) 0,1% SDS in dd H ₂ O
Washing solution 2:	0,2x SSC 0,1% SDS in dd H ₂ O

Rapid hyb buffer was heated at 65°C for at least 30 minutes in a hybridisation oven. Before hybridisation DNA blots were pre-incubated in 5 – 15 ml of hot Rapid hyb buffer (Amersham Pharmacia Biotech) for 30 minutes at 65°C. The labelled DNA probe was denatured for 7 minutes at 95°C, chilled on ice for 1 minute, pipetted directly into the buffer and mixed. For every 5 ml of buffer, 25% of the labelled probe was taken (see under 3.2.7.2). The blot was incubated in the hybridisation oven overnight with slow rotation at

65⁰C. The blot was washed once for 20 minutes at RT in solution 1 and twice for 15 minutes at 65⁰C in solution 2 (water bath). The efficiency of washing was controlled with a hand monitor and at the end was 35 – 45 desintegrations per second. The membrane was then sealed between plastic sheets to prevent its drying and exposed to a phosphoimager screen for 5 – 24 hours

In the present work murine cellular and mouse DNA were analysed to determine genotypes for mVti1b and mVti1a by hybridisation technique indicated above. Structures of wild type and homologous recombined *loci* and sequences of the chosen probes can be viewed in chapter “Results”. The expected fragments sizes for wild type and null-allele are indicated in table 1:

Table 1: Size of restriction fragments upon genotype analysis of ES cell transformants of mVti1b and mVti1a gene targeting

	mVti1b gene	mVti1b gene	mVti1a gene	mVti1a gene
Digestion with	EcoRI	XbaI	NdeI	XbaI
Wild type allele	4,0 kb	8,0	4,0 kb	6,0 kb
Null allele	4,8 kb	7,0	5,0 kb	4,0 kb

3.2.8 PCR method for DNA amplification

(adopted from Saiki et al. (Saiki et al. 1986; Saiki et al. 1988))

The polymerase chain reaction (PCR) is a method for amplification of certain fragments of DNA. The method was used for generation of DNA probes (see under 3.2.7.2) and for clarification of mice genotypes on certain *loci*.

The PCR is based on 3 steps, which are necessary for every DNA synthesis:

1. Template DNA denaturation to get single stranded DNA.
2. Annealing (binding of oligonucleotide primers to single strands).
3. Extension (synthesis of DNA, starting from bound primers)

10x PCR-dNTP-mix:	25mM of every dATP, dCTP, dGTP, dTTP in dd H ₂ O
10x reaction buffer	500mM KCl 100mM tris-HCl pH 9,0
Oligonucleotide primer 1	2 pmol / μ l
Oligonucleotide primer 2	2 pmol / μ l
Taq DNA polymerase	5U / μ l
MgCl ₂ was added till end concentration of 1,25 mM	

Cycles (example):

1. 95⁰C 40 sec
2. 50⁰C 40 sec for certain oligos the temperature was increased or decreased
3. 72⁰C 60 sec the time was increased or decreased if the length of amplified fragment was more or less then 1 kb

Typical 30 cycles

3.2.9 PCR on genomic DNA template for genotype analysis

To elucidate genotypes of mice obtained from breeding “mVti1b clone114 mouse strain”, two PCR series were applied using tail biopsy DNA (see under 3.2.2.7) as template.

To amplify 500bp of wild type or 1500bp of neo⁺ interrupted fragment of exon 123-180 of the mVti1b *loci* a PCR was done with the primers Seq5-Seq50.

Seq5-Seq50 PCR:

dd H ₂ O	33,5 μ l
10x reaction buffer	5 μ l
dNTP	5 μ l
MgCl ₂ 25mM	2,5 μ l (1,5 mM)
Oligonucleotide primer Seq 5	5 pmol (1 μ l)
Oligonucleotide primer Seq 50	5 pmol (1 μ l)
Genomic DNA	1 μ l
The mixture was heated at 95 ⁰ C for 5 minutes, then Taq polymerase was added	
Taq DNA polymerase	1 μ l (5U)

PCR reactions were done in a Thermocycler Master cycler gradient (Eppendorf) under the following conditions:

1. 95⁰C 40 sec
 2. 52⁰C 40 sec
 3. 72⁰C 50 sec
- Total 30 cycles

10 µl were then loaded onto an analytical agarose gel to estimate the length of amplified fragments.

To detect the presence or absence of neo+ interrupting cassette a Neo PCR was applied (amplifies 374 bp of neo+ cassette)

Neo PCR:

dd H ₂ O	13,8 µl
10x reaction buffer	2 µl
dNTP	0,4 µl
MgCl ₂ 25mM	1µl (1,5 mM)
Oligonucleotide primer AK30	5 pmol (1 µl)
Oligonucleotide primer AK31	5 pmol (1 µl)
Genomic DNA	0,6 µl
Taq DNA polymerase	0,2 µl (1U)

PCR reactions were done in GeneAmp9600 (Perkin Elmer) under following conditions:

1. 96⁰C 15 sec
 2. 58⁰C 30 sec
 3. 72⁰C 40 sec
- Total 30 cycles

For analysis 10 µl were then loaded onto an analytical agarose gel.

3.2.10 Methods of working with RNA

3.2.10.1 RNA extraction from mouse tissues

RNeasy® protect mini kit (see 3.1.6) was used to extract RNA from mouse liver, brain, kidney and spleen. The whole procedure was done according to the manual supplied.

Briefly 20 mg of each tissue was cut into a pre-weighted tube and immersed in 300µl of RNa protect buffer. The tissue sample was then cut into small (several millimetres) pieces

and left at 4°C till use. The tissue sample was then transferred into 350µl of lysis buffer RLT and the sample homogenised using Ultra-Turrax. The obtained homogenate was centrifuged for 3 min at maximal speed and 350µl of 70% ethanol were added to the supernatant. The obtained mixture was loaded onto a RNeasy column sitting in a 2 ml collection tube, centrifuged for 15 sec at 10000 rpm and the flow-through was discarded. 700µl of RW1 buffer were pipetted onto a column and centrifuged again with the same conditions. The column was placed into a new collection tube and loaded with 500µl of RPE buffer followed by a new centrifugation for 15 sec at 10000 rpm. That step was repeated once again with a centrifugation for 2 min. The column was placed into a 1,5 ml collection tube and the RNA was eluted in 2x40µl of RNase-free water for 1 min at RT with centrifugation for 1min at 10000 rpm. The concentration was determined at OD = 260 nm. One OD₂₆₀ corresponds 40 µg/ml RNA. The RNA samples were kept frozen at -80°C till use.

3.2.10.2 Agarose gel electrophoresis for RNA separation and northern blotting

Diethylpyrocarbonate (DEPC) – H ₂ O:	2,5L dd H ₂ O were mixed with 25ml of DEPC in a glass bottle at 37°C with rotation ON. The mixture was then autoclaved to destroy DEPC.
10x buffer for RNA electrophoresis:	200 mM MOPS 50 mM Sodium acetate 10 mM EDTA in DEPC - H ₂ O
2% agarose gel for RNA separation:	10 ml 10x buffer adjust volume till 100 ml with DEPC - H ₂ O, boil in microwave oven and chill to approx. 60°C, then add: 1,66 ml formaldehyde 15 µl ethyidiumbromide
Sample-buffer:	1 volume part of bromphenolblue 4 volume parts of DEPC - H ₂ O 4 volume parts of formamide 2 volume parts of formaldehyde 2 volume parts of MOPS 10x buffer

Glass beakers, measuring cylinders and chamber for electrophoresis were soaked in 1M NaOH for 2 h at RT to eliminate any RNase activity. All stuff treated by NaOH was then rinsed several times with dd H₂O and air dried. A gel was prepared as indicated above and

covered with 1x buffer for electrophoresis. DEPC-water was used for dilution of the buffer in NaOH treated glass beaker. Each pocket of the gel was loaded with 10 μ g RNA in sample buffer. Electrophoresis was done in a small chamber at a voltage of 3 – 4 V /cm. After electrophoresis the gel was put into a tray with 20x SSC for 20 min for equilibration and RNA was transferred onto HybondN membrane (nothern blot) as shown for DNA under 3.2.7.1, figure 6.

3.2.10.3 Hybridisation of Northern blots

Hybridisation solution:	72ml Formamide 36ml 20x SSC 1,5ml Tris-HCl 1M, pH=7,5 1,5g SDS 3ml Denhardt solution 50x 30ml 50% dextran sulfate (Pharmacia)
15g dextran sulfate were filled with ddH ₂ O till 30ml and dissolved at 80 ⁰ C; subsequently all other components were added and the volume was adjusted till 150ml with ddH ₂ O. The mixture was then incubated overnight at RT on a rocker with weak agitation and stored at 4 ⁰ C.	

For Vti1b mRNA blot the “probe 235” was used	1000bp from pCMV–SPORT2 (AA105524) were cut out by Sall + NotI; contains mVti1b cDNA sequence
For syntaxin 8 mRNA blot , following probe was used:	600bp from pBK ₄₅ were cut out by BamHI and EcoRI; contains cDNA of the syntaxin 8 soluble domain, encoding amino acids 1-213 (Antonin et al. 2000a); cDNA was amplified from lung cDNA library

Washing solution 1:	2x SSC (see under 3.2.7.1) 0,1% SDS in dd H ₂ O
Washing solution 2:	0,2x SSC 0,1% SDS in dd H ₂ O

The syntaxin 8 mRNA detection

The hybridisation buffer was heated at 42⁰C for at least 30 minutes in a hybridisation oven. Before hybridisation RNA blots were pre-incubated in 5 ml of hot hybridisation buffer for 30 minutes at 42⁰C. The labelled DNA probe was denatured for 7 minutes at 95⁰C, chilled on ice for 1 minute, pipetted directly into the buffer and mixed. For every 5 ml of buffer, 25% of the labelled probe was taken (see under 3.2.7.2). The blot was incubated in the

hybridisation oven overnight with slow rotation at 42⁰C. The blot was washed once for 20 minutes at RT in solution 1 and once for 30 minutes at 55⁰C in solution 2 (water bath). The efficiency of washing was controlled with a hand monitor and at the end was 35 – 45 desintegrations per minute. The membrane was then sealed between plastic sheets to prevent its drying and exposed to a phosphoimager screen for 5 – 24 hours.

Vti1b mRNA detection

The procedure for Southern blot hybridisation in the RapidHyb® buffer (Amersham, Braunschweig) was applied as described under 3.2.7.4, without any modifications.

3.3 Methods of cell biology and biochemistry

3.3.1 Methods for handling of eucaryotic cells

Cells were cultivated in water-saturated atmosphere under 5% CO₂ at 37⁰C. If not otherwise indicated, all media were pre-warmed till 37⁰C. In general cultivation was done in following media:

DMEM + 10%FKS + 1 x penicillin/streptomycin

Media for transfected embryonic stem cells contained additionally 335µg/ml of Gentamycine 418®

3.3.1.1 Trypsination of cells

Trypsin – EDTA solution:	0,05 % (w/v) Trypsin
	0,02 % (w/v) EDTA in modified Puck's salt solution

Passaging of cells was done regularly after they reached confluence. To do that medium was sucked off using a peristaltic pump and the cells were washed once with PBS. After PBS was removed by the same way, cells were incubated with trypsin – EDTA solution for about 5 minutes at 37⁰C till their attachment to each other and the culture dish was lost. The reaction was stopped by addition of serum – rich medium and cells were resuspended with pipette up and down several times till single cell suspension was obtained. Cells were counted in a Neubauer – chamber. Cells were then plated in desiraed amounts per plate or pelleted (1000 rpm, 5 min, Labofuge) for cryoconservation.

3.3.1.2 Cryoconservation of cells

Cryo - medium:	10 % (v/v) DMSO in corresponding cell culture medium
----------------	--

Cells were trypsinated, resuspended in medium, pelleted (1000 rpm, 5 min, Labofuge). After the supernatant was removed, cells were resuspended in 1ml ice – cold cryo – medium and transferred into a marked cryotube. The cryotube was immediately placed into a freezer (-80⁰C) and transferred by the next day into liquid nitrogen for storage.

3.3.1.3 Thawing and revitalising of cells

After taking a cryotube from liquid - nitrogen storage it was incubated at RT for about 1 min. The tube was thawed in 70% ethanol at 37°C till only a small piece of ice was seen inside. The cell suspension was transferred into a tube with 9ml of ice – cold medium using an aseptic pasteur pipette and the cell pellet were sedimented (1000 rpm, 5 min, RT, Labofuge). The supernatant was removed and the cells were resuspended in 5 ml of medium (37°C) and transferred into a cell culture flask or plate. The medium was changed the next day to remove rests of DMSO, dead cells and cell debris.

3.3.1.4 Isolation of hepatocytes

A collagenase independent method was applied for preparation of hepatocytes (Meredith 1988). The disintegration of liver tissue is based on disintegration Ca²⁺ dependent cell-cell contacts through Ca²⁺ depletion.

Solutions and buffers for isolation of hepatocytes	
Anesthetic mixture of drugs:	1 ml Ketavet® (Parke Davis; 100 mg /ml) 1 ml Rompun® (Bayer; 20mg / ml) 8 ml 0,9% NaCl water solution were mixed and sterile filtered
10x perfusion stock solution:	1400 mM NaCl 50 mM KCl 8 mM MgCl ₂ x 2H ₂ O 16mM Na ₂ HPO ₄ x 2H ₂ O 4 mM K ₂ HPO ₄ Resulting pH of the solution is 7,4. The solution was sterile filtered
Perfusion buffer:	1x perfusion stock solution 25 mM NaHCO ₃ 1mM EDTA 15 mM D-glucose x H ₂ O 2mM DL-lactate 0,2 mM Na-pyruvate The solution was always prepared fresh, sterile filtered and equilibrated with carbogen (95% O ₂ / 5% CO ₂) for at least 20 minutes before usage, so that the resulting pH of the solution was 7,4.
Wash buffer:	1x perfusion stock solution 1 mM CaCl ₂ The solution was sterile filtered and kept at room temperature

Percoll® gradient centrifugation medium	13,9 ml Percoll 2,1 ml perfusion stock solution
Gelatine solution	1g gelatine in 100 ml PBS (1%) was autoclaved and diluted with sterile PBS 1:10 (final concentration 0,1%)

Gelatine treatment of coverslips and 3 cm plates

0,5 ml or 1 ml of gelatine solution in PBS (see above) were put onto sterile coverslips or 3 cm plates and left overnight in an incubator at 37⁰C. Before using, the gelatine solution was removed and the surface was washed twice with sterile PBS. Coverslips and plates were left closed in the incubator till use.

***In situ* perfusion of mouse liver and generation of a hepatocyte suspension:**

(modified from Seglen P.O.(Seglen 1976))

A mouse was anesthetised by injection of 8,6 µl of narcotic solution per gram of body weight intraperitoneal. An abdominal cavity was opened along of linea alba, the liver with the vena portae was exposed by the displacement of the abdominal contents to the right (see figure 7). A ligature was placed around of vena portae to fix it on the catheter later (a 2 in figure 7). The catheter was inserted into the vena portae and pushed till a little bit before the porta of the liver and then fixed. After the catheter was filled with blood coming out, the pre-warmed and CO₂ equilibrated perfusion buffer was injected into the liver. The vena cava inferior must be cut immediately (a 1 in figure 7) to lower the pressure. The liver was perfused for 20 minutes at flow rate of 10ml / minute using a peristaltic pump (Pharmacia).

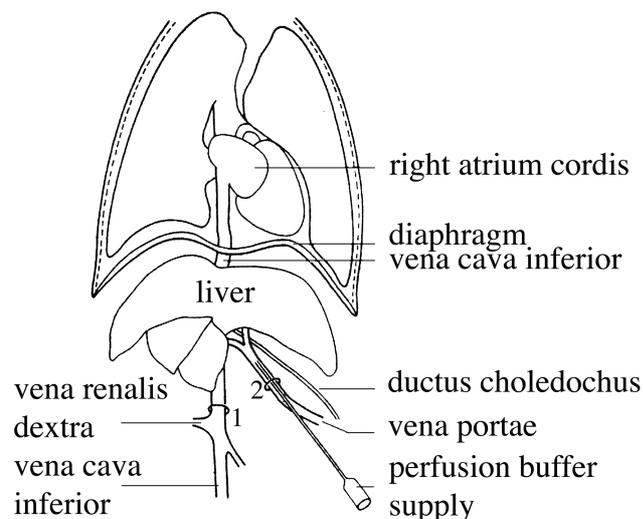

Figure 7: Schema of *in situ* liver perfusion

After completion of the perfusion, the liver was cut out carefully, without any damage to the liver capsule, and transferred into a 10 cm petri dish. About 25 ml of warm (37°C) washing solution was added and all connective tissue, and the gallbladder were removed. The liver capsule was destroyed using tweezers and nearly all cells were brought into suspension. The suspension was filtered through aseptic cotton gauze to remove the rest of the connective tissue. The suspension was centrifuged 5 minutes at 600 rpm for removal of non-parenchymal liver cells (kupffer-cells, ito-cells, endothelial cells). The obtained cell pellet was resuspended in 8 ml washing buffer and intact hepatocytes were fractionated through Percoll® density gradient.

Fractionation of hepatocytes via Percoll® density gradient:

To enrich vital hepatocytes in the cell pellet, the cell suspension described above (8 ml in washing solution) was mixed with 16 ml of warm (37°C) Percoll® gradient centrifugation medium (final concentration of Percoll® 58%) and centrifuged 5 minutes at 2800 rpm in a Heraeus –Megafuge. Dead hepatocytes, debris and non-parenchymal cells concentrated of surface of the gradient were removed together with centrifugation medium using a peristaltic pump. The remaining cell pellet with vital hepatocytes was resuspended in RPMI/10% FKS. Around $6,5 \times 10^5$ cells were plated onto gelatine treated 3 cm plate and $1,5 \times 10^5$ cells were put onto each coverslip. After 3 – 4 hours of cultivation the medium was changed. Cells were left in culture overnight and used for experiments.

3.3.1.5 Preparing of mouse embryonic fibroblasts (MEF)

Trypsin – EDTA solution: 0,25% (w/v) Trypsin, GIBCO BRL, Eggenstein
 0,02 % (w/v) EDTA in modified Puck's salt
 solution

A pregnant female of F1 generation was killed at the day 15th of pregnancy. The abdominal cavity was opened and the uterus was taken out. Embryos were released from the uterus into a petri dish with sterile PBS and washed. All next steps were done in aseptic environment. Heads and livers of embryos were removed. Heads of embryos were kept at 4°C to extract DNA from them later (genotyping via PCR). The rest of each embryo was cut into several pieces and put into a separate Erlenmeyer flask. Bottoms of the 25 ml Erlenmeyer flasks were covered with sterile glass beads and 5 ml of trypsin solution were put inside. The embryonic tissues were digested for 15 min at 37°C with vigorous shaking.

The reaction was stopped with 25 ml of medium and a cell suspension was obtained by pipetting the liquid up and down. Embryonic cells were pelleted in 50 ml Falcon® tubes at RT for 5 min at 1000 rpm in a Heraeus –Megafuge. Cell pellets were resuspended in 10 ml medium and placed onto 10 cm culture plates for overnight cultivation. Medium was changed the next day and cultivation was proceed till cells reached confluence. Fibroblasts of the first passage were divided in 3 cryotubes and frozen (see 3.3.1.2). One part of cultivated fibroblasts was kept in culture for establishment of the stable cell line.

Fibroblasts of passage 7 and older were used for the experiments.

3.3.2 Methods of protein biochemistry

3.3.2.1 Preparing of tissue – and cell homogenates for enzymatic assays and western – blot analyses

Set of protease inhibitors, final concentrations:	1mM PMSF 1mM EDTA 5mM JAA
For cultivated cells homogenates used in western blot analyses:	1mM PMSF 0,5 µg/ml Leupeptin 1,0 µg/ml Pepstatin

Tissue - homogenates:

For estimation of activities of lysosomal enzymes and analyses of different protein expression levels, fresh organs were weighted and each 100 mg tissue were supplemented with 900 µl TBS). Tissues were then homogenised using Ultra – Turrax. The obtained 10% homogenate was supplemented with 0,05% (w/v) Triton X-100 and diluted 1:10 and 1:100. These dilutions and 10% homogenate were frozen in aliquots at -80°C. 500µl of each 10% homogenate was supplemented with 1% Triton X-100 and set of protease inhibitors. That sample was stored at -20°C, used for protein concentration determination and western blot analyses.

Cell homogenates:

MEF or hepatocytes cultivated for one day were washed once with PBS and scraped in 400 – 600 µl of TBS, supplemented with protease inhibitors and 0,1% Triton X-100, and frozen at -20°C. Frozen homogenates were sonicated till homogenisation was complete and the protein concentration was determined.

3.3.2.2 Determination of protein concentration using Bradford reagent

Bradford reagent 4x: BIORAD, München

The reagent was diluted 1:4 right before usage from the stock solution. 1 – 5 μ l of tissue or cell homogenate were adjusted to a volume of 200 μ l. A solution of BSA protein (0,1mg/ml) was used as standard. 5, 10, 15, 20 μ g were pipetted and the volumes were adjusted till 200 μ l. In interval of 15 sec the reaction was started in the protein standards and then in the probes by addition of 800 μ l the BIORAD® reagent. After 20 minutes incubation at RT the extinction at $\lambda = 660$ nm was measured. A curve was plotted from the standard values and the protein concentrations in the probes were determined from that curve.

3.3.2.3 Measuring of activities of lysosomal enzymes in cells and tissues

Substrates for fluorometric estimation of enzymatic activities:	
Enzyme	Substrate
β -Hexosaminidase (β -Hex)	1 mM 4-Methyl-Umbelliferyl-2-acetamido-deoxy- β -D-glucoopyranosid
β - Mannosidase (β -Man)	1 mM 4 Methyl-Umbelliferyl- β -D-mannopyranosid
β – Glucuronidase (β -GlucUA)	1 mM 4 Methyl-Umbelliferyl- β -D-glucoopyranosid
β – Galactosidase (β -Gal)	1 mM 4 Methyl-Umbelliferyl- β -D-galaktopyranosid

Substrate buffer: 0,1 M Na citrate pH 4,6
0,08% (w/v) NaN_3
0,4% (w/v) BSA

Stop – solution: 0,2 M Glycine / NaOH pH 10,8

Assay mixture (see table 2): 1 – 10 μ l homogenate (1:10 or 1:100 diluted)
50 μ l substrate solution
were mixed on ice and incubated in a shaking water bath at 37⁰C for the time indicated in table 2

Stop: 2 ml stop solution

Measuring: 365 nm excitation
410 nm emission
in fluorescence spectrophotometer

The measured values were corrected with help of 4-Methylumbelliferone solution as reference probe values. To get stock solution, the powder of 4-MU (Sigma) was dissolved in methanol. Standard solutions of known 0,1nmol and 1,0 nmol concentrations were obtained by dilution of the stock with ddH₂O and used to draw a calibration curve for estimation of experimental product amounts. As 0 reference probe ddH₂O was used. All volumes of standard and 0 reference probes were adjusted till 60µl with ddH₂O and immediately supplemented with stop-solution. The activities of homogenate were calculated as mU/ml:

1mU of enzymatic activity corresponds to the accumulation of 1 nmol product per minute of incubation.

Determination of arylsulfatase A activity:

Substrate solution:	10 mM p-Nitrocatecholsulfate 10% (w/v) NaCl 1 mM Na – pyrophosphate 0,5 M Na – acetate pH 5,0
Stop – solution:	1 M NaOH
Assay mixture (see table 2):	1 – 10 µl homogenate (1:10 diluted) 200 µl substrate solution were mixed on ice and incubated in a shaking water bath at 37 ⁰ C for the time indicated in table 2
Stop:	600 µl of stop – solution were added
Measuring of OD at:	515 nm (ε = 12400 cm ² /mmol)

Calculating the enzymatic activity:

Measured values were corrected with the help of reference probe value (ΔE). To prepare a reference probe cell homogenates were mixed with the substrate solution and immediately supplemented with the stop solution. Reference probes were incubated together with other probes and then measured. The ASA activity resulted from:

$$\frac{\text{Assay – vol. in } \mu\text{l} \times 1000 \times \Delta E}{\text{Probe vol. in } \mu\text{l} \times 12,4 \times \text{min}} = \text{mU ASA / ml}$$

Table 2: Probe volumes and incubation times for measuring of lysosomal enzymes activities.

	liver	kidney	brain	spleen	fibro- blasts	serum
β - Hex	0,05 30	0,05 30	0,05 30	0,05 30	0,1 30	10 30
β -Gal	0,1 120	0,1 120	0,1 180	0,1 120	1 120	1 120
β - GlcUA	0,1 120	0,1 120	1 120	1 120	1 120	1 120
β -Man	0,1 60	0,1 60	1 60	1 60	2 60	1 60
ASA	1 300	1 300	1 300	1 300	1 300	1 480

The upper number indicates the probe volume of undiluted homogenate in μ l.

The lower number shows the incubation time in min. Abbreviations are explained in the text.

3.3.2.4 SDS –polyacrylamide – gel electrophoresis (SDS –PAGE) of proteins

Separation of protein mixes was done using discontinuous SDS-polyacrylamide-gel electrophoresis.

Buffer for SDS-PAGE (10x), 1l:	30,2 g Tris 144g glycine 10g SDS in bidistilled H ₂ O
3x probe buffer, 45ml:	4,5g SDS 18,8 ml 1M Tris-HCl pH 6,8 15g Sucrose ca. 5mg bromphenolblue (1 spatula –tip) add 100 μ l of β -mercaptoethanol to each 900 μ l of buffer before use
Acrylamide solution:	30% (w/v) acrylamide 0,8% (w/v) bisacrylamide in bidistilled H ₂ O
Ammoniumperoxidisulfate (APS):	10% (w/v) ammoniumperoxidisulfate in bidistilled H ₂ O

Table 3: Composition of resolving gel of different polyacrylamide (PAA) – concentrations.

PAA - concentration	5%	8%	11%	12,5%
1,5 M Tris-HCl pH 8,8 (ml)	3,75			
acrylamide solution (ml)	2,5	4,0	5,5	6,25
bidistilled H ₂ O	8,4	6,9	5,45	4,65
10%SDS (μl)	150			
10%APS (μl)	150			
TEMED(μl)	7,5			
H ₂ O	adjust till 15 ml			

Table 4: Composition of stacking gels

PAA concentration:	5,5%
1M Tris-HCl pH 6,8	936μl
Acrylamide solution	1,39 ml
10% SDS	75μl
10% APS	150μl
TEMED	7,5μl
H ₂ O	adjust till 7,5 ml

Electrophoresis was done always in vertical directed glass plates (the size of glass plates is: 18 x 14 cm, 1 mm spacer). Glass plates were put together with spacers between them and were hermetically sealed with 1% agarose in water. Freshly mixed separating gel was poured between plates and 500μl of H₂O was put on the top. After 30 min of polymerisation at RT, H₂O was sucked out using a pump, stacking gel was poured and a comb was inserted. After 10 min of polymerisation, the rack was removed and gel pockets were rinsed with water. Rests of polymerised gel were removed from the pockets with a hypodermic needle. Gel pockets were filled with buffer for electrophoresis (see above). Protein probes were mixed with 3x buffer (2:1), denaturated for 5 min at 95⁰C, centrifuged 1 min at 14000 rpm at RT and loaded into gel pockets. Electrophoresis was run at 32 mA for 2 – 3 hours.

3.3.2.5 Semi-dry protein transfer (western - blotting)

A buffer for semi – dry protein transfer (1L):	5,8 g Tris 2,92g glycine 3,7 ml SDS 10% pH about 9,2 and add H ₂ O to 800 ml and 200 ml of methanol
--	--

6 pieces of whatman GB 003 paper and nitrocellulose membrane (or PVDF membrane) were cut out in a size of the gel. PVDF membrane was soaked for 1 min in absolute methanol (Roth) or in 60% methanol (Westran®) depending on kind of purchased membrane. Whatman paper and membrane were pre- wet in a semi – dry buffer for 1min. Whatman paper was placed directly onto an electrode surface (3 layers), then membrane and all air bubbles were removed between them. After SDS-PAGE, the stacking gel was removed and the resolving gel was soaked in the semi – dry buffer shortly, before placing it onto the membrane. The gel surface was covered again by 3 layers of wet whatman paper and air bubbles were removed. A second electrode was put onto the top of the unit so the device was fully assembled and then connected to a power supply. The transfer followed from cathode to anode for 1h under 1mA/cm². The efficiency of the transfer was controlled using Ponceau® solution that stains protein bands on membranes. The membrane was soaked in the solution for 5 – 20 min and rinsed with water till an excess of Ponceau was removed. The membrane was air – dried and stored at RT till use in ECL protein detection assay.

3.3.2.6 Antibody – staining and enhanced chemiluminiscent (ECL) assay for protein detection

Background information:

The protein of interest was identified via interaction with a mouse or rabbit antibody specific to that protein, which was detected by goat-HRP (horse-redish-peroxidase) conjugated antibody directed against either mouse or rabbit IgG.

Table 5: Antibodies dilutions for ECL-detection assay

Protein	MW	Primary antibody dilution	Secondary antibody dilution
Cathepsin D, murine	50, 30, 14	1:200	1:20000
Lamp1, murine	110	1:300	1:10000
Lamp2, murine	110	1:100	1:10000
LimpII, rat, luminal domane	90	1:500	1:10000
MPR-46, cytoplasmic domain	46	1:272	1:10000
mVti1a	27	1:3000	1:20000
mVti1b	29	1:3000	1:20000
SNAP - 29	29	1:1000	1:20000
Syntaxin 7	30	1:1000	1:20000
Syntaxin 8	27	1:1000	1:20000
Transferrin receptor, human	180	1:1000	1:10000
EGF-R	170	1:200	1:10000

Solutions:

PBST:	PBS with 0,1% Tween-20®
Blotto:	2% milk powder in PBST (for nitrocellulose membrane) or 5% milk powder in PBST (for PVDF membrane)
SuperSignal® chemiluminiscence substrate	PIERCE, mix in equal amounts directly before use

A protein – blot (see under 3.3.2.5) was washed in water till the Ponceau disappeared and soaked in blotto for 30 min. The desired primary antibody was diluted (see 3.1.8.1) in blotto and the blot was put into its solution in a sealed plastic bag (to reduce volume of antibody used). The blot was then incubated for 1 – 2 h, followed by washing in PBST 3 times for 5 min and then incubated again for 1 h with anti- mouse or anti- rabbit secondary

antibody diluted in PBST. Finally the blot was washed 5 times 5 min with PBST and one time with PBS. The membrane was put into SuperSignal® mixture for 5 minutes with shaking and then exposed to KODAK film or luminescent image analyser for different times, depending on signal intensity.

3.3.2.7 Metabolic labelling of cells for immunoprecipitation of lysosomal protease Cathepsin D

Adherent mouse embryonic fibroblasts and hepatocytes were incubated in the presence of radioactive [³⁵S] – methionine for later immunoprecipitation of the lysosomal enzyme cathepsin D.

Starvation medium:	5% (v/v) dialysed, heat – inactivated FKS in DMEM without methionine
Labelling medium:	100 – 200 µCi/ml [³⁵ S] – methionine in starvation medium
Chase medium supplement (100x):	25 mg/ml L-methionine in H ₂ O, sterile filtered
Lysis – buffer:	0,1% (w/v) Triton X-100 1 mM PMSF 1 mM EDTA 5 mM JAA in TBS pH 7,4

Metabolic labelling of adherent cells with [³⁵S] – methionine:

Cells were plated in 3 cm culture dishes one day before labelling. The amount of fibroblasts was chosen so that on the day of the experiment cells were almost confluent. Hepatocytes were always plated after their isolation at $6,5 \times 10^5$ cells per plate (see under 3.3.1.4). Cells were washed once with PBS and once with starvation medium and then incubated in 1 ml of starvation medium for 1h at 37⁰C, 5% CO₂. After that the medium was changed to 0,6 ml of radioactive labelling medium and plates were put into an incubator again for 1 h (“pulse”). For starting of the chase period (1-6 h) 6 µl of 100x methionine stock – solution were added to the labelling medium (end concentration: 250µg/ml). Media after the chase periods were collected, centrifuged 1 min at 14000 rpm to remove cell debris and supernatants were frozen at –20⁰C till use in the immunoprecipitation experiment. Cells were washed twice with cold PBS and scraped off in 2 x 200 µl cold lysis buffer using a cell scraper. The obtained cell lysates were stored at –20⁰C till use.

3.3.2.8 Washing of pansorbin

The desired amount of pansorbin (usually 1ml) was put into a 2 ml eppendorf tube and centrifuged 1 min at 10000 rpm at RT. The obtained pellet was resuspended in 1ml of PBS and centrifuged again with same conditions. The procedure was repeated 4 times and then pellet was resuspended in starting volume of PBS and stored at 4°C overnight till use.

3.3.2.9 Immunoprecipitation of metabolically labelled cathepsin D

All steps for the immunoisolation were done in a cold room, or on ice using cold solutions.

Wash – immunomix (IMM):	1% (w/v) Triton X-100 0,05% (w/v) Na – deoxycholate 10 mM Na – phosphate, pH 7,4 0,15 M NaCl store at –20°C
2M KCl - immunomix	2M KCl in wash – immunomix store at –20°C
Neufeld – buffer:	10 mM Tris, pH 8,5 0,6 M NaCl 0,1% SDS 0,05% NP-40 store at –20°C
Precipitation – immunomix (PIM):	0,2% SDS 10% BSA 1mM PMSF 1 mM EDTA 5mM JAA in wash – immunomix
Protaminsulfate:	3% protaminsulfate,(SERVA) in H ₂ O always fresh prepared
Pansorbin:	was washed as described under 3.3.2.8
Destaining solution for SDS-PAGE:	50% methanol (technical grade) 10% acetic acid (technical grade) 40% H ₂ O

Cell lysates and media after metabolic labelling (see under 3.3.2.7) were thawed and put on ice. Cell lysates were then sonicated (30 sec at max) till complete homogenisation was achieved. Cell debris was removed by centrifugation for 5 min at 14000 rpm and clear cell lysates were transferred into new tubes. 0,8 volume precipitation immunomix (PIM) (480 µl to each media and 320 µl to each cell lysate) was added to each tube. To remove

genomic DNA, 1/100 volume of protamin sulfate solution was added to each tube of cell lysate and incubated on ice for 10 min with following centrifugation for 2 min at 14000 rpm. Clear lysates were transferred into new tubes. Afterwards 3µl of preimmune serum and 60µl of non-washed pansorbin were added to all tubes. Tubes were incubated on a lab – rotator for 6 h followed by centrifugation for 10 min at 14000 rpm. Clear liquids were transferred into new tubes without taking any pansorbin and 3µl of α-mouse cathepsin D antibody were added. Tubes were incubated on a rotator ON with slow rotation. 60µl of pre – washed pansorbin were added and tubes incubated for 1h with rotation. Tubes were centrifuged 10 min at 14000 rpm, supernatants transferred into new tubes and frozen at – 20°C. Pansorbin pellets were washed with 0,8 ml of:

- 1) neufeld buffer
- 2) wash-immunomix
- 3) KCl-immunomix
- 4) PBS (1:10)

; each time resuspended and centrifuged 1 min at 14000 rpm, the supernatant was removed with a peristaltic pump. The pellet was resuspended in 60µl of 2x stop buffer (see under 3.3.2.4) and incubated 5 min at 95°C to solubilize immunoprecipitated protein. Tubes were again centrifuged 3 min at 14000 rpm at RT and 35µl of the supernatants were loaded onto 12,5% SDS-PAGE. After electrophoresis (see under 3.3.2.4) the gel was soaked in destaining solution for 30 min with shaking on a rocker. The gel was then rinsed 3 times with water and left on a rocker for 5 min in water, placed between 2 cellophane sheets and dried for about 1,5 h. The dry gel was exposed with a phosphoimager – screen for 1-4 days and the image obtained was quantified using the Image Gauge software (Fuji).

3.3.2.10 Degradation of long – live proteins by mouse hepatocytes

To estimate rates of autophagocytosis in control and mVti1b deficient cells an in-vivo labelling with [¹⁴C] – valine was applied.

Krebs-Heinseleit buffer:	SIGMA, Deisenhofen add 2,1g/L NaHCO ₃ to solution, store at 4°C
RPMI medium:	GIBCO BRL, Eggenstein 5% FKS dialysed, heat inactivated

Mouse hepatocytes were isolated as described under 3.3.1.4. Each time 6 plates of control and 6 plates of *Vti1b* deficient hepatocytes cultivated overnight were taken for an experiment. Cells were washed with PBS once to remove dead cells and incubated in 1ml [¹⁴C] – valine RPMI medium for 24h (0,63μCi/ml). The medium was removed and cells were washed twice with Krebs-Heinseleit buffer to remove radioactive valine in the medium. Two plates were then incubated for 1h with 1 ml of Krebs-Heinseleit buffer + 0,1% BSA + 15 mM “cold” valine to induce autophagocytosis because of the removal of serum and four plates were incubated same time with 15 mM non-radioactive valine containing RPMI medium. After finishing of the 1h chase period, media were collected to compare how fast short-live proteins were degraded in both groups of cells studied. New portions of buffer and medium were added to the plates. Cells were incubated with Krebs-Heinseleit buffer for 3h more, medium was then collected and cells were scraped up in 500μl of PBS + 0,1% Triton X-100. Two plates were incubated with non radioactive valine medium for 11h and two plates for 23h, medium was then collected and cells were scraped off in 500μl of PBS + 0,1% Triton X-100. Soluble radioactivity was separated from insoluble via TCA precipitation. 1/5 volume of 50% TCA (trichloroacetic acid) were added to collected media and cells and mixed. After 10 min of incubation on ice, precipitates were separated from supernatants after 10 min centrifugation at 14000 rpm, 4⁰C. Pellets were solubilised in 500μl of 500 mM NaOH solution. All soluble and insoluble radioactivity was counted in a scintillation counter and protein degradation was expressed as % of soluble radioactivity in relation to total radioactivity.

3.3.2.11 Immunofluorescent localisation of proteins

For comparison of protein distribution in MEF and cultivated hepatocytes an immunofluorescent localisation was done on control and knock-out cells.

Mouse embryonic fibroblasts were plated on coverslips about 3-4 days before experiment so, that on a day of experiment cells were almost confluent. Hepatocytes were plated in an amount of $1,5 \times 10^5$ cells per coverslip (see under 3.3.1.4).

Table 6: Antibodies dilutions for immunofluorescent protein localisation

Protein	Primary antibody dilution	Secondary antibody type	Secondary antibody dilution	Method of fixation
Cathepsin D, murine	1:100	α -rabbit	1:200	methanol
Lamp1, murine	1:200	α -rat		methanol
Lamp2, murine	1:200	α -rat		methanol
MPR-46, cytoplasmic domain	1:100	α -rabbit		PFA
mVti1a	1:400	α -rabbit		PFA
mVti1b	1:400	α -rabbit		PFA
Syntaxin 7	1:200	α -rabbit		PFA
Syntaxin 8	1:200	α -rabbit		PFA
γ -adaptn	1:100	α -mouse		methanol

Paraformaldehyde (PFA) fixation method for immunofluorescent localisation:

Cells were washed once with PBS at RT and incubated for 30 min with 3% PFA in PBS. Fixed cells were washed twice with PBS and blocked with 50mM NH₄Cl solution in PBS for 10 min. Then cells were permeabilised with 0,05% Triton X-100 in PBS and blocked with 1% BSA in PBS solution. Primary antibodies were diluted as indicated in table 6 in 1% BSA – PBS and 15 μ l of the solution was dropped onto parafilm. Coverslips were taken out from a 24 –well culture plate with tweezers and turned upside down onto the antibody solution. Cells were incubated in that way for 1h in a humid dark chamber and then returned to the 24-well plate (turned again, so cells were always exposed to the solution). Coverslips were washed with PBS 3 times for 5 min and incubated with 10% goat serum in PBS for 20 min. Secondary antibodies (Cy2, Cy3, FITC or TR-conjugates) were diluted as indicated in table 6 and coverslips were incubated with 15 μ l of the appropriate solution in a humid dark chamber like it was done before with the primary antibodies. Cells were then washed 5 times for 5 min with PBS and rinsed 3 times with

water. Fully treated coverslips were mounted into a special mounting medium (DAKO®, Carpinteria, CA) and left ON at RT to solidify the mounting medium.

Methanol fixation method for immunofluorescent localisation:

Cells were washed twice with pre-warmed at 37⁰C PBS + 5mM glucose and put on ice. One washing step more with ice-cold PBS was done before cells were fixed with -20⁰C methanol for 5 min. Coverslips were then washed twice with PBS-glucose at RT and twice with PBS at RT. After that cells were blocked with 1% BSA in PBS solution.

Incubation with diluted primary antibodies as well as all later steps were done as described above for the PFA fixation method.

3.3.2.12 FITC-dextran uptake by mouse embryonic fibroblasts (MEF)

Control and mVti1b deficient MEF were grown on coverslips till they almost reached confluence. FITC-dextran (MW=14000) solution (100mg/ml) was thawed and spun down for 15 sec at 13000 rpm, 4⁰C. The supernatant was used for the experiment. 2,8 ml of DMEM supplemented with 10% FKS were mixed with 56 µl of the supernatant. 200µl of the mixture obtained was used to cover cells and they were put immediately into an incubator at 37⁰C for 1h (pulse). After the FITC-dextran incubation cells were washed once with PBS at 37⁰C and kept for the chosen chase periods with DMEM at 37⁰C.

Following chase periods were done afterwards:

- 1) 0 min
- 2) 30 min
- 3) 1h
- 4) 2h

The cells were then fixed with 3% PFA in PBS for 30 min at RT, washed twice with PBS, rinsed with water and mounted in DAKO® medium (see 3.3.2.11)

3.3.2.13 Endocytosis of fluorescently labelled LDL

Vti1b deficient and control MEF were grown on coverslips till they were almost confluent. Cells were washed twice with PBS to remove dead cells and FKS from the medium and incubated with serum-free DMEM supplemented with 1% BSA for 2h at 37⁰C (starvation). Starvation medium was then replaced with DMEM + 1% BSA + 10µg/ml fluorescently labelled low-density-lipoprotein (BODIPY®, Molecular Probes, USA) and cells were put

on ice for 90 min (receptor binding). Cells were washed with PBS at RT twice and incubated for following chase periods at 37⁰C in DMEM + 1% BSA:

- 1) 0 min
- 2) 15 min (fluorescent signal in lysosomes)
- 3) 30 min (fluorescent signal in lysosomes)
- 4) 1h (partial degradation was expected)
- 5) 3h (complete degradation was expected)

After finishing of each chase period coverslips were washed twice with PBS at RT, then fixed with 3% PFA in PBS for 30 min at RT, washed twice with PBS, rinsed with water and mounted in DAKO® medium (see 3.3.2.11).

3.3.2.14 Epidermal growth factor receptor (EGF-R) uptake and degradation in MEF and cultivated hepatocytes

Background information:

EGF is known to be endocytosed together with its receptor, which is then transported to lysosomes for degradation.

Starvation medium for MEF:	DMEM + 1% BSA, without FKS
Starvation medium for hepatocytes:	RPMI + 1% BSA, without FKS
Lysis – buffer:	0,1% (w/v) Triton X-100 1 mM PMSF 1 mM EDTA 5 mM JAA in TBS pH 7,4
Epidermal growth factor (EGF), murine	sterile 100 µg/ml stock solution in H ₂ O, Calbiochem, Frankfurt
rabbit α EGF-R antibody:	200µg/ml, 1:200 dilution, Santa Cruz Biotechnology Inc. ;1:10000 dilution of secondary antibody

Mouse embryonic fibroblasts were plated on 3 cm plates so that on the day of the experiment they were confluent. Hepatocytes were plated at 6,5x10⁵ cells per 3 cm plate (see 3.3.1.4). 6 control and 6 “knock-out” plates were used for each experiment.

On the day of the experiment, cells were washed twice with 1 ml of starvation medium and left in same medium at 37⁰C for 1 h (starvation). One experiment was done with starvation for 2h resulting in more strong EGF-R signal. Two control and two “knock-out” plates were then put on ice for collecting the cells, which have the starting amount of EGF-R.

Medium was replaced with medium containing 500 ng/ml (for MEF) or 100 ng/ml EGF (for hepatocytes) and cells were left in an incubator at 37°C for different chase periods:

2h

4h

After finishing of every chase period, plates were put on ice, washed twice with cold PBS and scraped off in 2x200 µl of lysis buffer. Cell lysates were frozen at -20°C till use for determination of the protein concentration (see 3.3.2.2). 100µg protein was separated by an SDS-PAGE using a 5% gel (3.3.2.4), western blotting (3.3.2.5). Western blots were incubated with anti-EGF-R antibodies and protein bands were visualised after using ECL assay in the CCD-camera. Bands were quantified using AIDA software (Fuji). Finally EGF-R degradation rate was expressed in % of intensity of the band after the chase in comparison to its starting amount (0 min) after detection of EGF-R bands in ECL assay (3.3.2.6)

3.3.2.15 Uptake and degradation of ¹²⁵I-asialofetuin in mouse hepatocytes

(modified from Tolleshaug et al.(Tolleshaug et al. 1977))

Background information:

The asialoglycoprotein receptor (ASGR) expressed in hepatocytes allows for the endocytosis of asialoglycoproteins within short periods of time. ASGR is then recycled back to the plasma membrane whereas endocytosed material is transported to lysosomes for degradation. Iodinated asialofetuin is used in this assay as tracer of endocytosis, lysosomal delivery and degradation. Upon measuring of the soluble radioactivity in medium and cells, rates of lysosomal degradation can be calculated as percents of total radioactivity.

Iodination of asialofetuin:

Elution buffer	0,1%KJ, 0,05% BSA in PBS
NAP-column (Pharmacia):	Equilibrate with 30 ml of elution buffer
IODO-Gen® pre-iodinated tubes	PIERCE, Rockford, IL, USA
Na ¹²⁵ I	Amersham- Buchler, Braunschweig
Asialofetuin	Sigma, Diesenhofen

One mg/ml of asialofetuin was dissolved in PBS and 64 μ l (64 μ g = 1 nmol) were diluted with 186 μ l PBS. The obtained solution was loaded onto the bottom of a IODO-Gen® tube and 1 μ l (100 μ Ci) of Na¹²⁵I was added under a fume hood. The tube was incubated at RT for 15 min with careful flicking. After incubation the radioactive mixture was removed from the IODO-Gen® tube and transferred into an eppendorf tube containing 250 μ l of elution buffer. The obtained mixture was loaded onto a NAP-column, rests of the mixture from eppendorf tube were diluted with 500 μ l of elution buffer and also loaded onto the column. The protein was eluted in 10x 500 μ l of elution buffer with collecting all 10 fractions in separate tubes. Two μ l of each fraction were measured for radioactivity in γ -counter. In our case fractions 7 and 8 contained the desired radioactive asialofetuin. These fractions were pooled and used for the uptake assay. Labelled asialofetuin solution was stored at 4⁰C for up to four weeks.

Uptake and degradation of labelled asialofetuin by adherent hepatocytes:

Hepatocytes were prepared as described in 3.3.1.4. Eight plates of each type, control and Vti1b deficient hepatocytes were used. Cells were washed twice with RPMI without FKS supplemented with 0,1% BSA and starved in that medium for 4h. Starvation medium was replaced with new starvation medium containing 10pmol/ml of ¹²⁵I-asialofetuin (1:100 dilution of labelled solution, 6 μ l in 600 μ l of medium for each plate). Two 600 μ l aliquotes of radioactive medium were pipetted into separate tubes for control of background degradation of asialofetuin in the medium. The first tube was placed on ice immediately and second one after the end of the last chase period. All plates were exposed to the radioactive medium for 20 min (pulse). After the end of the pulse period, plates were washed once with 1ml non-radioactive medium and supplemented with 600 μ l of new medium. The following chase periods were started:

0 min

30 min

60 min

120 min

Two control and two Vti1b knock-out plates were used for each time point. After the end of the chase period, medium was collected in separate tubes and plates were washed twice with PBS. Cells were scraped off in 500 μ l of PBS+0,2% Triton X-100 and lysates were transferred into screw cup tubes. The collected medium and cell lysates were precipitated

with 10% TCA for 10 min on ice. Soluble and insoluble radioactivity was separated by centrifugation at 14000rpm, 4⁰C and supernatants were transferred into new tubes. TCA pellet were dissolved in 500μl of 0,5M NaOH. The radioactivity of all obtained probes was then measured in γ-counter. Degradation of asialofetuin was calculated as % of the sum of soluble radioactivity in the medium and cells compared to the sum of soluble radioactivity and the insoluble radioactivity in the cells.

4 Results

4.1 Generation of *Vti1b* deficient mice

4.1.1 Isolation of genomic DNA for *Vti1b*, characterisation of *Vti1b* chromosomal region and construction of a targeting vector

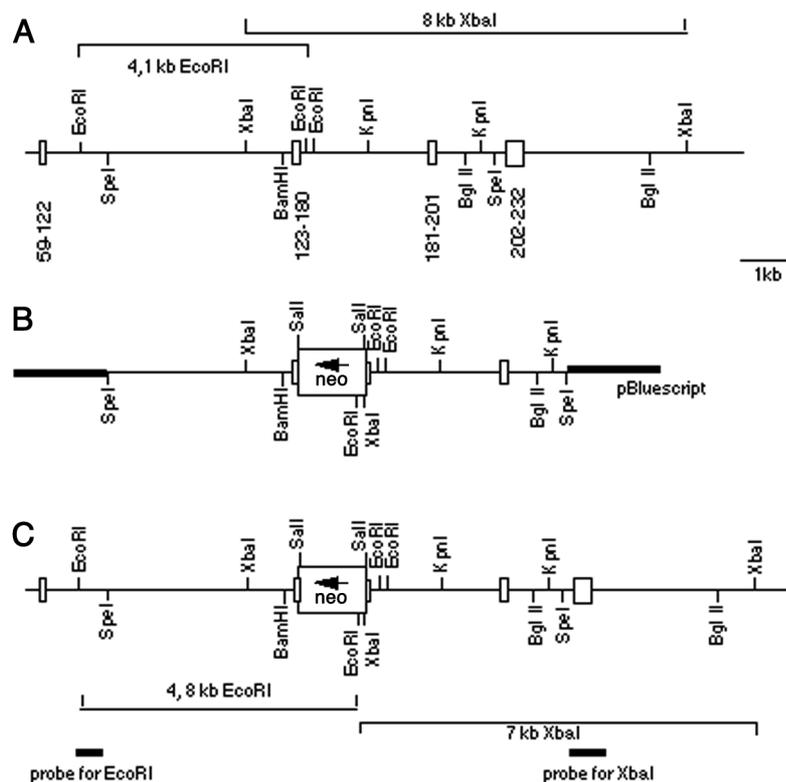

Figure 8: Schema of *Vti1b* genomic sequence, targeting vector and the screening strategy for detection of positive ES clones. A) m*Vti1b* genomic sequence; B) targeting construct; C) strategy for detection of positive ES cell clones using DNA hybridisation techniques

An EST (express sequence tag) clone (Genebank accession number AA105524) was purchased from American Type Culture Collection (ATCC). The clone “235” contained the whole coding sequence of m*Vti1b*, 70bp 5`untranslated region and 200bp 3`untranslated region as cDNA in a pCMV-SPORT2 vector. The insert was cut out by Sall+NotI digestion and used as DNA probe for screening of a λ -phage mouse genomic DNA library of the strain Sv129 Ola as described under 3.2.7.2, 3.2.7.3 and 3.2.7.4. One phage clone was detected (“phage A”), its DNA amplified and the 15 kb mouse DNA insert was cut out of the phage vector using NotI. This chromosomal DNA fragment was subcloned into the

pSK⁺ Bluescript vector and mapped. A simplified map of the mVti1b chromosomal region is shown in fig.8

The obtained mVti1b chromosomal DNA fragment contains 4 exons, starting from the exon encoding amino acids “59-122” and ending with the exon encoding the C-terminal amino acid residues 202-232 and the 3` untranslated region. The exon “123-180” encodes part of the SNARE motif that is crucial for Vti1b function. Disruption of the exon “123-180” by the Neo-cassette would prevent synthesis of Vti1b protein even in the unlikely case that the resulting mRNA is stable. The subcloned 7 kb-long SpeI DNA fragment containing the exon 123-180 was used for making a targeting construct. A SalI- endonuclease recognition site was introduced into the exon “123-180” by site-directed mutagenesis and a targeting vector constructed by inserting the Neo-cassette into this site. The construct has 3,5kb DNA for homological recombination on each side of the exon interrupted by the Neo-cassette. Sequences on both sides of the SpeI fragment were known from phage mapping and used for design of DNA probes. The plasmid pVA₁₂ was obtained by SpeI shrinking of the plasmid pVA₄ containing the complete 15kb of the phage DNA insert. pVA₁₂ contains the first part of the phage with exon 59-122 til the first SpeI site. The 5` external probe “EcoRI-derived probe” consists of a 400bp fragment obtained by restriction digestion of the pVA₁₂ DNA with EcoRI. pVA₇ contained exon “202-232” inside of a 3,2kb BglII DNA fragment from phage A . Using oligonucleotides CCATGAATTGTCACTGTCC as forward and CAAGCTATTAATGTTATACATG as reverse primers and pVA₇ as template the 3` external probe “XbaI PCR probe” was obtained by PCR and has 490bp in length. The targeting vector was transferred into embryonic stem cells (E-14) via electroporation. Selection of transformants was done using Gentamycin 418®.

4.1.2 Obtaining of Vti1b null mutants

Isolated DNA of each transformed ES-cell clone was digested with EcoRI and loaded onto 0,7% agarose gels and southern-blots were obtained. Using DNA hybridisation techniques all clones were checked for homologous recombination with the “EcoRI-derived probe”. The probe recognises a 4kb wild-type EcoRI fragment and a 4,8kb mutant one because of the presence of an EcoRI site inside of the Neo-cassette. DNA of clones turned out to be positive (8) in that screening was checked for homologous recombination again using XbaI

digestion. “XbaI PCR probe” detects an 8kb wild-type XbaI fragment and a 7kb recombinated one because of the presence of a XbaI site at the beginning of the coding region for the Neo-cassette.

7 clones were double positive out of 96 clones analysed (see fig. 9). These clones had homologous recombination in the *Vti1b* locus. Clones 114 and 177 were used for blastocyst microinjection.

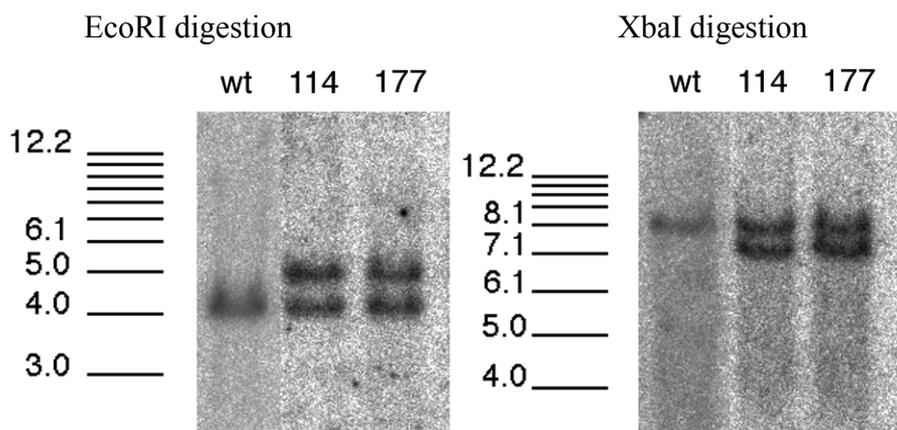

Figure 9: Analysis of ES mutant cells Clones 114 and 177 have one wild type and one mutant copy of *Vti1b*

Two male mice with 50-60% of chimerism were obtained after injection of clone 114. These chimeras were used for crossing with C57BL females to obtain F1 generation with mice heterozygote for the mutant *Vti1b* locus. To check for their genotype, a PCR strategy was developed (fig. 10).

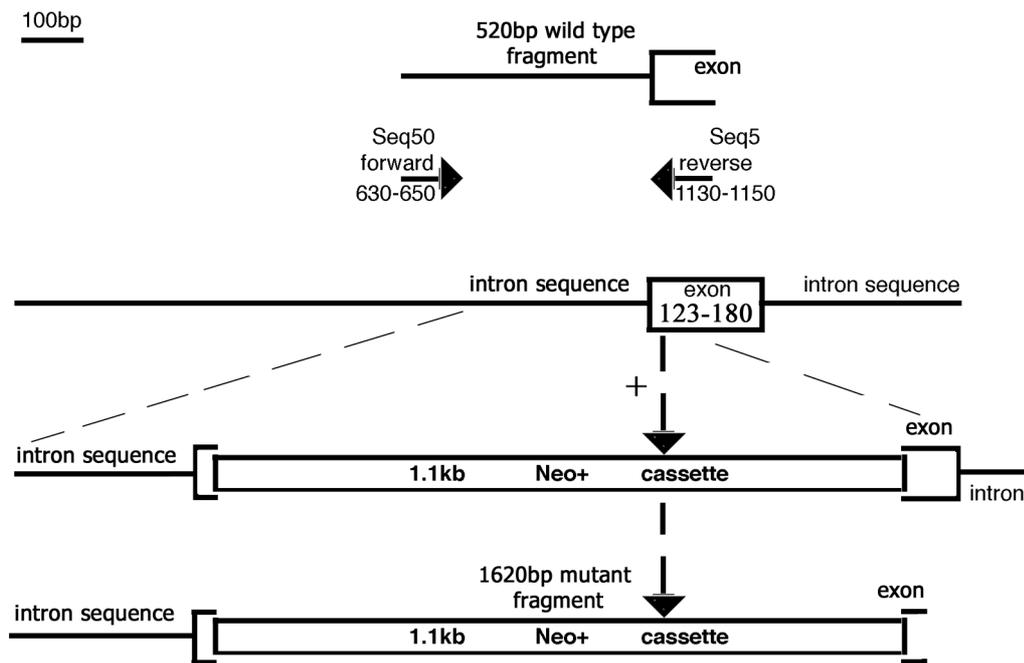

Figure 10: PCR strategy for determination of wild type and *Vti1b* mutant genotypes

Primers Seq5 and Seq50 (nucleotide sequences are CTCTTCTATGATTTCTGTACC and GAGGGATCCAATACCTTCTC respectively), amplifying a 520bp fragment of the wild type genomic region including exon 123-180 and a 1620 bp fragment of the mutated *Vti1b* region were used for routine PCR analysis (fig.11). In addition, a 375bp fragment derived from the neo-gene was amplified using primers AK30 and AK31 (nucleotide sequences are CCGATCAAGCGTATGCAGCCG and CAAGATGGATTGCACGCAGG respectively).

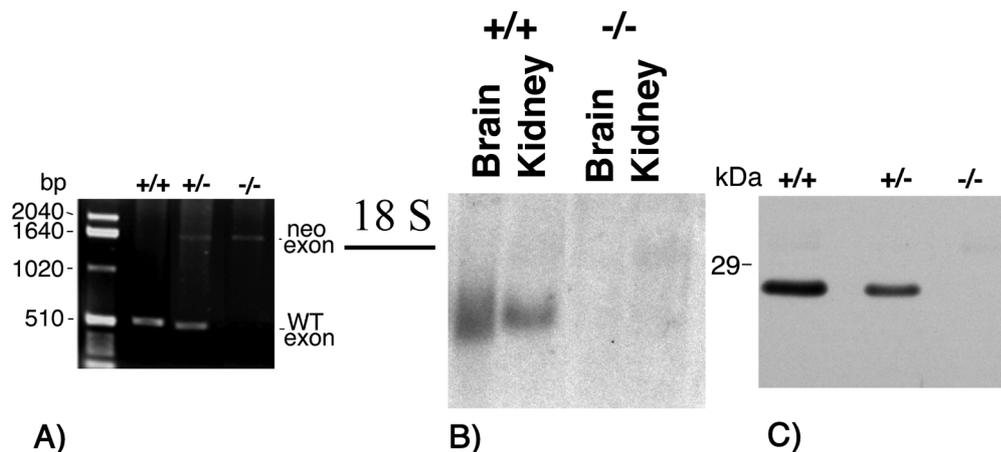

Figure 11: *Vti1b* mRNA and protein is missing in *vti1b* -/- cells

A) PCR analysis of genomic DNA using seq5 and seq50 oligos; B) northern-blot analysis of *Vti1b* mRNA using probe "235"; C) western-blot analysis of MEF protein extracts using *Vti1b* antibodies

After crossing of heterozygous F1 mice, homozygous mVti1b deficient mice were obtained.

Vti1b deficiency was inherited with almost mendelian distribution. 24,8% wild type mice, 55,3% heterozygote and 19,9 % homozygote Vti1b deficient mice (expected would be 25%) were detected among 226 mice from 24 litters. An interruption of exon “123-180” with the Neo-cassette resulted in total loss of Vti1b mRNA (fig 11). Moreover, a total loss of Vti1b protein was seen in deficient fibroblasts by western-blot with anti-Vti1b antibodies. Reduced levels of Vti1b protein was observed in heterozygous mice because of a gen-dosis effect (fig 11).

4.2 Analysis of *Vti1b* deficient mice

4.2.1 The phenotypic manifestation of *Vti1b* deficiency

Vti1b deficient mice were viable and fertile. The phenotype of *Vti1b* deficient mice was heterogenous, there were mice of normal size and small ones (fig 12).

From 162 deficient mice 28 ones became small, that is 17,3%. These mice were of normal size during the first two - three weeks after birth. At the age of 3 weeks (this period corresponds to changing from mother-milk to self-dependent feeding) these mice have a critical point of their life and some of them die (fig 13 A).

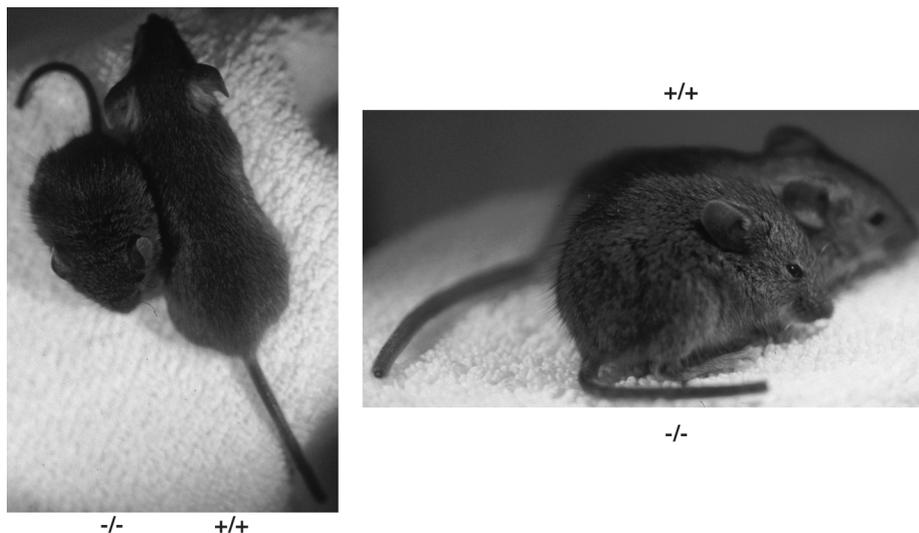

Figure 12: Some *Vti1b* deficient mice are smaller

In that period 6 deficient mice died that is 3,7% of the *Vti1b* knock-outs. Altogether, one newborn and 8 small *Vti1b* knock out mice were found dead after different periods of postnatal development. Some mice lost weight in that time period and stayed smaller than their litter mates (fig 13 B). The small mice were fertile and had both small and normal size descendants.

Some *Vti1b* deficient mice had different pathologies of internal organs. Three small knock-out mice had abnormally big gallbladders (fig 14). One of them had an obstruction of the colon. One small deficient mouse had multiple liver cysts, of up to 3cm of size. One deficient mouse of normal size had gall stones. Another *-/-* mouse of normal size was killed at an age of 16 months because it looked sick.

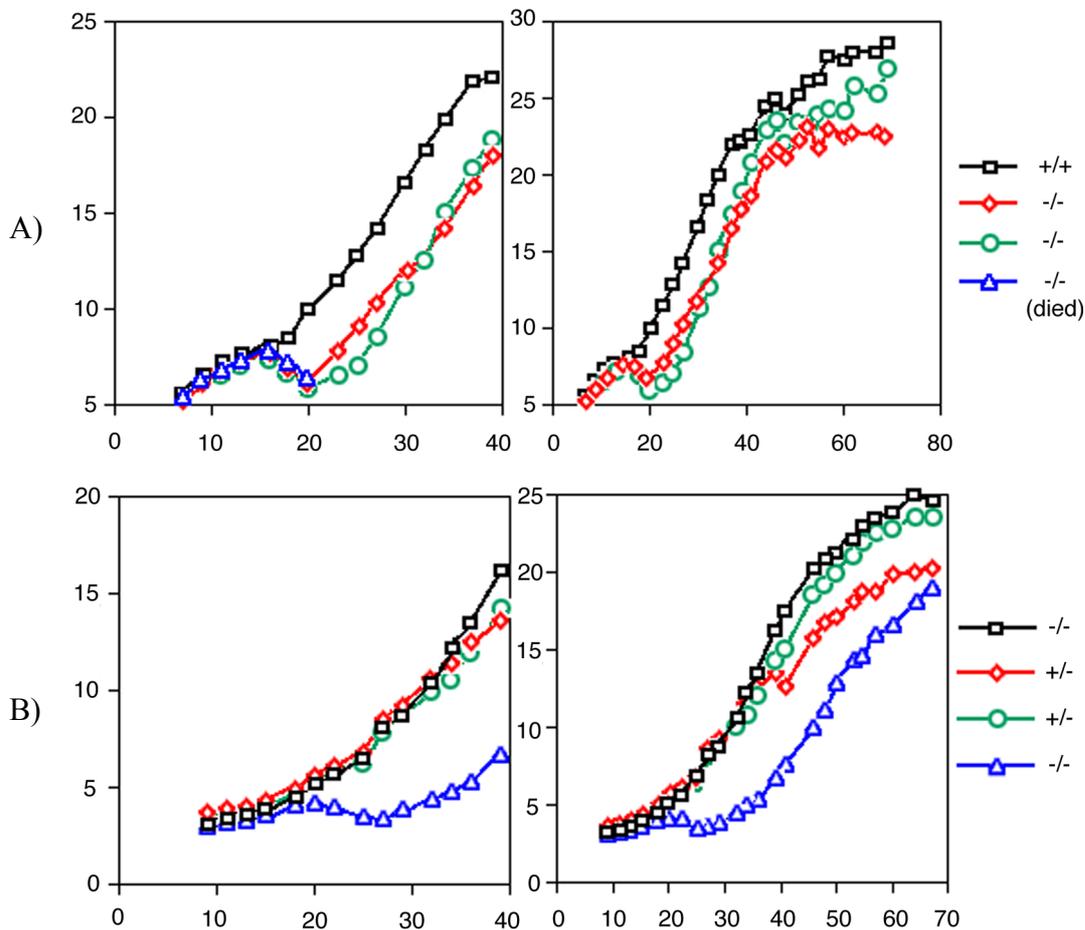

Figure 13: Growth of *Vti1b* litter/mates

X axis represents age in days, Y axis – weight in grams. A) Some small *Vti1b* deficient mice die when they are 3 weeks old. B) Development of surviving small mouse.

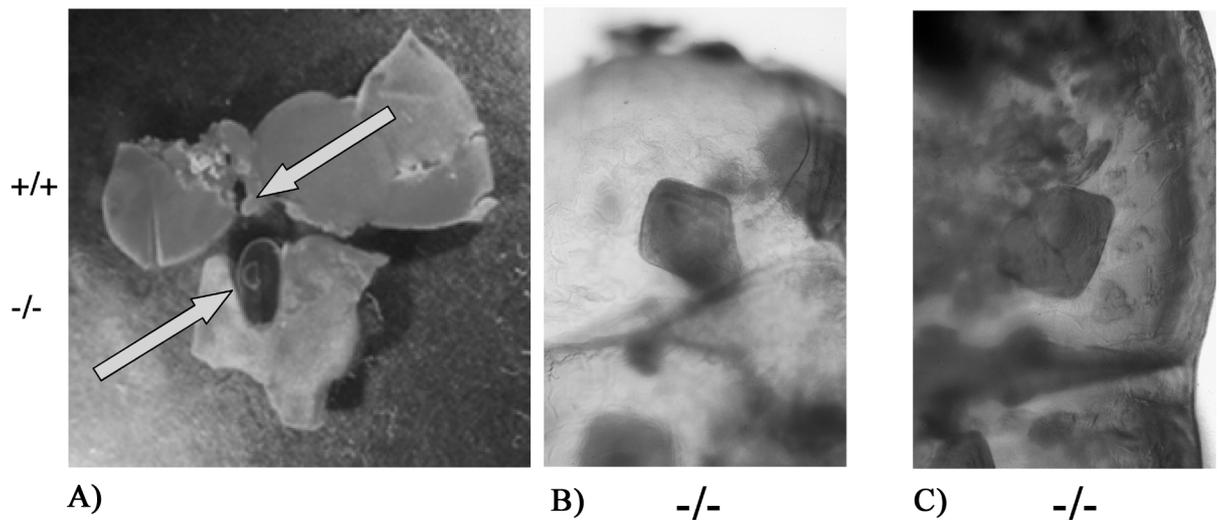

Figure 14: Gallbladder abnormalities in a few Vti1b deficient mice

A) Arrows (left) indicate gallbladder of wild type and Vti1b knockout mouse; B) and C) Gall stones of normal size Vti1b deficient mouse

It had an abnormally shaped gallbladder, splenomegaly and the stomach, appendix, intestines were abnormally enlarged and filled. No wild-type mice examined in parallel had any visible pathologies.

4.2.2 Immunofluorescent localisation of different proteins in mouse embryonic fibroblasts

Mouse embryonic fibroblasts (MEF) were obtained from embryos of day 13,5. Experiments were started after 4 passages. Morphologically Vti1b deficient fibroblasts were indistinguishable from wild type MEFs. Both cell types reached confluency at similar rates. To check if the patterns of distribution of several SNAREs, lysosomal and receptor proteins were changed in knock-out cells, immunofluorescent microscopy was performed. Vti1b in control cells was localized to the perinuclear area and extended into the periphery of the cell. No Vti1b staining was observed in deficient cells (fig 15 B).

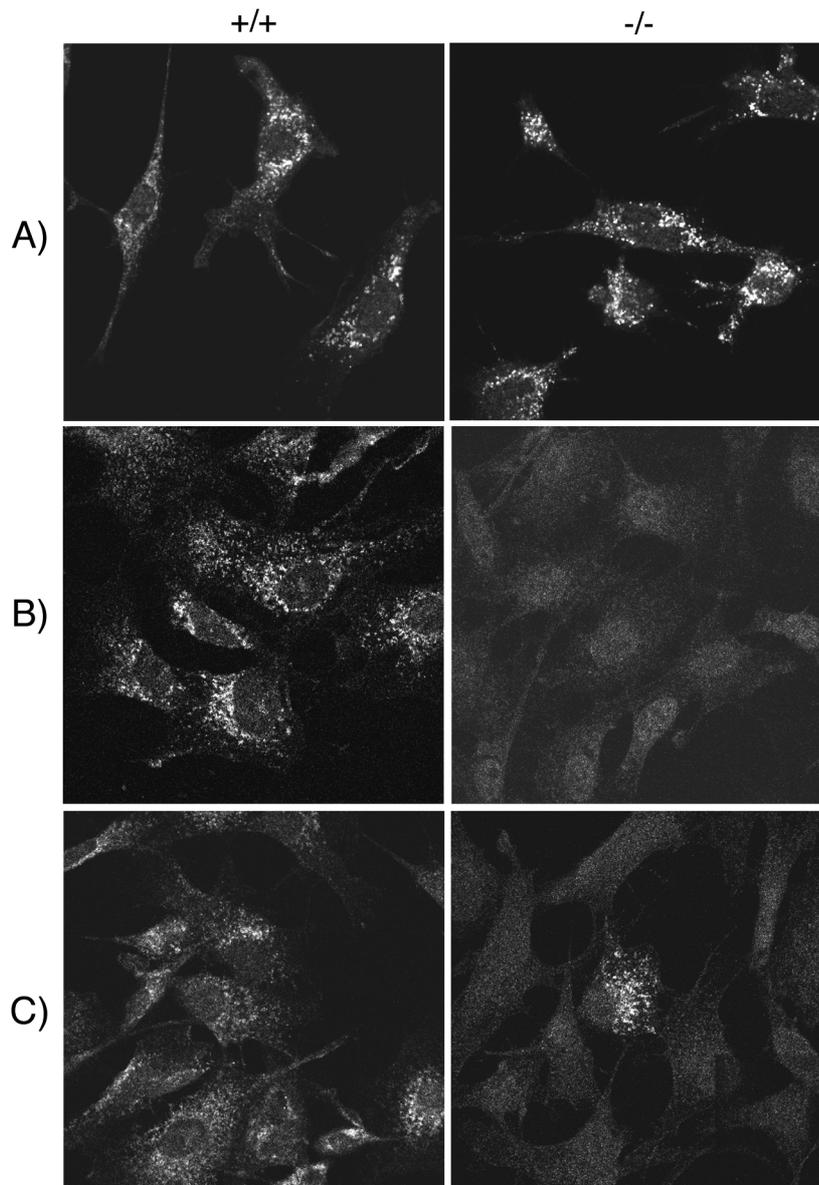

Figure 15: Immunofluorescent localisation of LIMPII, Vti1b and syntaxin 8 in wild type and Vti1b deficient MEF

A) Similar distribution of LIMPII; B) Vti1b staining in wild type cells and no signal in Vti1b knockout MEF ;C) Low levels of syntaxin-8 in Vti1b $-/-$ embryonic fibroblasts

Vti1a was found on perinuclear structures in both cell types compared (not shown). MPR-46 antibodies stained parinuclear area and many vesicular structures throughout cytoplasm. LAMP1, LAMP2, LIMPII showed similar patterns marking distributed vesicular structures. Vti1a, LAMP1, LAMP2, LIMPII and MPR-46 showed distributions in Vti1b $-/-$

cells very similar to that of wild type cells. Figure 15 A) illustrates the similar staining for LIMPII indicating that lysosomal morphology is not affected in *Vti1b*^{-/-} MEF.

By contrast, syntaxin-8 had low levels of fluorescent staining in deficient MEFs. Figure 15 C) shows staining of *Vti1b* deficient and wild type cells with syntaxin-8 antibodies. As syntaxin-8 forms a SNARE complex with *Vti1b* this indicates that the absence of *Vti1b* may destabilise its SNARE partner.

4.2.3 Immunofluorescent localisation of different proteins in cultivated hepatocytes

Hepatocytes of normal size *Vti1b* deficient and wild type mice were cultivated for one day and also used for localisation of several proteins using different antibodies (Fig16)

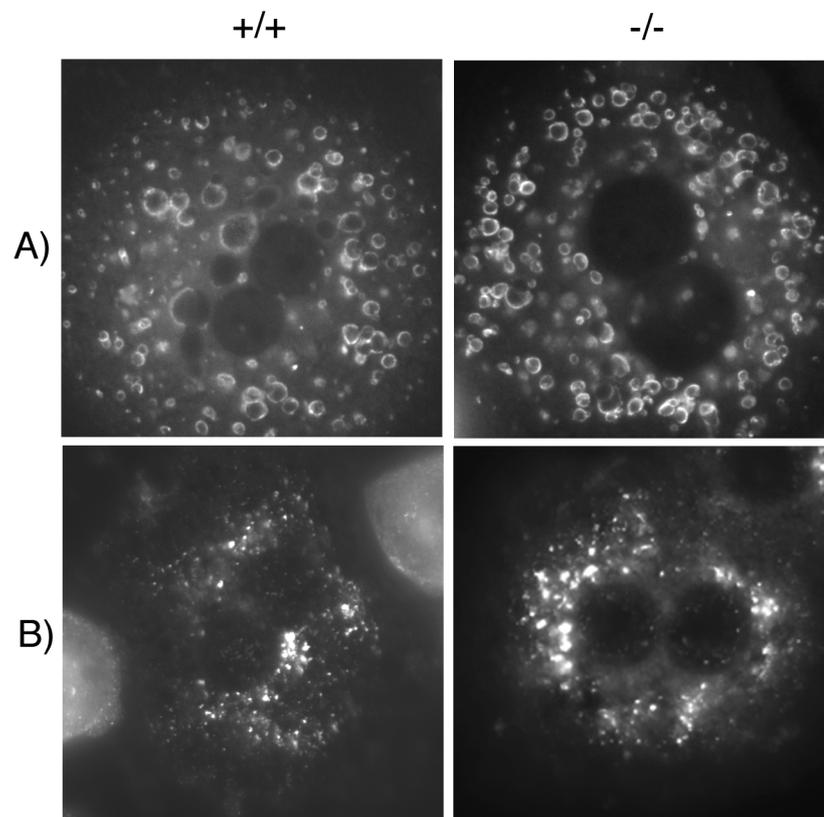

Figure 16: Localisation of adipophilin and MPR-46 in hepatocytes isolated from wild type and normal size *Vti1b* deficient mice A) Staining with anti-adipophilin antibodies; B) Staining with anti- mannose 6-phosphate receptor antibodies

LAMP1, LAMP2 containing structures were stained similarly (fig 17 B) or were slightly enlarged in cells of *Vti1b*^{-/-} mice. The soluble lysosomal hydrolase cathepsin D (fig 17 A)

colocalised with LAMP1 and LAMP2 in both $-/-$ and $+/+$ hepatocytes (not shown). MPR-46 and LAMP1 did not colocalise with each other (not shown).

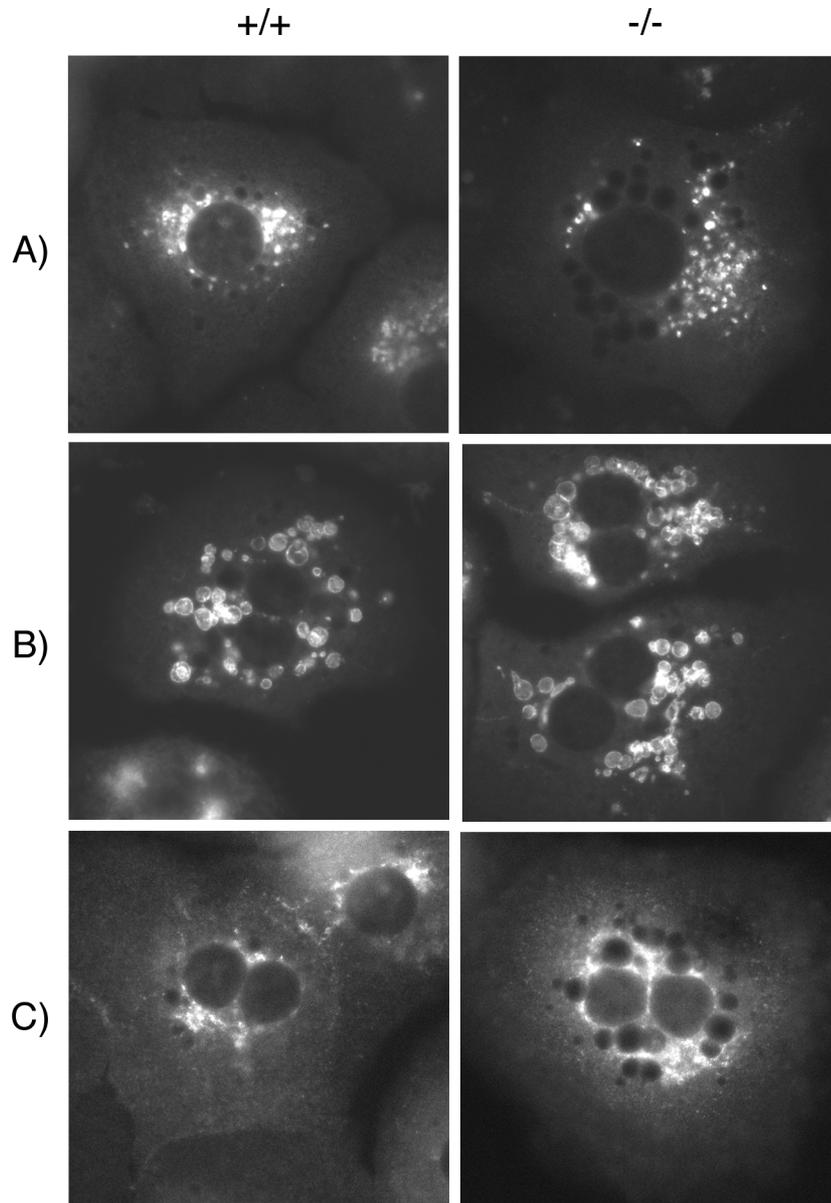

Figure 17: Localisation of cathepsin D, LAMP1 and γ -adaptin in hepatocytes isolated from wild type and normal size *Vti1b* deficient mice A) Cathepsin D antibodies; B) LAMP1 antibodies; C) γ -adaptin antibodies

Similar distribution of the TGN protein γ -adaptin was seen in cells of both genotypes (fig 17 C). The number and size of lipid droplets which were stained by neutral lipid dye Nile red or by adipophilin (fig 16 A), a marker protein of lipid-containing vesicles, had

probably no connection to the absence of Vti1b and was dependent on stored body fat. The more fat mice had on their internal organs, the more and bigger structures stained with adipophilin antibodies were seen in cells of both genotypes. The absence of Vti1b did not alter distribution of the examined lysosomal, TGN and late endosomal proteins in hepatocytes of normal size Vti1b deficient mice.

4.2.4 Activities of lysosomal enzymes in serum and organs of these mice

Activities of lysosomal hydrolases were determined in serum and organ homogenates of control and Vti1b deficient mice. Calculation of these activities in blood serum is shown in table 7:

Table 7: Activities of lysosomal enzymes in serum of Vti1b deficient and wild type mice

Lysosomal enzyme	Activity, mU/ml	
	Deficient mice n=4	Control mice n=2
β-Hexosaminidase	62,9±16,8	61,9±5,1
β- Galactosidase	0,5±0,1	0,6±0,1
β-Mannosidase	2,4±0,7	1,4±0,6
β-Glucuronidase	0,6±0,3	0,6±0,3

Numbers show average values ± standard deviation.

Activities of lysosomal hydrolases were measured in liver, brain, kidney and spleen homogenates at an age of 3 - 9 months. The activities were very variable for all analysed enzymes even within wild type mice.

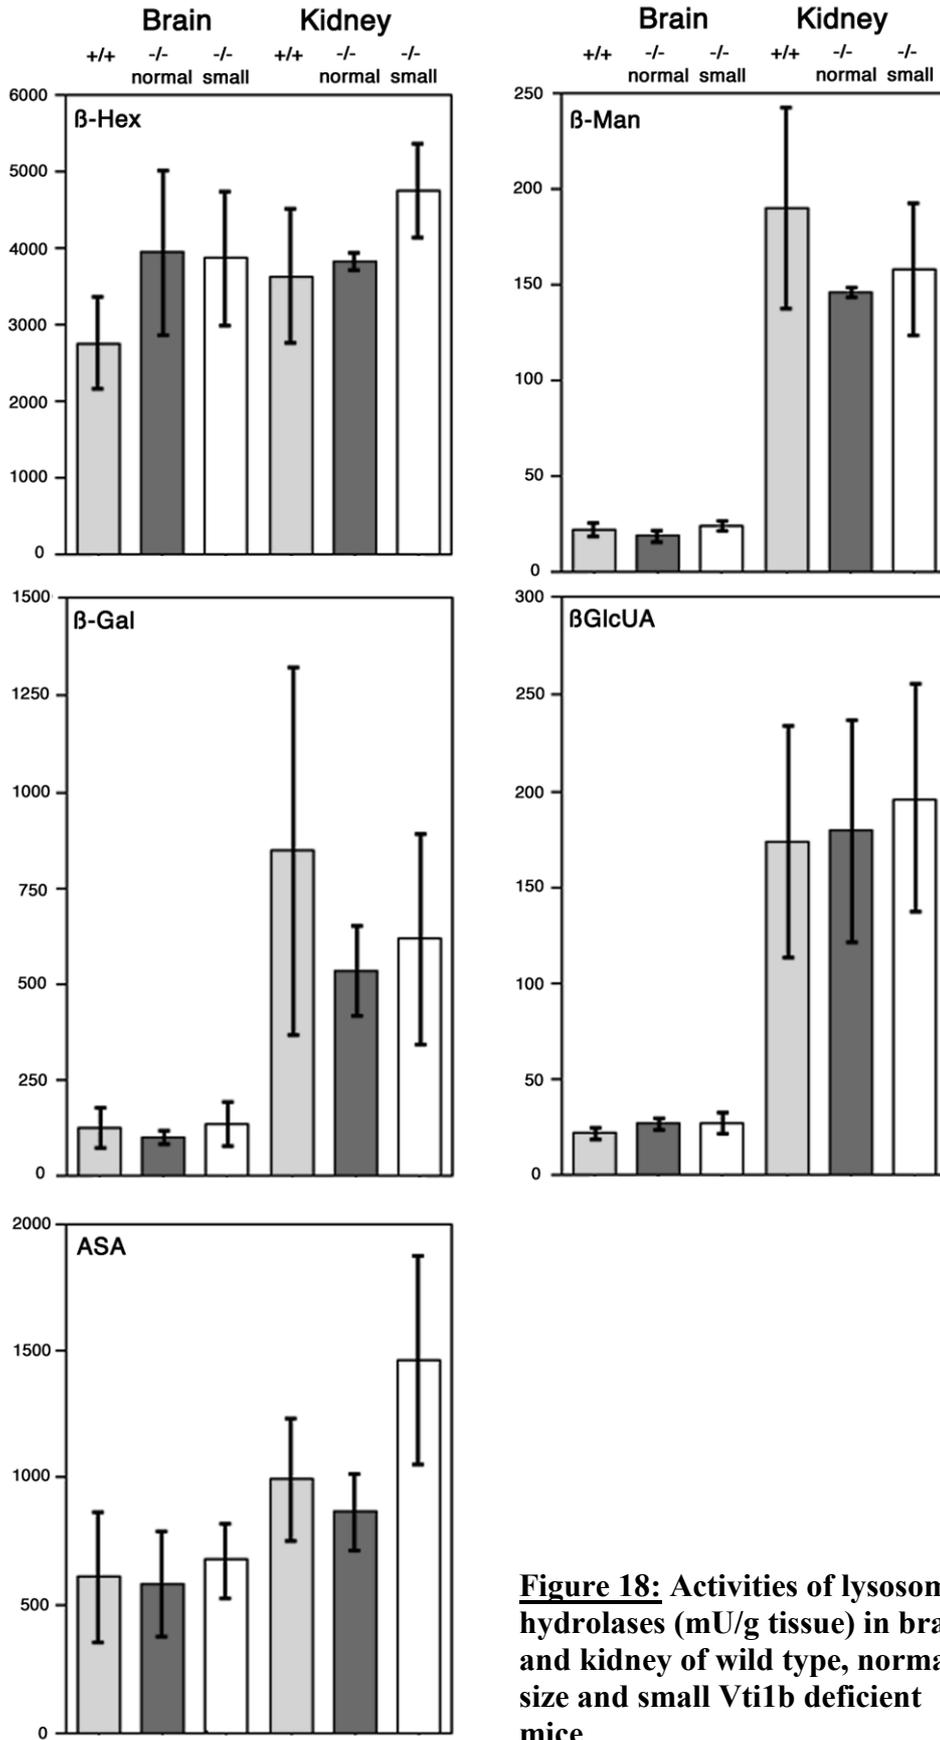

Figure 18: Activities of lysosomal hydrolases (mU/g tissue) in brain and kidney of wild type, normal size and small *Vti1b* deficient mice

Figure 18 shows that in brain and kidney activities of β -Hexosaminidase (β -Hex), β -Mannosidase (β -Man), β -Glucuronidase (β -GlcUA) and Arylsulfatase A (ASA) in Vti1b deficient mice in general stay within limits of control values. In liver and spleen activities of lysosomal enzymes also stay within limits of control values in case of normal size and small deficient mice. In a single case, lower β -Galactosidase activity of 118 mU/g in a liver of small Vti1b deficient mouse could be seen. The average control value for β -galactosidase in liver was 293 ± 133 mU/g, the activity of β -galactosidase in liver of normal size knock-out mice was 300 ± 229 mU/g. The activities of lysosomal enzymes did not increase or decrease significantly during lifetime of knock-out mice, as seen in Vti1b deficient and wild type analysed at an age of 9 months. MEF homogenates also showed very similar pattern of activities.

4.2.5 Levels of several proteins in Vti1b deficient cells and tissues

Expression of several proteins was compared in control and deficient cells and tissues to determine whether Vti1b deficiency had an influence on lysosomal and receptor protein levels. Cultivated MEFs and hepatocytes were homogenised and protein suspensions were separated using SDS-PAGE. The same was done for tissue homogenates.

LAMP1, LAMP2, LIMPII are equally abundant in cultivated MEFs as well as in liver, brain and kidney of control and Vti1b deficient mice. There was no obvious difference in the amount of these proteins in tissues between control, normal size knock-out mice and small knock-out mice (fig19).

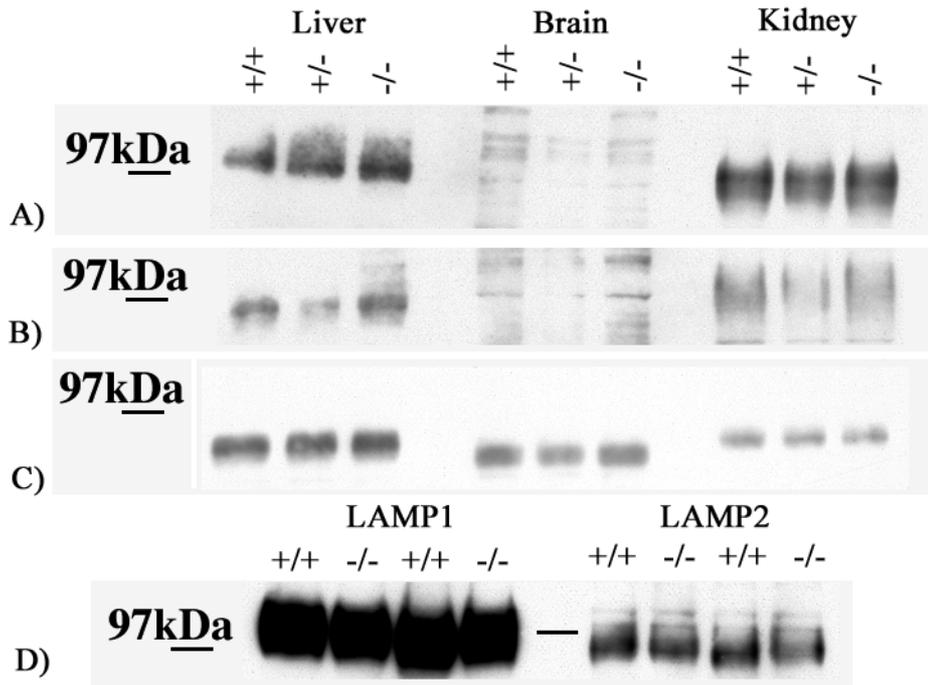

Figure 19: Levels of lysosomal proteins in control, heterozygote and *Vti1b* deficient tissues and MEFs A) LAMP1 antibodies used; B) LAMP2 antibodies used; C) LIMPII antibodies used; D) Levels of lysosomal proteins in wild type and *Vti1b* deficient MEFs

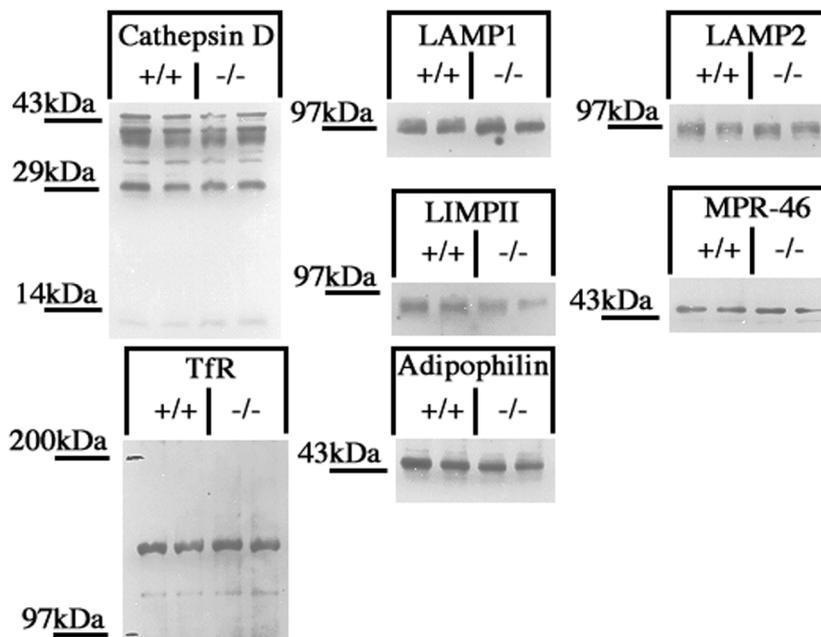

Figure 20: Analysis of the amounts of several lysosomal and receptor proteins in control and *Vti1b* deficient hepatocytes from normal size mice

The lysosomal proteins cathepsin D, LAMP1, LAMP2, LIMPII were equally abundant in wild type and *Vti1b* deficient hepatocytes. The same could be observed for MPR-46, transferrin receptor (TfR) and adipophilin, a marker protein of lipid droplets (fig 20). In summary *Vti1b* deficiency had no obvious effect on the levels of the analysed proteins in cells isolated from normal size mice.

4.2.6 Syntaxin 8 and other SNAREs expression in *Vti1b* deficient cells and tissues

Syntaxin 8 is a SNARE partner of *Vti1b* in a SNARE complex mediating fusion of late endosomes together with syntaxin 7 and endobrevin (Antonin et al. 2000a). The first indication that syntaxin 8 levels were affected in *Vti1b* deficient cells came from the immunofluorescence (4.1.5). In *Vti1b* deficient MEFs only a few cells showed a fluorescent signal after staining them with anti-syntaxin 8 antibodies (see fig.15C). The levels of the *Vti1b* SNARE partners were examined in control and *Vti1b* deficient tissue homogenates. Figure 21 shows that syntaxin 7 and endobrevin had amounts similar to control in *Vti1b* deficient tissues. On the contrary amounts of syntaxin 8 were reduced already in *Vti1b* heterozygous tissues. *Vti1b* deficient tissues had much less syntaxin 8 than *Vti1b* heterozygous tissues and of course wild type ones (fig 21). These results were in agreement with data of the immunofluorescence.

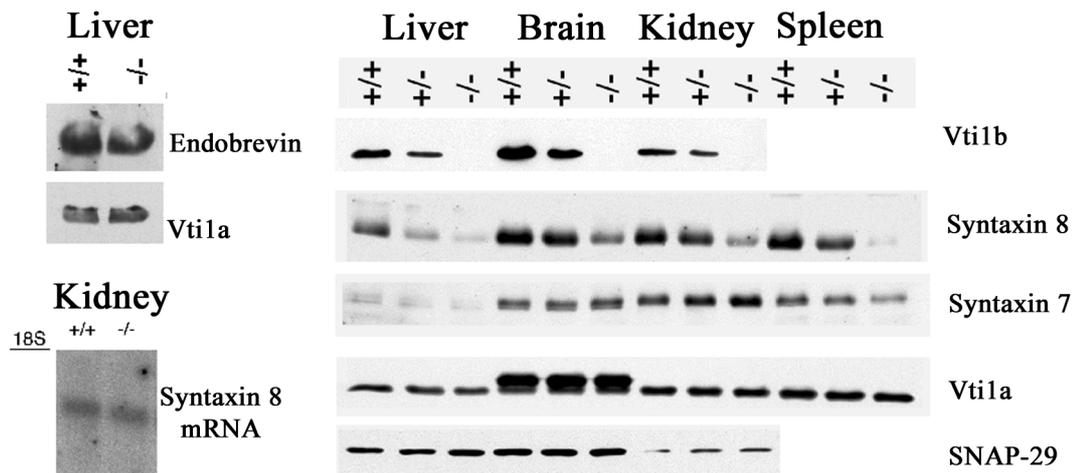

Figure 21: Levels of SNARE proteins in wild type, heterozygote and *Vti1b* deficient mice

Syntaxin 8 was a very long-lived protein. Even though syntaxin 8 could be immunoprecipitated the radioactive labelled form was not visible even after 4h in vivo labelling with [³⁵S]-methionine (not shown). Expression of syntaxin 8 mRNA was

unchanged in Vti1b deficient tissues (fig 21) compared to wild type tissues. Therefore a possible explanation for the low syntaxin 8 protein levels would be that the protein is degraded due to the absence of its complex partner Vti1b.

Vti1b deficient mice are viable and fertile. Most of these mice show no visible abnormalities in their postnatal development. An explanation for this lack of phenotype could be that some SNARE or SNAREs fulfil the function of the absent Vti1b and the reduced syntaxin 8 in tissues of knock-out mice. As Vti1b and Vti1a are homologues, the expression of Vti1a was checked in control and knock-out tissues. A second candidate for overtaking the functions of both Vti1b and syntaxin 8 in the late endosomal SNARE complex is SNAP-29, which has two SNARE motifs. Its expression was also checked in both control and knock-out mice. Results are shown in figure 21. The levels of these proteins stayed similar to control in deficient tissues. There was no visible difference in the amounts of Vti1a and SNAP-29 in control, normal size (not shown) and small Vti1b deficient tissues (figure 21). However this does not exclude their possible role in a functional compensation for Vti1b and syntaxin 8 deficiency.

4.2.7 Fluid-phase endocytosis in control and deficient MEFs

In order to get a deeper insight into fluid phase endocytosis along the endosomal/lysosomal apparatus in MEFs, the fate of internalised fluorescein isothiocyanate-labeled dextran (FITC-dextran) during constitutive fluid-phase endocytosis was studied. This fluid-phase and pH marker is taken up by cells without being absorbed to membranes and is not degraded inside lysosomes ((Thilo and Vogel 1980; de_Chastellier et al. 1983; Klein and Satre 1986). The fluid-phase internalisation is partially clathrin-mediated. Clathrin heavy chain-deficient mutants of amoeba *Dictyostelium discoideum* had a 90% reduced fluid-phase endocytosis activity (O_Halloran and Anderson 1992). Constitutive fluid-phase endocytosis (pinocytosis) has attracted less attention although most cell types are capable of internalizing quite large volumes of medium by this pathway (Steinman et al. 1983) in a clathrin independent way.

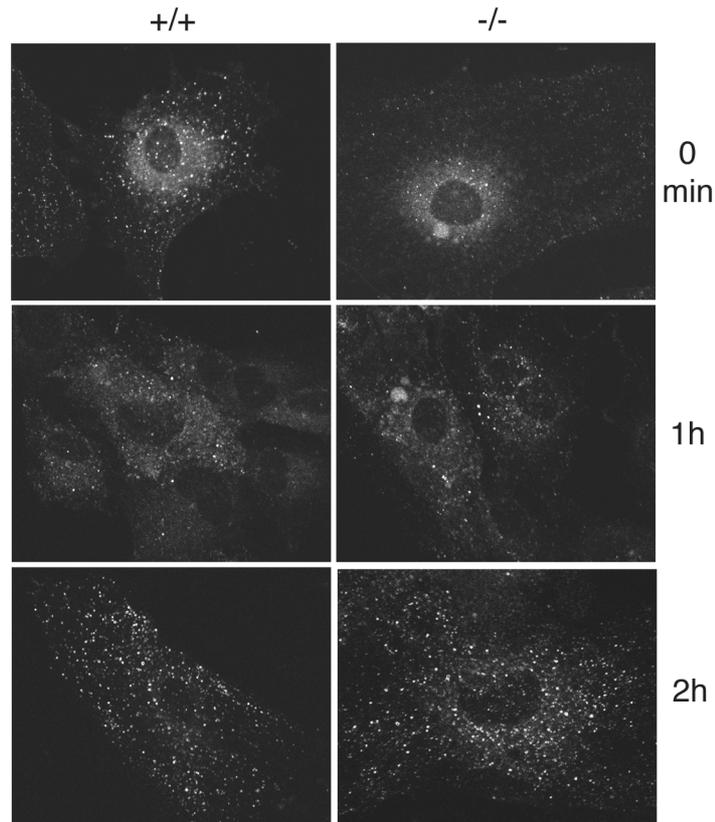

Figure 22: FITC-dextran uptake by control and Vti1b knock-out MEFs

Cells were grown on coverslips till they reached confluency. To stimulate uptake, cells were incubated in serum-free medium for 1h. Afterwards 200 μ l FITC-dextran (MW=14000) solution (2mg/ml) in medium was added for 1h (pulse). Cells were washed with PBS and incubated for chosen chase periods of 0min, 1h and 2h with fresh medium. Figure 22 shows that control and Vti1b deficient cells internalised FITC-dextran in a similar way. There was no retardation of the uptake of FITC-dextran into endosomes in deficient fibroblasts (0min). After 1h FITC dextran reached lysosomes and accumulated there (2h chase). There was no visible differences in its accumulation between control and Vti1b knock-out MEFs. These data indicate that fluid-phase endocytosis and transport to lysosomes was not affected enough in Vti1b deficient cells to produce an obvious defect in this microscopical assay.

4.2.8 Fluorescent-LDL uptake and degradation in control and knock-out MEFs

Lysosomal degradation of ligands following receptor mediated endocytosis via clathrin coated vesicles is a major pathway. Examples for ligands are asialoglycoproteins, epidermal growth factor (Dunn and Hubbard 1984), and low-density lipoproteins, LDL (Anderson et al. 1976). LDL receptors are found on nearly all human and animal cells (Brown and Goldstein 1976). The LDL-receptor pathway is a model for receptors which participate in receptor-mediated endocytosis and are reutilized or recycled, thus allowing each receptor molecule to deliver many ligands to their ultimate destination through multiple rounds of endocytosis. It is recycled very efficiently since each LDL receptor can internalize more than 150 LDL particles during its 30-hour life-span (Brown et al. 1982). Cells were washed twice with PBS to remove dead ones and FKS from the medium and incubated with serum-free medium for a time period of 2h (starvation). Starvation medium was then replaced with fluorescently labeled low-density-lipoprotein (10 μ g/ml, BODIPY®, Molecular Probes, USA) in starvation medium and cells were put on ice for 90 min (receptor binding). Cells were washed with PBS at room temperature twice and incubated for several chase periods.

Control and Vti1b deficient cells internalised and processed fluorescently-labelled LDL in a similar way (fig 23). There was no retardation of the uptake of labelled-LDL into endosomes in Vti1b deficient fibroblasts (30min). After 1h LDL reached lysosomes and accumulated there, starting to degrade.

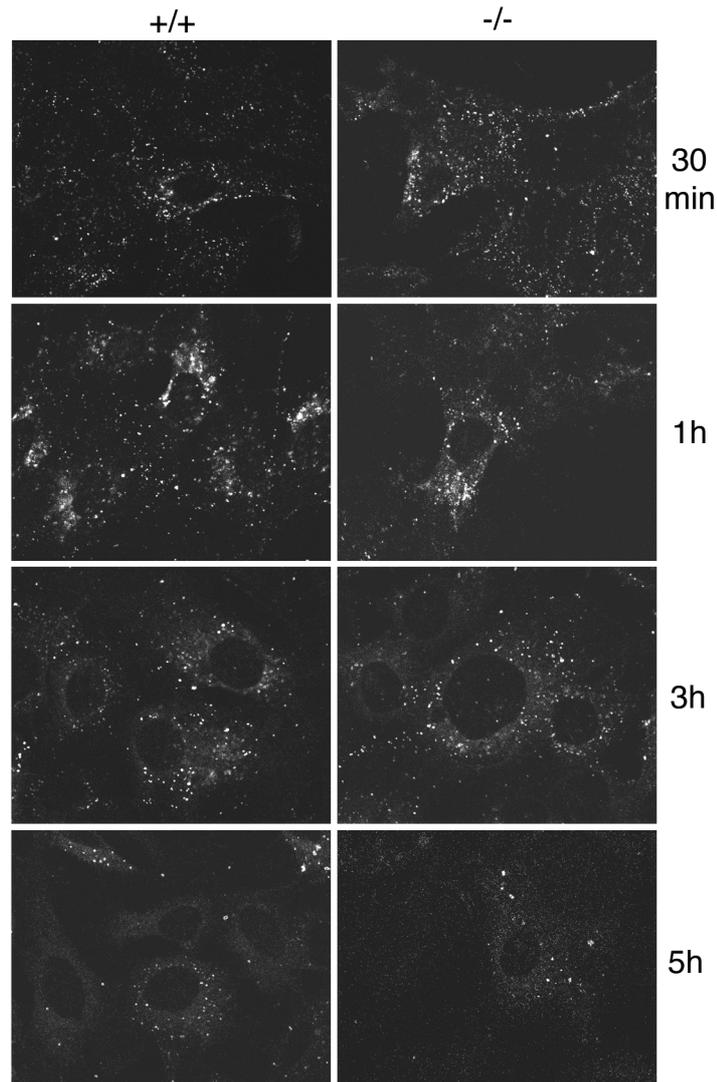

Figure 23: Fluorescent LDL uptake and degradation in control and knock-out MEFs

There was no visible differences in its degradation between control and knock-out MEFs (3h chase). After 5h chase almost all internalised LDL was degraded in both cell types. These data indicate that *Vti1b* deficiency has no visible effect on LDL traffic in MEF cells in this microscopical assay.

4.2.9 EGF-R uptake and degradation in *Vti1b* deficient hepatocytes

Epidermal growth factor (EGF) is known to bind its receptor, EGF-R at the plasma membrane and to induce endocytosis of the complex. The receptor and EGF are then transported to lysosomes for degradation. EGF-R typically recycles through the early endosome back to the plasma membrane an estimated 3-5 times before it is selected for degradation in a stochastic manner by transport via the late endosomal compartments. At

steady state, 70-80% of the EGF-occupied EGF-R is endosomal (Sorkin et al. 1988). Using antibodies directed against EGF-R the rates of ligand induced receptor degradation can be compared after different chase periods.

Mouse hepatocytes were isolated using a collagenase-independent method and Percoll® density gradient centrifugation as described under 3.3.1.4 and cultivated overnight in RPMI medium supplemented with 10% FKS. Isolated hepatocytes were starved for 2h in serum-free medium. Two plates of each type were put on ice and cells were collected (0min). To the other plates 100 ng/ml purified EGF in serum-free medium was added followed by an incubation for 4h. Cells were scraped off in 200µl of 0,1% TritonX-100 in TBS, sonicated and protein concentration was determined. 100µg total protein of the obtained homogenate per lane was separated using 5% SDS-PAGE followed by western-blotting. EGF-R was detected in western-blot by antibodies using an ECL-detection assay. Pictures were taken with an luminiscent image analyser and AIDA software was used for quantification of blots. An average amount of EGF-R in homogenates obtained from cells without EGF addition was used as 100%.

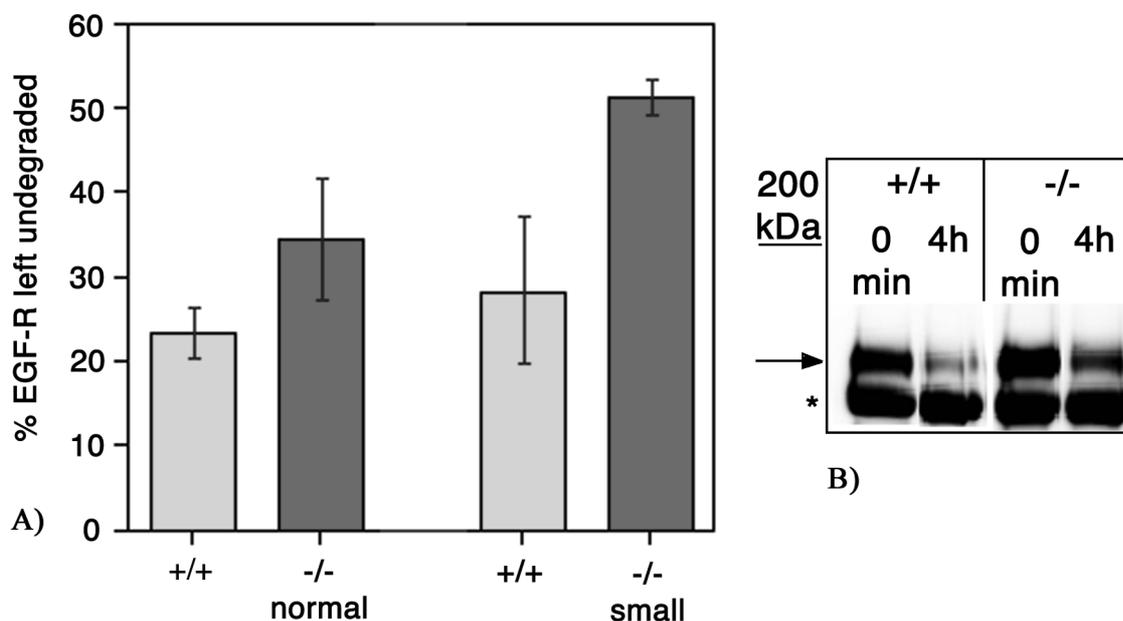

Figure 24: EGF-R degradation after 4h in control and knockout Vti1b hepatocytes

A) Quantitative comparison; B) Original western-blot data; An arrow shows EGF-R band, an asterisk non-specific band ; -/- is small mouse N33

After 4h 23,3 ± 3,5 % of the EGF-R remained in wild type hepatocytes, whereas Vti1b deficient cells from normal size mice had 34,4 ± 7,6 % undegraded EGF-R (n=4, two

independent experiments). The difference in EGF-R degradation between control hepatocytes and hepatocytes from small knock-out mice was greater. Control cells had $28,2 \pm 8,9$ % of the EGF-R left over after 4h and hepatocytes from small knock-out mice kept $51,2 \pm 2,0$ % (n=2, one experiment) (fig 24). So there was a retardation of EGF-R delivery to or degradation in lysosomes.

4.2.10 Uptake and degradation of ^{125}I -asialofetuin in *Vti1b* deficient hepatocytes

The cell biology of the asialoglycoprotein receptor (ASGP-R) system provides insights into the fundamental process of receptor-mediated endocytosis. The asialoglycoprotein receptor is found exclusively in hepatic parenchymal cell membranes. It recognises carbohydrate moieties with a terminal galactose in ligand molecules. The ASGP-R mediates the specific recognition and receptor-mediated hepatic uptake of glycoproteins with a terminal galactose (Breitfeld et al. 1985). After internalisation with its bound ligand, this empty receptor is recycled back to the cell surface, whereas the ligand is transported to lysosomes for degradation. Products of degradation can be detected in the medium.

^{125}I -asialofetuin was used as ligand of ASGP-R to monitor receptor-mediated endocytosis in wild type and *Vti1b* deficient hepatocytes. Cells were starved in serum-free RPMI medium supplemented by 0,1% BSA for 4h. Starvation medium was replaced with starvation medium containing 10pmol/ml (126600 cpm/plate) of ^{125}I -asialofetuin (1:100 dilution of labelled solution, 6 μl in 600 μl of medium for each plate for 4h and iodinated asialofetuin was added and incubated with the cells for 20 min at 37 $^{\circ}\text{C}$ (pulse). Afterwards, the radioactive medium was removed, cells were washed with medium and incubated with new portions of fresh medium for 30min, 60 min and 120min (chase). Medium and cells were collected, soluble (amino acids) and insoluble (protein bound) radioactivity was separated after TCA precipitation. Degradation rates were calculated as % of TCA soluble radioactivity in comparison to the sum of soluble radioactivity and cell associated insoluble radioactivity for each time point. About 8000-16000 cpm were taken up by the cells depending on cell density.

Wild type hepatocytes and hepatocytes of normal size *Vti1b* knockout mice degraded asialofetuin at similar rates(fig 25). An average of $46,5 \pm 4,1$ % of the asialofetuin was degraded in wild type hepatocytes after 30 min of chase (three independent experiments with double values). *Vti1b* deficient hepatocytes from normal size mice degraded $47,6 \pm$

3,6 % asialofetuin in same time (double values of one experiment). Other chase periods also showed insignificant differences between these cells (see fig 25)

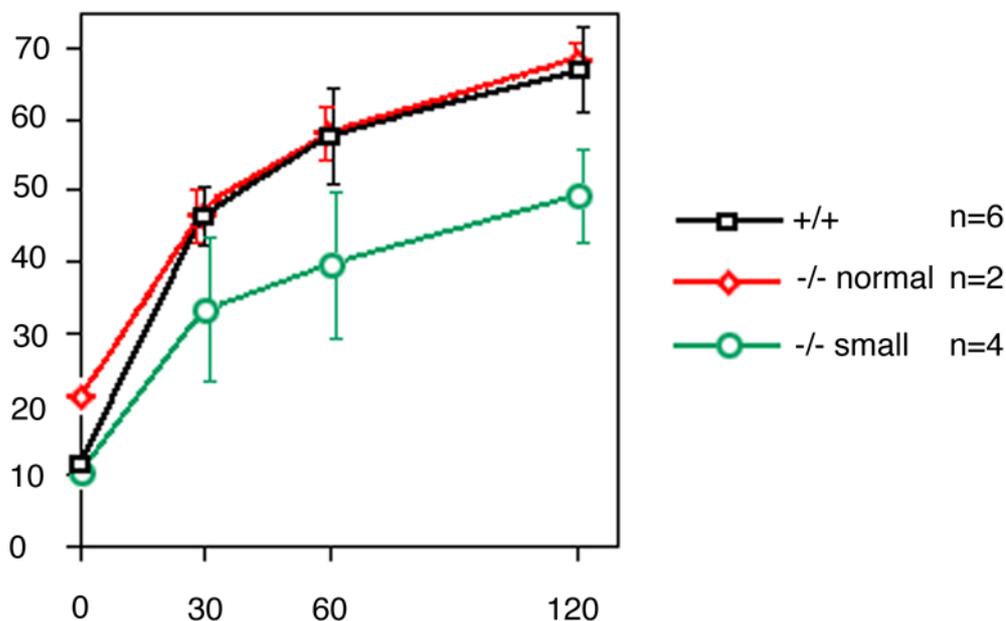

Figure 25: J125-asialofetuin degradation after 20 min pulse, different chase periods

X axis indicates time in min, Y axis - % of degradation of asialofetuin (soluble radioactivity in the assay); -/-small are mice N33 and N101

However, hepatocytes from small Vti1b deficient mice had slower rates of asialofetuin degradation. After 30min they had only $33,1 \pm 8,8$ % soluble radioactivity (two independent experiments with double values). The same tendency could be observed after 60min and 120min. After 60min deficient hepatocytes from small mice had $39,6 \pm 9,0$ % asialofetuin which was much less than $58,1 \pm 6,9$ % for wild type cells. After two hours chase control hepatocytes had $66,7 \pm 6,3$ % soluble radioactivity which was significantly higher than $49,4 \pm 4,3$ % for hepatocytes from small Vti1b knockout mice.

Asialofetuin degradation in hepatocytes from small Vti1b deficient mice was retarded. By contrast, no defect in asialofetuin degradation was observed in hepatocytes derived from normal size Vti1b deficient mice.

4.2.11 Transport of newly synthesised cathepsin D in MEFs and cultivated hepatocytes

Usually the lysosomal protease cathepsin D is transported from the TGN to endosomes and then lysosomes via a manose-6-phosphate receptor dependent pathway. Some fraction of

the precursor, procathepsin D, fails to be captured by the MPR-46 receptor. This procathepsin D is secreted and then endocytosed with the help of MPR-300. Procathepsin D (55kDa) is processed in lysosomes to an intermediate form of about 45kDa which is then cleaved into two mature forms of 30kDa and 14 kDa.

To trace procathepsin D processing wild type and Vti1b deficient MEFs were incubated for 1h with [³⁵S]-methionine (pulse). An excess of non-radioactive L-methionine was then added and cells were incubated for 1h, 2h and 4h (chase). For hepatocytes chase periods of 2h and 4h were applied. Afterwards cathepsin D was immunoprecipitated from medium and cell homogenates, separated by SDS-PAGE and analysed using a phosphoimager.

Experiments using MEFs

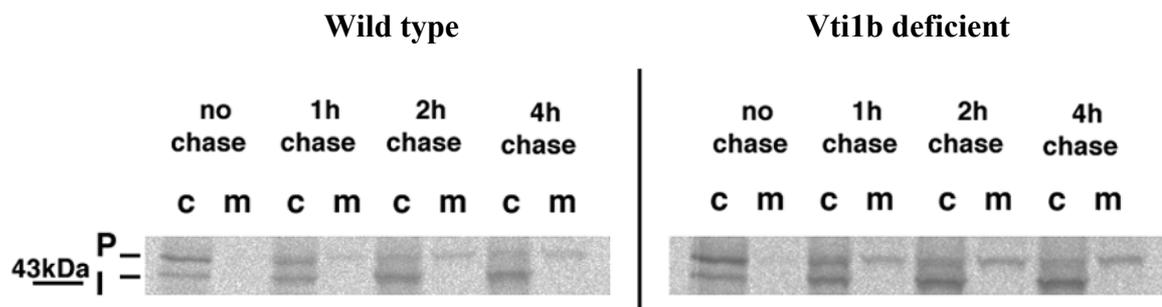

Figure 26: Processing of cathepsin D in control and Vti1b deficient MEFs

P- precursor; I – intermediate form; “c”- precursor and intermediate form in cell homogenates, “m”- cathepsin D secreted into the medium

Figure 26 shows processing of cathepsin D precursor to intermediate form in MEFs. The sum of procathepsin D, intermediate form and secreted cathepsin D is set to 100% for each time point.

Control fibroblasts secrete 10% of the new synthesised precursor into the medium after 4h. Vti1b deficient MEFs secreted slightly more (15%).

In general strong differences between control and Vti1b deficient fibroblasts in cathepsin D maturation were not observed (three independent experiments). Table 8 shows quantified results of a single experiment.

Table 8: Quantitative analysis of cathepsin D processing in MEFs

	Precursor		Intermediate form		Secreted into medium	
	+/+	-/-	+/+	-/-	+/+	-/-
no chase	72	71	28	29	---	---
1h chase	47	36	47	51	6	13
2h chase	23	23	67	63	10	14
4h chase	20	15	70	70	10	15

Values show % of cathepsin D from total amount

Experiments using isolated hepatocytes

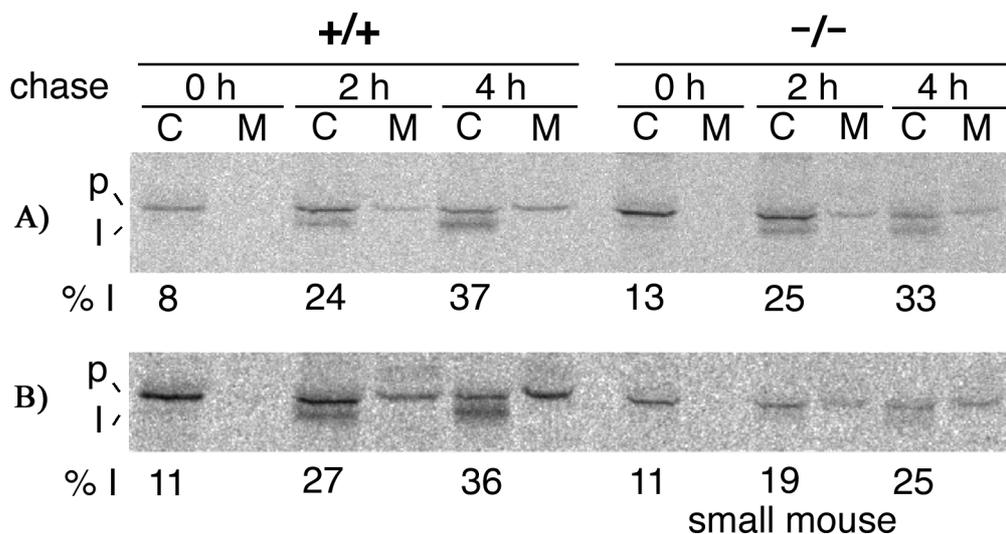

Figure 27: Visible delay of Cathepsin D maturation in hepatocytes of small Vti1b deficient mice

Panel A: Similarity of cathepsin D processing in hepatocytes of control and of normal size Vti1b knock-out mice; Panel B: Difference in the amounts of cathepsin D intermediate form between wild type hepatocytes and hepatocytes of small size Vti1b knock-out mouse N101. Numbers under the panel indicate percents of intermediate form

Figure 27 shows the processing of new synthesised cathepsin D in wild type and Vti1b deficient hepatocytes. Wild type hepatocytes and hepatocytes of normal size Vti1b knock-out mice showed similar cathepsin D maturation (panel A). Control hepatocytes had $23,8 \pm 5,0$ % intermediate form after 2h and $36,6 \pm 6,8$ % (n=6) after 4h of chase. This was not

significantly different in hepatocytes of normal size *Vti1b* deficient mice ($24,6 \pm 3,4$ % intermediate form after 2h, $33,3 \pm 5,7$ % after 4h) Hepatocytes of small deficient mice (panel B) had slightly less intermediate form after 2h ($18,5 \pm 2,5$ %) and 4h (25 ± 2 %) (fig 28). This experiment was not repeated due to the limited number of small *Vti1b* deficient mice but fits with the defects in endocytosis and lysosomal degradation seen in these mice (4.1.11 and 4.1.12).

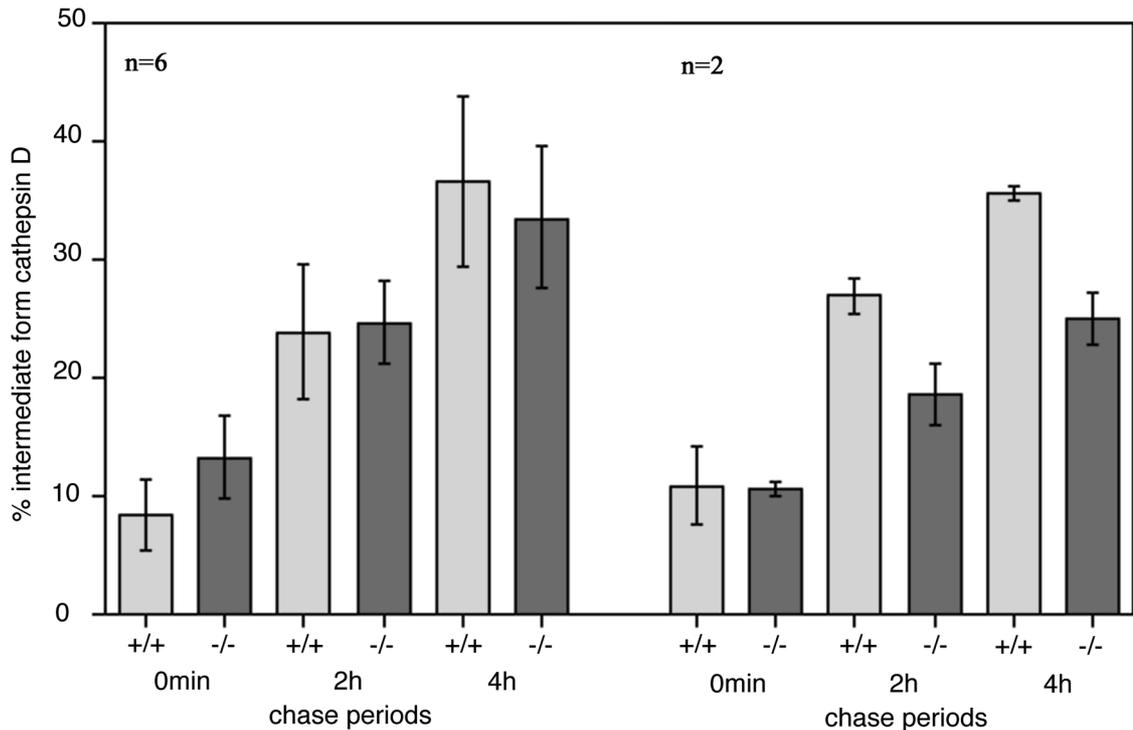

Figure 28: Quantitative comparison of the cathepsin D processing in hepatocytes of wild type, normal size (left panel) and small (right panel) *Vti1b* deficient mice

The left panel of figure 28 shows similar maturation pattern of cathepsin D in control and normal size *Vti1b* knock-out mice (n=6, three independent experiments with double values). The right panel demonstrates a slight retardation of cathepsin D processing in small knock-out mice (n=2, one experiment with double values).

4.2.12 Rates of autophagocytosis in hepatocytes of normal size deficient mice

Degradation of long-lived proteins occurs mainly by autophagy (Henell et al. 1987). Cells lacking LAMP-2 accumulate autophagic vacuoles (Tanaka et al. 2000). To find out if autophagy is affected in *Vti1b* deficient cells, an assay applied by Tanaka et al. was used.

Autophagosomes fuse with lysosomes during their maturation resulting in the subsequent degradation of the enclosed material. Amino acid deprivation is a potent inducer of autophagy. For labelling of all newly synthesised proteins hepatocytes were incubated with [^{14}C]-valine for 24 hours then washed with medium twice and exposed to salt solution or fresh medium for 1h. During that time short-lived proteins were degraded. Medium was changed and one group of hepatocytes was incubated for 3h with basic salts solution (no amino acids) to stimulate autophagocytosis strongly. Other groups of hepatocytes were incubated with normal medium supplemented by 5% serum for 11h and 23h to observe background levels of autophagocytosis. Medium and cell homogenates were collected. After TCA precipitation insoluble radioactive material (proteins) was separated from soluble (amino acids). Rates of autophagocytosis were calculated as % soluble radioactivity of the total radioactivity in cell homogenates and medium.

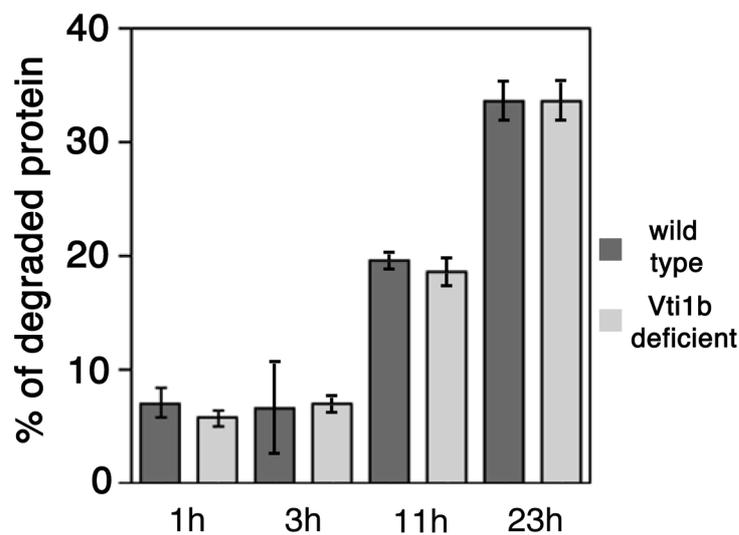

Figure 29: Induced and basic autophagy in control and Vti1b^{-/-} hepatocytes

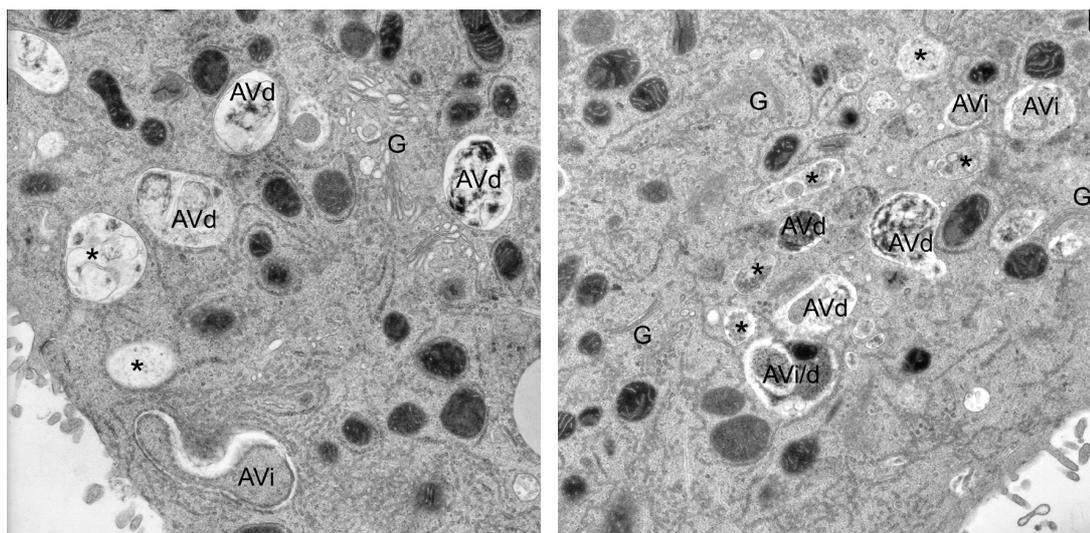

n=4, two independent experiments with double values

Wild type hepatocytes and hepatocytes of normal size knock-out mice showed similar behaviour in this assay (fig 29). The average values of protein degradation after stimulation for 3 h without amino acids were $6,6 \pm 3,4$ % in wild type and $6,9 \pm 0,9$ % in Vti1b knock-out hepatocytes. The basic autophagic degradation of long-lived proteins after 11h was $19,5 \pm 0,6$ and $18,6 \pm 1,6$ % in wild type and Vti1b deficient hepatocytes, respectively. After 23h identical values were obtained in control and deficient cells ($33,5 \pm 1,8$ % and $33,5 \pm 1,8$ %).

This information correlates with data of electron microscopy, where autophagic vacuoles are morphologically very similar in control hepatocytes and cells of normal size knock-out mice (fig 30, under 4.2.13).

4.2.13 Electron-microscopic study of *Vti1b* deficient hepatocytes

Cultivated hepatocytes of wild type and *Vti1b* deficient mice were studied by electron microscopy by Eeva Liisa Eskelinen, University of Dundee, UK. This gives information about morphology of endosomal and lysosomal structures and autophagic vacuoles. Isolated hepatocytes were fixed in 2% glutaraldehyde in 0,2M HEPES, pH 7,4. The cells were scraped off the culture dish and postfixed in 1% OsO₄ for 1h, dehydrated in ethanol and embedded in Epon. Micrographs were taken with a primary magnification of x10,000. Vacuoles were classified as early (AVi), containing morphologically intact cytoplasm or late (AVd), containing partially degraded but identifiable cytoplasmic material.

B)

Figure 30: Morphology of endosomes, lysosomes and autophagic vacuoles in wild type hepatocytes and hepatocytes from *Vti1b* deficient mice of normal size

(provided by Eeva Liisa Eskelinen) AVi – early, AVd – late autophagic vacuoles; G indicates Golgi stack, stars present endosomes and lysosomes; Panel A) represents wild type, panel B) – *Vti1b* deficient hepatocytes

There were no obvious morphological differences between wild type hepatocytes and hepatocytes from *Vti1b* deficient mice of normal size. Both showed some autophagic vacuoles in the cytoplasm, both early (AVi) and late (AVd). There was no accumulation of AVi or AVd in the deficient cells, as compared to controls. Endosomes and lysosomes had

similar morphology in *Vti1b* deficient hepatocytes from mice of normal size and wild type hepatocytes (fig 30).

Hepatocytes of small deficient mice showed a very different pattern. They accumulated both early and late autophagic vacuoles. Interestingly, a close contact between different autophagic vacuoles and/or between multivesicular bodies was often observed. In addition, several of these vacuoles had lost their limiting membranes in the contact zone but had still retained their morphology, indicating they were in the process of fusion (fusion profiles). There were a lot of small multivesicular bodies in hepatocytes of small size knock-out mice. Some multivesicular bodies were inside of autophagic vacuoles (fig 31).

4.3 Isolation of genomic DNA for Vti1a, characterisation of the chromosomal region of Vti1a and construction of targeting vectors

Two EST (express sequence tag) clones containing Vti1a coding sequence were used as DNA probes to screen a λ -phage mouse strain Sv129 Ola genomic DNA library for Vti1a genomic fragments. One of them, probe “237”, contained the complete coding sequence for Vti1a plus 100bp upstream of the ATG codon and 60bp downstream of the stop codon as cDNA.

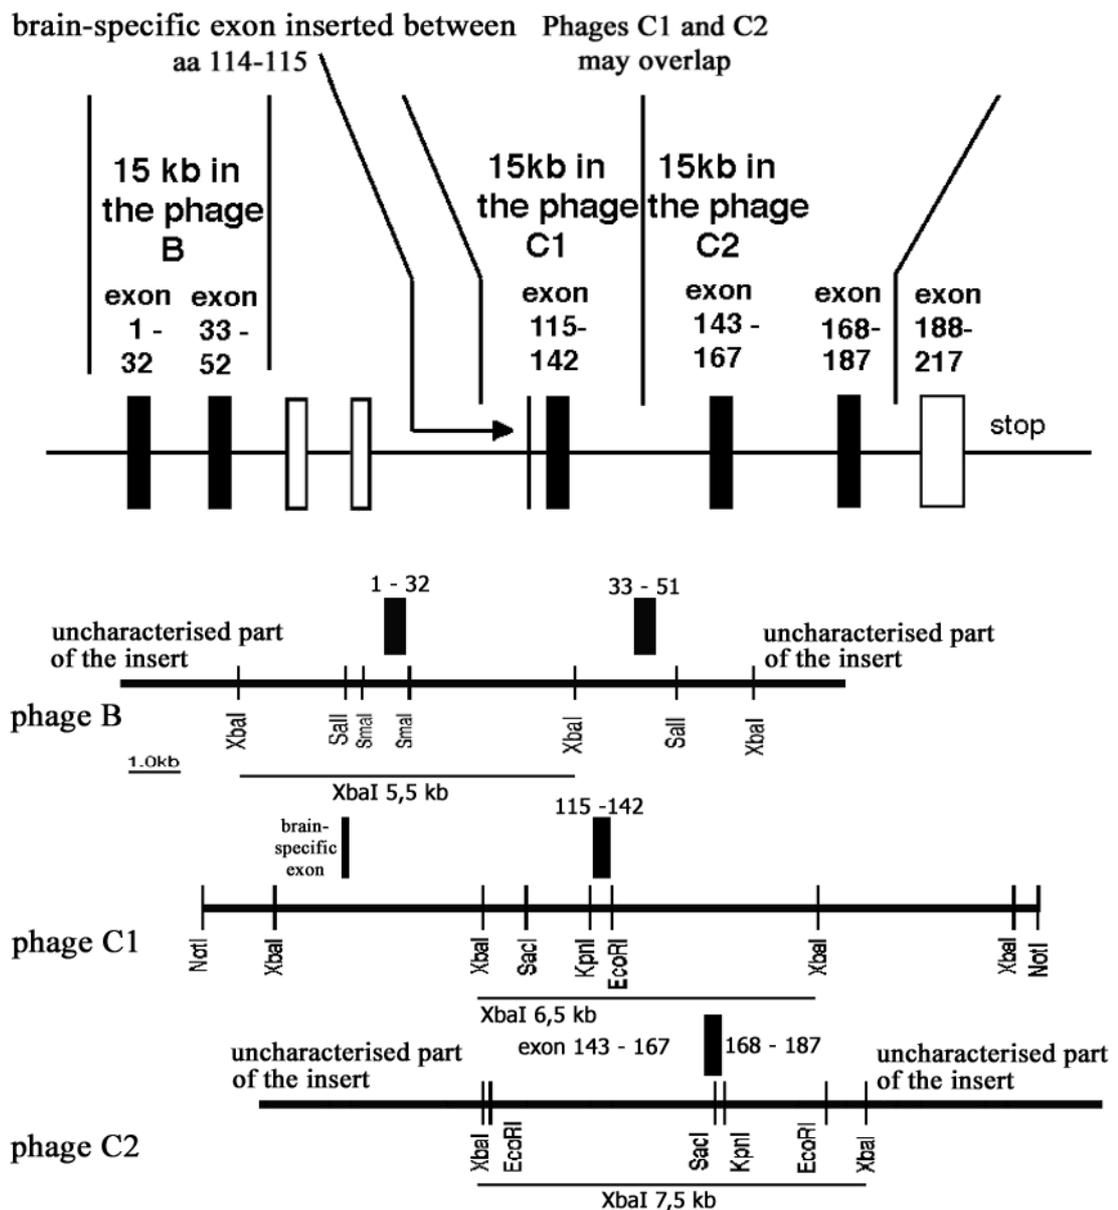

Figure 32: Fragments obtained of the Vti1a genomic region

The probe was obtained from the EST clone AA016379 which contains these sequences inside of the pT7T3D plasmid by XhoI/NotI digestion. The second one, “EST probe”, contained 100bp 5` untranslated region, the first exon and 750 bp intron sequence of Vti1a. This probe was obtained after digestion of the plasmid pT7T3D (AA097517) with XhoI/NotI. Three phage clones were detected (“phage B”, “phage C1”, “phage C2”). Probe “EST” allowed to detect phage “B”, probe “237” detected phages “C1” and “C2”.

The chromosomal region for Vti1a was at least three times larger than the one for Vti1b. Not all exons were present in the three phages isolated (fig 32). Important for working out the knock-out strategy was to obtain the exon encoding amino acids 115-142 which was contained inside of “phage C1”. This exon encodes part of the SNARE motif which is responsible for complex formation and is therefore critical for Vti1a function. Desruption of exon 115-142 would prevent synthesis of functional Vti1a protein even in the unlikely case that its mRNA should be stable.

Phage B contained exons “1-32” and “33-52” (figure 32), phage C1 contained a small exon encoding 7 amino acids of the brain specific insertion and exon “115-142”, phage C2 contained exons “143-167” and “168-187”.

A) Strategy for constitutive knock-out

A chromosomal DNA insert of 6,5kb length was cut out from “phage C1” by XbaI and subcloned into pBluescript SK+ plasmid for characterisation (pVA₂₈) . A 6kb fragment of that DNA subcloned using XbaI/AvrII endonucleases and used for targeting vector construction. Since the exon of interest (“exon 115-142”) contains a KpnI site it was possible to subclone the Neo⁺ disruption cassette into this KpnI site with the coding sequence on the opposite strand as Vti1a without other DNA - manipulations (fig 33).

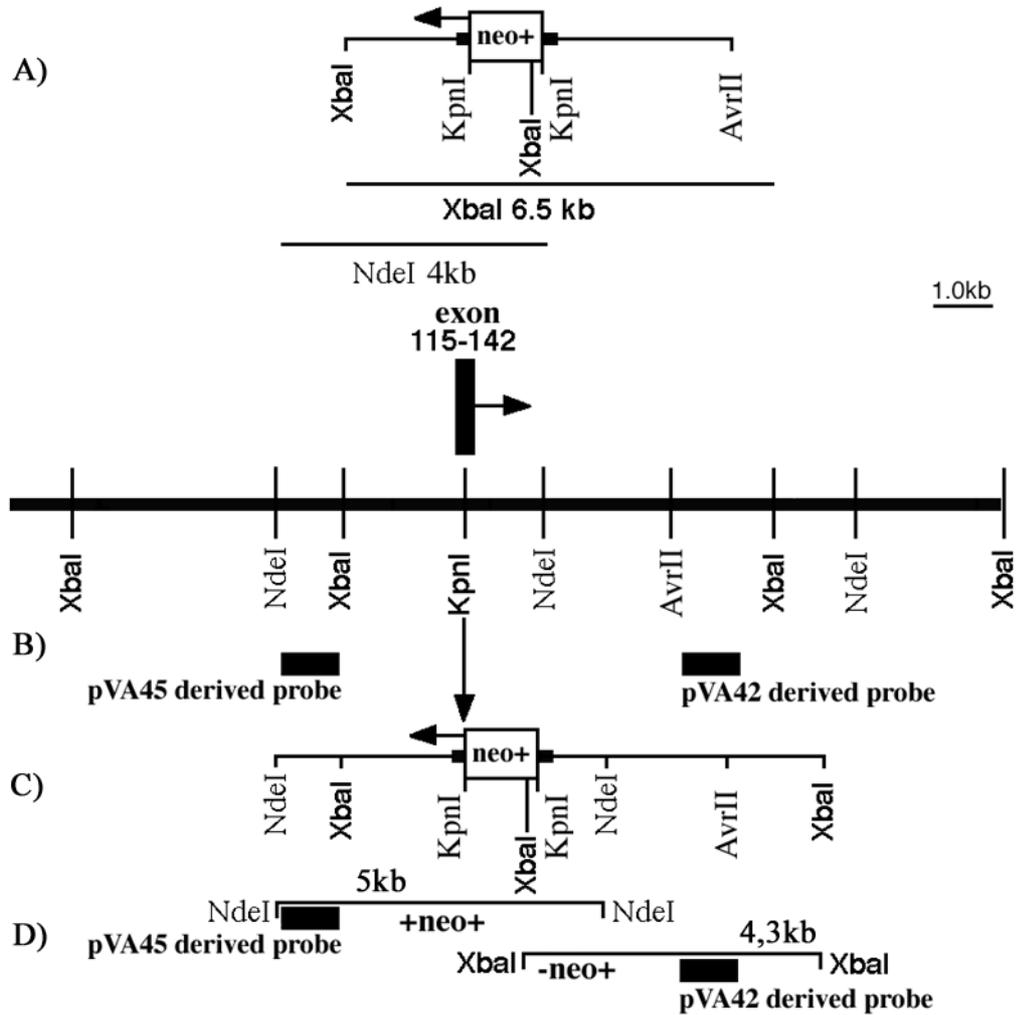

Figure 33: Scheme of the *Vt1a* targeting construct and screening strategy

A) the insert of the *Vt1a* targeting vector; B) scheme of *Vt1a* chromosomal region; C) *Vt1a* chromosomal region after homologous recombination; D) size of fragments to be recognised by the chosen probes

Two DNA probes were designed for screening for positive ES cell transformants. “pVA₄₂ derived” probe was obtained after *SpeI*/*AvrII* shrinking of pVA₂₈ bearing an insert of 1,4 kb (pVA₄₂). This probe was 700bp-long and was cut out by *XbaI*/*EcoRV* enzymes.

“pVA₄₅ derived” probe was obtained after *EcoRI* shrinking of the phage DNA insert of pVA₄₁ which contained 4,3kb upstream of the *XbaI* fragment with exon “115-142”. This probe was 490 bp-long was cut out by *XbaI*/*EcoRI* enzymes.

Upon screening for positive ES clones using DNA hybridisation techniques, the 5’ outside probe derived from pVA₄₅ would recognise a 5kb *NdeI* fragment with the Neo-insertion after homologous recombination together with a 4kb wild type one. The 3’ outside probe

derived from pVA₄₂ would recognise a 4,3kb XbaI fragment with the Neo-insertion after homologous recombination and a 6,5 kb wild type one.

The targeting vector was introduced into embryonic stem cells of MPI ES cell line. A homologous recombination was observed in only one clone among 130 clones tested.

Figure 34 shows that clone number 8 had an insertion of the Neo-cassette into the Vti1a locus. It was used for microinjection of blastocysts.

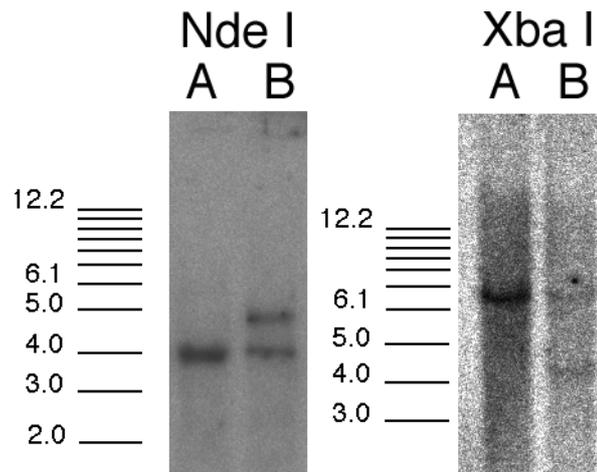

Figure 34: MPI ES clone 8 is positive Vti1a targeted A – wild type, B – mutant clone 8

Chimeric mice were obtained. Six male mice with low chimerism (5-20%) and one mouse with 60% chimerism were used for mating but no germ line transmission was obtained.

Recently a new positive clone was obtained (clone 132) which belongs to another ES cell type E-14. Transfer of the clone 132 into blastocysts was done recently.

B) Strategy of conditional knock-out

It is unknown if Vti1a deficiency is lethal. In case of early embryonic lethality it would be impossible to get any embryonic fibroblasts and study the functional role of Vti1a. Another knock-out strategy was worked out, namely a conditional knock-out (fig 35)

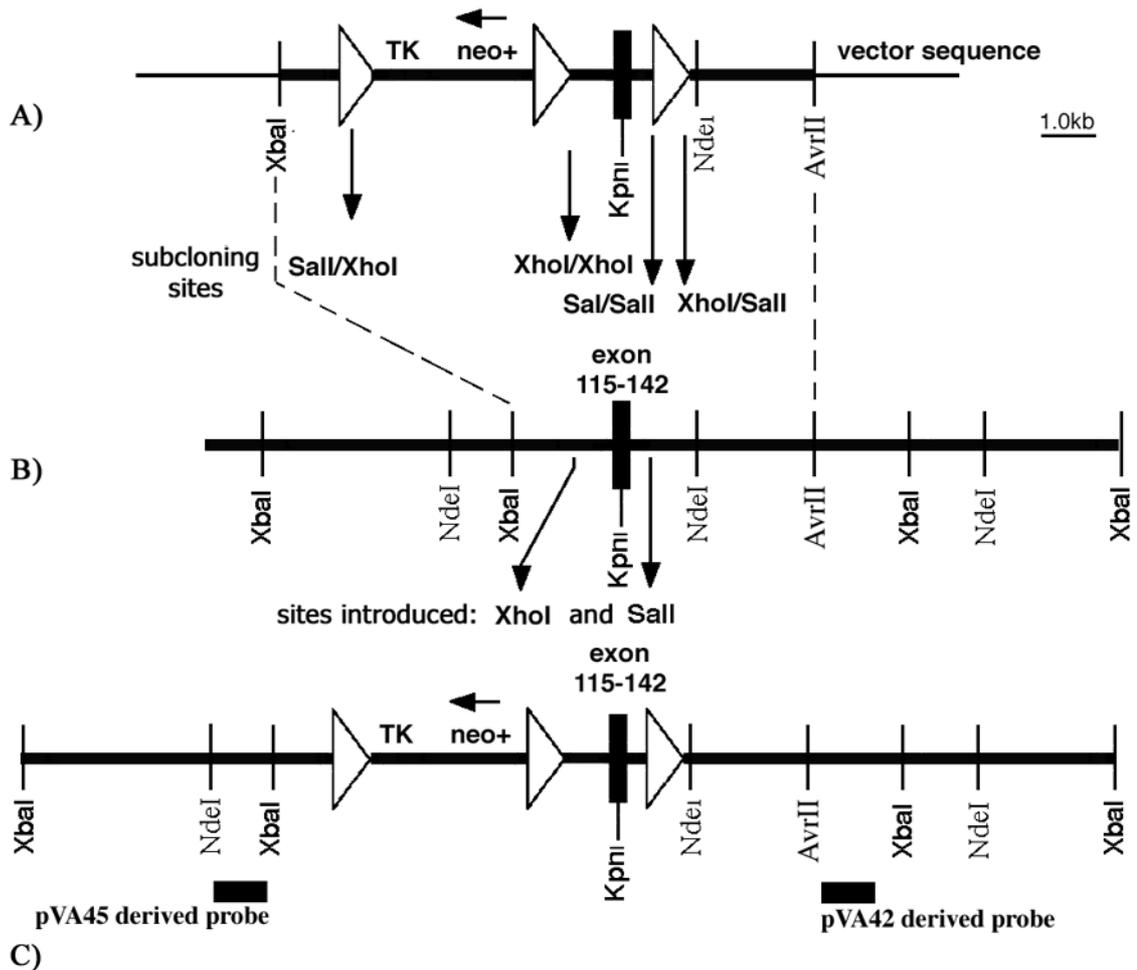

Figure 35: Scheme of the targeting strategy and the construct for *Vti1a* conditional knock-out

A) Targeting construct; B) Untargeted chromosomal *Vti1a* region; C) Mutant *Vti1a* chromosomal region after homologous recombination

The same genomic fragment containing “exon 115-142” that was shorted by XbaI/AvrII endonucleases was used to make a new construct. LoxP sites for recognition of DNA by Cre-recombinase were introduced before and behind the exon of interest. Using oligonucleotide-directed mutagenesis SalI and XhoI sites were introduced into the 6,5 kb XbaI chromosomal *Vti1a* region contained in pVA₅₄. For introducing a SalI site 120bp downstream of the exon into pVA₅₄ following primers were used CGACAATTGGGAGCTTATTTGC and ACCCAATATGTAAACCACATC. The resulting plasmid pVA₅₆ was used as template to introduce a XhoI site 134bp upstream of the exon. The following PCR primer pair was used for that: GAGAACTGTCTGCTAAAATTTAAC and GAGAGGAAACACAACAATAGAC.

Thymidin-kinase and Neo⁺ cassettes flanked by two LoxP sites (altogether 3kb-long) were subcloned into the XhoI site of the plasmid pVA₅₇ obtained after two mutagenesis. One additional 140 bp-long DNA fragment containing a LoxP site of same orientation was subcloned into the SalI site, giving raise to pVA₅₉ (targeting construct). Upon screening for positive ES clones using DNA hybridisation techniques, one of the chosen probes would recognise a mutant 7,2kb NdeI fragment together with a 4kb original one. The other probe would recognise a 9,5kb mutant XbaI fragment and a 6,5 kb native one.

Positive clones will be expanded and Cre-recombinase will be added to induce excision of the TK-Neo⁺ containing DNA fragment. In this case the same probes will be used for the screening strategy. Upon screening for positive ES clones using DNA hybridisation techniques, one of the chosen probes (“pVA₄₅ derived”) would recognise the exon flanked by two LoxP sites as 4.4kb NdeI fragment and a 3,9kb fragment if the exon has been excised. Another probe (“pVA₄₂ derived”) would recognise a 4,5kb fragment after XbaI+KpnI digest if the exon is flanked by two LoxP-sites and a 6,5kb fragment if the exon has been removed.

5 Discussion

5.1 Generation of deficient mice to characterise the role of Vti1b in endosomal traffic

The present work demonstrates that Vti1b is a non-essential protein in mice. Lack of Vti1b does not cause abnormalities in most mice, but a few mice are smaller in size. Vti1b is needed *in vivo* for proper endosomal traffic in hepatocytes of small Vti1b deficient mice, but its absence can be compensated for in Vti1b deficient mice of normal size. The absence of Vti1b leads to reduced levels of syntaxin 8.

5.1.1 Homology of mouse Vti1 proteins

Vti1b and Vti1a are SNAREs. They possess each a SNARE motif and a transmembrane domain. The overall homology between them is only 30% amino acid identity. Vti1b and Vti1a are Qb-SNAREs, however Vti1a has an aspartate in the 0 layer. Aspartate like glutamine has a carbonyl group as side chain and is similar in size to glutamine. Because arginine interacts with the carbonyl group of glutamine in the 0 layer, an aspartate residue should therefore be able to interact with the arginine of the R-SNAREs. The amino acid identity of Vti1b and Vti1a in the SNARE motif is 42% and that makes it possible that they have different functions in membrane traffic.

Vti1b and Vti1a genes are located on different chromosomes. Human Vti1b is located on chromosome 14q23 at 65,5 Mb. Accordingly to chromosomal homologies between mouse and human it can be proposed that mouse Vti1b is encoded on chromosome 12 at 39-40 cM. In both organisms the 3' untranslated ends of Vti1b and Arginase II cDNAs overlap. Vti1a is encoded on human chromosome 10q25 and probably on mouse chromosome 19 at 50cM. In this work it is shown that the chromosomal region encoding Vti1a is at least three times larger than the chromosomal region of Vti1b.

An alignment of sequences with exon/intron boundaries of mammalian Vti1 proteins is shown in fig 36

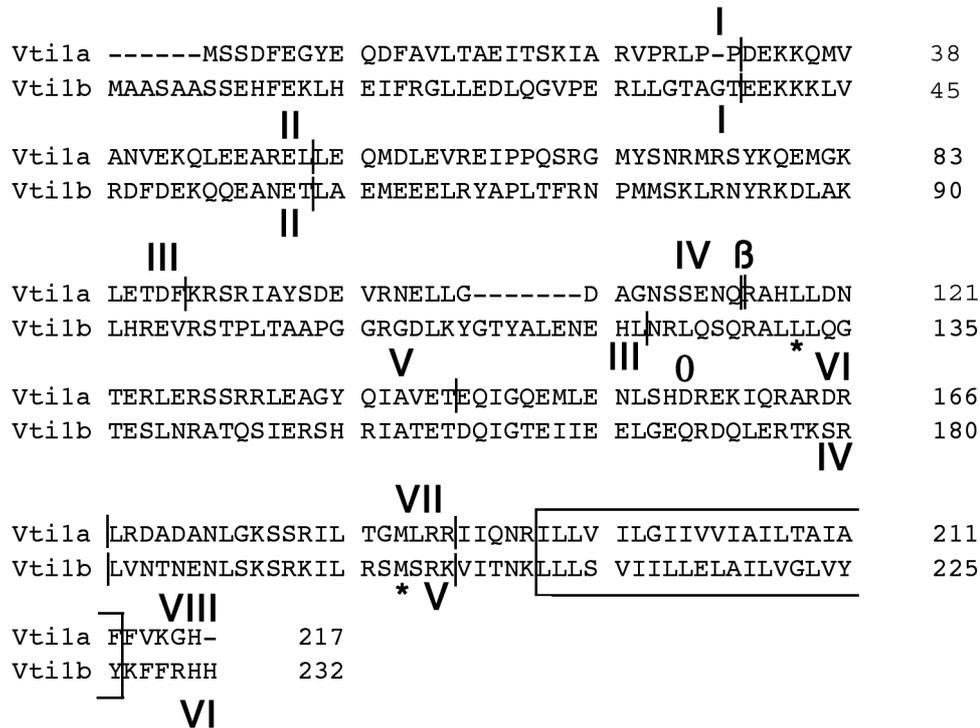

Figure 36: Exon/intron structure in mouse Vt1a and Vt1b proteins

| exon/intron boundaries; **I-VIII** numbers of exons; * boundaries of the SNARE motif; **β** place of additional exon in Vt1a-β; **0** - 0 layer

The mouse chromosomal DNA sequences characterised in this work did not include the complete genes. In case of Vt1b the first two exons were absent in the obtained DNA fragment. Hence, the first exon/intron boundary for Vt1b were taken from human the Vt1b sequence in the Genbank database. Of course the real position of this boundary in mouse Vt1b gene may still be different. The characterised fragments of Vt1a chromosomal DNA contained exons I, II, but not III and IV, therefore the boundary between exons III and IV is derived from the human sequence in fig36. An additional exon of Vt1a that encodes the brain-specific insertion of 7 amino acid residues giving rise to the splice form of Vt1a, termed Vt1a-β, is located at a distance of 4,2kb upstream of exon V.

Vt1b consists of 6 exons, Vt1a of 8 exons plus the alternatively spliced brain specific exon. It is striking that 4 of the intron-exon boundaries in Vt1b are found in homologous positions in Vt1a, boundaries of exons I and II match for Vt1b and Vt1a genes. This may suggest that the intron-exon structure developed before the gene duplicated and evolved into 2 different genes.

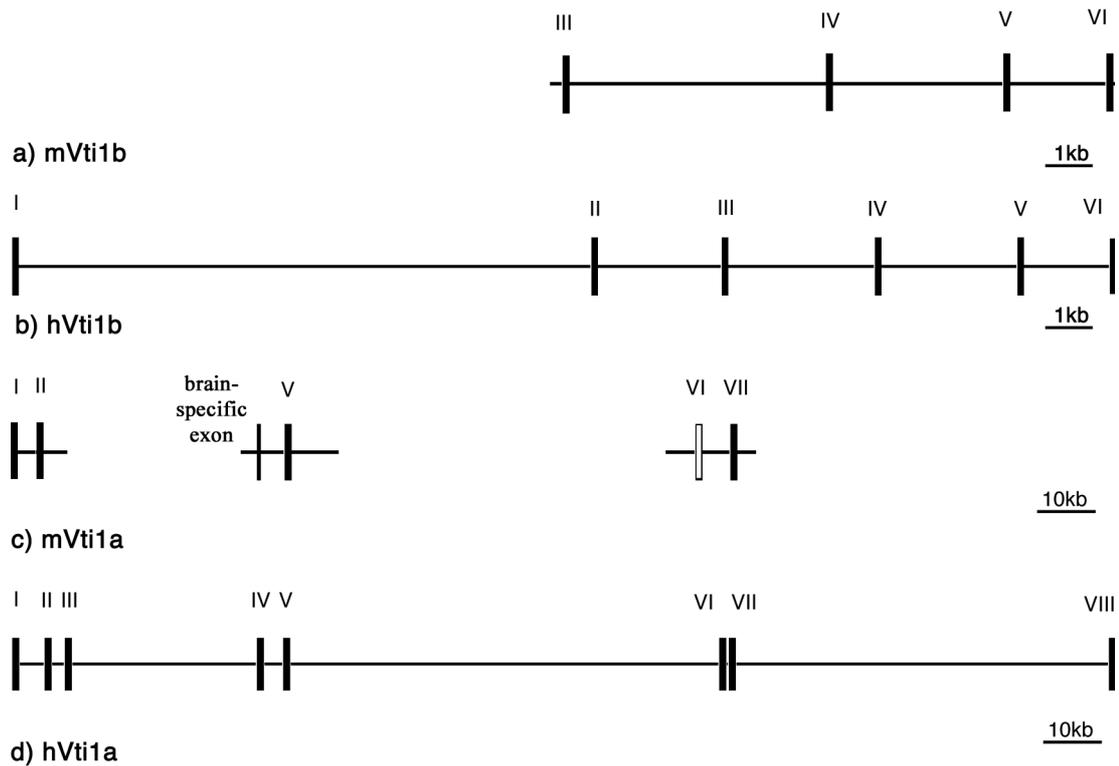

Figure 37: Comparison of mouse and human Vti loci

⊥ determined position of an exon; ⊥ undetermined position of an exon

The Vti1a chromosomal DNA with exons I, II, V, VI and VII was obtained in three phage vectors with 15kb long inserts each. The mouse Vti1a gene locus is at least 50 kb long and may be more compact than the Vti1a region of human DNA having altogether 370kb. The characterised mouse Vti1b genomic region has 15 kb in length for exons III-VI and is of similar size in comparison to the complete human Vti1b locus with 23 kb in length (fig 37).

5.1.2 Phenotypic heterogeneity of Vti1b deficient mice

There were two pools of Vti1b deficient mice, mice of normal size and small Vti1b deficient mice. Both types are fertile. Normal size mice have no higher postnatal lethality than wild type mice. Small mice had a critical point in their life that was reached at about three weeks. In that time they had to start to be self-dependent in their feeding. Some of small Vti1b deficient mice do not survive that critical point. The weight of small mice stayed reduced in comparison with control littermates during the complete postnatal

period. These small *Vti1b* deficient mice have reduced amounts of body fat. There were no detectable skeletal abnormalities in normal size and small *Vti1b* deficient mice.

Several knockout studies have shown phenotypically manifested dwarfism. A targeted disruption of the insulin – like growth factor II (IGF-II) causes decreasing of body weight till 60% of wild type littermates even on heterozygous level (DeChiara et al. 1990). A knockout of thyroid hormone $\alpha 1$ receptor causes increased mortality and dwarfism in mice (Kaneshige et al. 2001). These studies describe an obligatory phenotype, where all descendants are affected and show reduced weight in comparison to wild type mice.

LAMP2 knockout study provides an example of phenotypical heterogeneity, observed also in the case of *Vti1b* deficiency. LAMP-2 deficient mice have an increased mortality and loss of weight (Tanaka et al. 2000). About 50% of the LAMP-2 deficient animals died between postnatal day 20 and 40. In addition, LAMP-2 deficient mice are smaller than the wild type. The weight difference is maximal (35 - 40%) between day 20 and 30. In older mice (over 60 days) the weight difference is 10 – 15%. The situation in LAMP-2 deficiency resembles in this aspect that in *Vti1b* deficiency. Some *Vti1b* knockout mice (17,3% of the total number) stay smaller than their littermates, whereas some of them died. However, reasons for reduced size and body weights in some *Vti1b* knockout mice are unknown so far and have to be investigated. Retardation in fusion with lysosomes may contribute to this phenotype (see 5.1.4).

5.1.3 Syntaxin 8 protein levels in deficient cells and tissues

The only clear difference, distinguishing *Vti1b* deficient from control mice is in syntaxin8 protein levels.

Vti1b deficient mice had much less syntaxin 8 protein than control ones. This trait was found in all small and normal size *Vti1b* knockout mice and was seen by western blotting of different tissues and of MEFs as well as by immunofluorescent localisation of syntaxin 8 in MEFs. Reduction in syntaxin 8 amounts could be seen already in heterozygotic *Vti1b* mice (+/-), and therefore it was correlated with the gene-dosis effect of *Vti1b* expression in these mice. Syntaxin 8 is one of three partners of *Vti1b* in a SNARE complex, including also syntaxin 7 and endobrevin (Antonin et al. 2000a). The amounts of syntaxin 7 and endobrevin in *Vti1b* deficient mice were unchanged in comparison to control mice.

Comparing neuronal and endosomal SNARE complexes *Vti1b* and syntaxin 8 take the

position of both neuronal SNAP-25 helices in the endosomal complex. Vti1b was equivalent to the N-terminal helix of SNAP-25, syntaxin 8 - to the C-terminal one (Antonin et al. 2002). Although truncated and/or partial complexes can be generated for the neuronal complex, they are less stable than the ternary complex (Calakos et al. 1994; Hayashi et al. 1994). However, all four endosomal SNAREs were required to form a stable, folded complex (Antonin et al. 2000a).

The expression of syntaxin 8 mRNA is unaffected in Vti1b deficient mice, therefore it is likely that the syntaxin 8 protein is degraded. It is possible that due to the lack of Vti1b, syntaxin 8 is unable to form a complex and is available for the proteolytic machinery in the monomeric form. Another possibility is that Vti1b is required for the localisation of syntaxin 8. In the absence of Vti1b the mislocalized syntaxin8 may be subject to proteolysis. As syntaxin7 and endobrevin were stable in the absence of Vti1b these data indicate that the closest relationship within the complex is between Vti1b and syntaxin8. Some knockout studies of proteins involved in membrane transport also point to secondary changes in protein expression. RIM1 α is an active zone protein that was identified as a putative effector for the synaptic vesicle protein Rab3A. RIM1 α forms a protein scaffold for regulating neurotransmitter release at active zones. When RIM1 α is deleted, Munc13-1 shows a change in the protein amount, decreasing by about 60 % in the knockout mice. Presumably it happens because Munc13-1 binds to RIM1 α and becomes destabilized in its absence. An isoform Munc13-3 was moderately affected. An additional isoform of Munc13-1, Munc13-2 that does not bind RIM1 α showed no decrease. Similarly to changes in syntaxin 8 levels in our case, RIM1 α heterozygous mice also showed decrease in Munc13-1 expression (Schoch et al. 2002).

A similar situation was observed in a Rab3A knockout study. Rabphilin-3A is a peripheral membrane protein of synaptic vesicles, which binds Ca²⁺ and phospholipids. Rab3A or Rab3C recruit rabphilin-3A to the synaptic vesicle membrane. In Rab3A knockout mice, the steady-state concentration of rabphilin-3A is decreased by 70% in spite of normal mRNA levels. The immunoblot data are also confirmed by immunofluorescence. In the absence of Rab3A or Rab3C isoforms, rabphilin-3A fails to reach the synapse and is degraded (Li et al. 1994).

Mice lacking the δ subunit of the AP-3 complex due to its targeted disruption show no detectable protein levels of the other subunits β 3, μ 3, σ 3, belonging to the AP-3 complex.

These three subunits of the AP-3 complex became presumably unstable and rapidly degraded (Kantheti et al. 1998).

An abolishment of μ 1A-adaptin leads to reduction in amounts of other AP1 complex members, namely γ - and σ 1-adaptins. γ - adaptin protein levels were reduced to 70% of control and σ 1-adaptin to 30% of wild type. On the mRNA expression level there were no changes observed for both of genes (Meyer et al. 2000). A parallel to syntaxin8 reduction can be drawn in these cases. Vti1b and syntaxin 8 are members of SNARE complexes while adaptins are members of adaptor complexes. However, an adaptor complex remains assembled, while SNARE complexes undergo cycles of assembly and disassembly during the fusion reaction. Transient interactions are also typical for RIM1 α and Munc13 and for Rab3A and rabphilin.

5.1.4 Retardation of endosomal cargo delivery to lysosomes in Vti1b deficient hepatocytes

Transport to the lysosome was analysed in Vti1b deficient mice. Binding of the ligand EGF induces endocytosis of the EGF-EGF-R complex, transport via the early and late endosome to the lysosome and lysosomal degradation. Hepatocytes from normal size Vti1b knockout mice had only a moderate retardation of EGF-R degradation, whereas degradation of the EGF-receptor was significantly slowed in hepatocytes from small Vti1b deficient mice. Degradation of asialofetuin is also a marker for the endocytic pathway and lysosomal degradation. ASGP-R is recycled each time to cell surface to enter a new cycle of endocytosis, but the internalised ligand asialofetuin is transported to lysosomes for degradation. Hepatocytes of normal size Vti1b knockout mice degraded asialofetuin with a similar kinetic as wild type cells, but the rate was reduced in hepatocytes of small Vti1b deficient mice. Cathepsin D is transported from the TGN via the late endosomes to lysosomes. Hepatocytes of small Vti1b knockout mice had a slightly retarded processing of cathepsin D precursor to the intermediate form. Cathepsin D processing was normal in hepatocytes derived from normal size Vti1b deficient mice. These data fit with electronmicrographs of hepatocytes. Wild type and Vti1b deficient hepatocytes from normal size mice were indistinguishable. Abnormalities were observed in hepatocytes derived from small Vti1b deficient mice. The number of multivesicular late endosomes and of autophagosomes was higher than in wild type hepatocytes. Quite often autophagosomes were in close contact with each other or with multivesicular bodies and

were in the process of fusion. These structures are not seen in wild type hepatocytes. These observations are consistent with the model that SNAREs are not required for docking, but in a late step during membrane fusion.

Together these data indicate that fusion with lysosomes was slowed down but not completely abolished in hepatocytes of small *vti1b* deficient mice. Retardation in autophagocytosis and in transport to the lysosome in hepatocytes may compromise liver function. As the liver has a central role in the metabolism of mammals this may lead to reduced growth rates. LAMP-2 deficient mice are also smaller and show delays in autophagocytosis (Tanaka et al. 2000). However, these defects were not observed in the majority of *vti1b* deficient mice.

5.1.5 Comparison of membrane traffic in *Vti1b*-deficient cells with in vitro studies of endosomal trafficking

Works of several groups showed that *Vti1b*, syntaxin 7, syntaxin 8 and endobrevin participate in endosomal trafficking.

Syntaxin 7 associates with endobrevin (VAMP-8) and is specifically required for the fusion of late endosomes *in vitro*. Antibodies against syntaxin 7 inhibit fusion of late endosomes with lysosomes (Mullock et al. 2000). Expression of mutant syntaxin 7 lacking the transmembrane domain alters the morphology and distribution of endosomes and blocks endocytic transport to late endosomes (Nakamura et al. 2000). Homotypic lysosome fusion is *in vitro* inhibited by syntaxin 7 antibodies in dose-dependent manner (Ward et al. 2000).

VAMP-8 antibodies inhibit homotypic fusion of both early and late endosomes (Antonin et al. 2000b). It is possible that syntaxin 7 participates in two different SNARE complexes. Using B16 melanoma cells, it was shown that syntaxin 7 coimmunoprecipitates with *Vti1b*, syntaxin 6, VAMP8 as well as VAMP7 (Wade et al. 2001).

It has been proposed that syntaxin 7 and syntaxin 8 mediate distinct steps of endosomal protein trafficking. Syntaxin 7 is mainly localized to early endosomes and may be involved in protein trafficking from the PM to the EE. Syntaxin 8 is supposed to mediate clathrin independent step of transport from EE to LE. In permeabilised HeLa cells antibodies against syntaxin 8 retard transport of EGF to lysosome, but have no effect on recycling of transferrin receptor between plasma membrane early endosome and recycling endosome (Prekeris et al. 1999). Syntaxin 8 was found on early and late endosomes in PC12 and

COS7-cells and clearly on TGN (Prekeris et al. 1999). Another group localised syntaxin 8 in NRK cells to early endosomes. Small fractions were found on late endosomes, plasma membrane and coated pits. It was shown that syntaxin 8 coimmunoprecipitates with Vti1-rp1 (Vti1b) (Subramaniam et al. 2000).

However, other data indicate that syntaxin7 and syntaxin8 act in a common step. It was shown that Vti1b, syntaxin 8, syntaxin 7 and endobrevin are members of the same SNARE complex. Endocytic transport and lysosomal degradation of EGF was retarded by Fab fragments specific for endobrevin, Vti1b, syntaxin 7 and syntaxin 8. In addition, antisera directed against Vti1b, syntaxin7 and syntaxin8 inhibited fusion of late endosomes but not of early endosomes in vitro (Antonin et al. 2000a). The crystal structure of the complex consisting of the SNARE motifs of Vti1b, endobrevin, syntaxin 7 and syntaxin 8 was solved recently (Antonin et al. 2002). It is remarkably similar to the crystal structure of the neuronal SNARE complex. Our data show that Vti1b deficient hepatocytes from small mice have a retardation in delivery of endosomal cargo to the lysosome. This supports a role of characterised SNARE complex in late endosomal fusion.

5.1.6 What may be reasons for the phenotypic heterogeneity of Vti1b deficient mice?

The phenotype of Vti1b deficient mice may be heterogenous because they are genetically heterogenous. The E-14 embryonic stem cells used in the present work have the genetic background Sv129Ole (Hooper et al. 1987). Vti1b heterozygous mice were obtained by crossing germ-line producing chimeras with C57BL mice. Afterwards, the mice were crossed among each other. Hence Vti1b knockout mice have genetic information from both mouse strains, Sv129Ole and C57BL.

Given that there is only a mild phenotype in some mice and no detectable defects in most Vti1b deficient mice the question arises what compensational mechanism can exist? One possibility would be that other SNARE proteins can substitute for the absent Vti1b and the reduced syntaxin 8 and form a late endosomal complex together with syntaxin 7 and endobrevin. This hypothesis would explain why syntaxin 7 and endobrevin (VAMP8) are not degraded in Vti1b deficient tissues. Several SNAREs have been shown to form multiple core complexes in vivo, and many SNAREs bind to each other in vitro after tissue solubilisation. Furthermore, recombinant purified SNAREs can bind to each other in certain combination in vitro, although the stability of the complexes greatly varies (Jahn

and Sudhof 1999). SNARE complexes always require four helices, one from each subfamily. Many SNAREs are already known and classified onto SNARE subfamilies.

Vti1b is a Qb SNARE, syntaxin 8 is Qc SNARE (Bock et al. 2001). Therefore we have to search for possible candidates among known Qb and Qc SNAREs.

The first and best candidate could be SNAP-29, because it has both Qb and Qc SNARE motifs and can in this case act as Qb and Qc SNARE. SNAP-29 is predominantly soluble and its function in membrane traffic and SNARE partners remain unclear. SNAP-29 does not coimmunoprecipitate with syntaxin7 and endobrevin in wild type cells (Antonin et al. 2000a). However, SNAP-29 shares only 24,6% amino acid identity with Vti1b and 28,1% with syntaxin 8 in the SNARE motif (Antonin et al. 2000a).

Second candidates could be Vti1a (Qb) and syntaxin 6 (Qc). They coimmunoprecipitate together with VAMP4 and syntaxin 16 and form a SNARE complex of conserved structure because one SNARE motif of each subgroup is present. The complex may play a role in early endosomal fusion (Kreykenbohm et al. 2002). Experiments of Mallard et al. provide interaction data suggesting the formation of a specific SNARE complex between syntaxin 6, syntaxin 16 and Vti1a. By coimmunoprecipitation it was shown that syntaxin 6/syntaxin 16/Vti1a interact with either VAMP3/cellubrevin or VAMP4, but not with VAMP7/TTI-VAMP or VAMP8/endobrevin. The authors state as unpublished data that syntaxin 6 but not syntaxin 5 stimulated binding of syntaxin 16 to GST-VAMP4 (Mallard et al. 2002). It is still possible that in the absence of its homologue and with reduced levels of syntaxin 8 Vti1a and syntaxin 6 can form a lower affinity complex and participate in an additional fusion step. It is supported by the fact that syntaxin 6 is most homologous to syntaxin 8 (Subramaniam et al. 2000). Syntaxin 8 and syntaxin 6 share 32% amino acid identity in the SNARE motif (Steggmaier et al. 1998). As Vti1a is distributed among several organelles small amounts are present in late endosomes. Vti1b and Vti1a proteins have 39% of amino acid identity in the SNARE motif. An experiment using Vti1b knockout tissue homogenates could clarify whether SNAP-29 or Vti1a/syntaxin 6 participate in a late endosomal complex together with syntaxin 7 and endobrevin.

Less plausible would be a participation of membrin (Qb) and mbet1 (Qc) in a late endosomal complex of Vti1b deficient cells. They do not participate in endosomal membrane traffic, but are involved in ER to Golgi transport as members of a SNARE complex with sec22b and syntaxin 5 (Xu et al. 2000).

Always there is a possibility that yet undiscovered SNAREs or proteins which have not yet been characterised as SNAREs can participate in a late endosomal SNARE complex. Vti1b deficient mice of normal size may express substituting SNAREs at a higher level than small mice.

Another possibility is that completely different SNARE complex may fulfil the function of the endobrevin, syntaxin 7, Vti1b, syntaxin 8 complex and fuse late endosomes efficiently. This redundant SNARE complex should only have a minor role in the presence of Vti1b, because antibodies against Vti1b, syntaxin 7, syntaxin 8 and endobrevin reduced fusion of late endosomes *in vitro* by 75% (Antonin et al. 2000a). Wade et al. coimmunoprecipitated syntaxin 7 with Vti1b, endobrevin and small amounts of syntaxin 6. Authors propose that syntaxin 7/mVti1b/syntaxin 6 may form SNARE complexes with either VAMP7 or VAMP8 to regulate fusion events within the late endosomal pathway in melanoma cells (Wade et al. 2001).

In streptolysin-O-permeabilized cells, antibodies against VAMP-7 inhibit the breakdown of epidermal growth factor but not the recycling of transferrin (Advani et al. 1999). A significant proportion of VAMP7 was found in syntaxin 7 immunoprecipitate (Wade et al. 2001). A bacterially expressed human VAMP7 lacking the transmembrane domain inhibited both late endosome-lysosome fusion and homotypic lysosome fusion *in vitro* (Ward et al. 2000). These data support the hypothesis that another SNARE complex may in parallel regulate fusion of late endosomes. However, other SNAREs of this complex are not known so far. In small Vti1b deficient mice such compensation may be kept only at background levels for unknown reasons. The genetical background probably plays a role here. It is possible that cells of normal size Vti1b knockout mice express proteins of a parallel operating SNARE complex at higher level than cells of small Vti1b deficient mice do. It is also possible that the localisation of other SNAREs differs or that lysosomal transport works more efficient due to other components of the transport machinery and their regulation.

5.1.7 Comparison of Vti1b deficiency to other knockout studies and an overview of existent organellar disease models

There are several studies that utilise a knockout strategy to understand the role of particular SNARE proteins in membrane traffic and cellular metabolism. One of such studies was done to show whether VAMP-3 is required for GLUT4 recruitment to the cell surface.

Enhanced glucose uptake in response to physiological stimuli was previously shown to recruit GLUT4 protein from intracellular vesicles to the cell surface (Lund et al. 1995; Olson et al. 1997). Several studies indicate that syntaxin4 and SNAP-23 on the plasma membrane are required for fusion of GLUT4 vesicles. These GLUT4 vesicles contain both VAMP2 and VAMP3/cellubrevin. To distinguish between the functional properties of VAMP2 and VAMP3 in that case, VAMP3 targeted disruption was applied. The data clearly demonstrate that VAMP3 absence has no significant effect on whole-body glucose metabolism or insulin-stimulated glucose uptake. Researchers found VAMP3 even dispensable for both insulin- and exercise-stimulated glucose uptake in vivo (Yang et al. 2001b). It is most likely that VAMP2 can compensate for the genetic loss of VAMP3 during muscle and adipose tissue development because VAMP2 and VAMP3 differ only in a single amino acid residue in the SNARE motif.

Another study was intended to show the role of syntaxin4 for GLUT4 protein translocation after insulin stimulation. Syntaxin4 deficient mice have early embryonic lethality, so it was impossible to study phenotypes in its full absence. Syntaxin 4 shares 42% amino acids identity with its closest homolog syntaxin1B, but syntaxin1B which is expressed predominantly in neurons cannot complement for the loss of syntaxin4. A lack of complementation by related protein may be due to expression patterns, localisation or failure to interact with other components of the fusion machinery. Heterozygous syntaxin4 mice have 40% less syntaxin4 and were shown to develop insulin resistance, as manifested by significant decreases in rates of whole-body glucose disposal and glycolysis. The decrease in insulin-stimulated skeletal muscle glucose uptake occurred in parallel with a reduction in GLUT4 translocation. So syntaxin4 was shown to be important in GLUT4 translocation in skeletal muscle (Yang et al. 2001a).

An aim of another study of a SNARE protein was to show the role of synaptobrevin 2 in synaptic transmission. Synaptobrevin 2 (VAMP2) knockout mice die immediately after birth. It was still possible to study a role of that protein in cultured hippocampal neurons using electrophysiological methods. In the absence of synaptobrevin 2, spontaneous synaptic vesicle fusion and fusion induced by hypertonic sucrose were decreased ~10 fold, but fast Ca^{2+} -triggered fusion was decreased more than 100-fold. Thus, synaptobrevin 2 may function in catalysing fusion reactions and stabilizing fusion intermediates but may not absolutely be required for synaptic vesicle fusion (Schoch et al. 2001). The R-SNARE

VAMP4 which is also localised to synaptic vesicles (Kreykenbohm et al. 2002) may substitute for synaptobrevin.

Currently several human diseases and mouse mutants are described that are supposed to be connected to the formation of lysosomes and lysosome-related organelles. Most of these disorders are accompanied by abnormal pigmentation. Lysosomes are morphologically heterogeneous, often resembling other organelles of the endocytic and secretory pathways. Therefore, they are currently distinguished from other organelles on the basis of an operational definition, which describes them as membrane-bound acidic organelles that contain mature acid-dependent hydrolases and LAMPs but lack mannose 6-phosphate receptors (MPRs). Properties of lysosomes are shared with a group of cell-type specific compartments referred as “lysosome-related organelles”, which include melanosomes, lytic granules, MHC class II compartments, platelet-dense granules, basophil granules, azurophil granules and *Drosophila* pigment granules. Mouse mutants can be good models to study human diseases.

The *mocha* mutant has defect melanosomes, abnormal lysosomes and platelet dense granules. This mutant is a model for type 2 of Hermansky-Pudlak syndrome, which is also characterised by neurological defects. Mutation in AP-3 δ in the *mocha* mouse links endosomal transport to storage deficiency in platelets, melanosomes and synaptic vesicles (Kantheti et al. 1998).

Defects in platelet dense granules and pigmentation characterise the mouse mutant *pallid* (*pa*). This mutant is probably defective in a more downstream event of vesicle trafficking – vesicle docking and fusion. The affected protein termed pallidin interacts with syntaxin 13. Participation of syntaxin 13 in endosomal trafficking was described by two independent groups (Advani et al. 1998; Prekeris et al. 1998). The level of syntaxin 13 is reduced approximately 50% in *pa* animals compared to C57BL/6J mice. The mRNA level is not affected, suggesting that loss of pallidin may lead to instability of syntaxin 13 (Huang et al. 1999). In this type of storage pool deficiency (SPD) reduction of syntaxin 13 amounts resembles destabilization of syntaxin 8 studied in this work.

Enlarged melanosomes have also been described for *pale ear* melanocytes. Ammonia - induced secretion of lysosomal hydrolases is defective in *pale ear* fibroblasts (Brown et al. 1985).

A characteristic feature of Chediak-Higashi syndrome at the cellular level is the presence of giant lysosomes, melanosomes, MIIC, lytic granules and azurophil granules. Mouse model for Chediak-Higashi syndrome is the *beige* mouse strain that carries a mutation in the LYST/Beige protein.

Abnormal organelle morphology also has been reported for neuroectodermal melanolysosomal disease (Elejalde et al. 1979). Even though they seem not to be connected to SNAREs directly, they show the importance of having proper lysosomal function.

5.1.8 Outlook

Vti1b deficient mice are good model to study late endosomal trafficking. A central goal of later studies should be to determine the reasons for compensatory mechanisms of Vti1b deficiency.

To get rid of the genetical heterogeneity of the Vti1b deficient mice they could be crossed back to Sv129Ole mice or to C57BL mice. Both crossings are going on at this time. If the heterogeneity is due to the genetic background, this would lead to increasing numbers of small mice in later generations of deficient mice of either genetic background.

Immunoprecipitation of SNARE complexes from knockout tissue homogenates have to be done using antibodies directed against syntaxin 7 and directed against the putative novel partners SNAP-29, Vti1a and syntaxin 6. Expression of other SNAREs has to be examined in more detail to find out if their levels are changed in deficient tissues. More attention should be paid to liver pathologies of these mice. The question why only some mice stay smaller than their littermates is still open and should be answered. Degradation of long-lived proteins has to be examined in hepatocytes of small mice. Interesting could be the comparison of syntaxin 7 as well as endobrevin localisation in cells from wild type, Vti1b deficient mice of normal size and of small size using electron microscopy. If novel SNAREs are recruited into a SNARE complex with syntaxin 7 it should be analysed whether their subcellular distribution is changed. An in vitro late endosomal fusion assay established from wild type as well as Vti1b deficient embryonic fibroblasts, would be helpful to determine which complex in cells of normal size mice operates in that fusion step.

6 Summary

Genomic DNA for *Vti1b* and *Vti1a* was isolated and the chromosomal regions characterised. Using targeted gene disruption mouse mutants lacking *Vti1b* constitutively were generated. It was shown that *Vti1b* was a non-essential protein. The absence of *Vti1b* reduced the levels of syntaxin 8 protein in all cells and tissues while syntaxin 8 mRNA levels remained unchanged. *Vti1b* knockout had phenotypic heterogeneity which was manifested by the appearance of mice of normal and small size. Normal size *Vti1b* knockout mice showed no detectable defects in late endosomal trafficking, whereas hepatocytes from small ones displayed a retardation in cargo transport from late endosomes to lysosomes marked by slower EGF-R degradation, delayed asialofetuin degradation and reduced cathepsin D maturation. Electron microscopic data showed that the number of multivesicular late endosomes and of autophagosomes was higher in hepatocytes of small *Vti1b* deficient mice, quite often autophagosomes were in close contact and were in the process of fusion. That was not observed in hepatocytes of wild type and normal size *Vti1b* deficient mice.

It was also shown that the *Vti1a* chromosomal region is at least three times larger than the *Vti1b* locus. Two targeting DNA constructs were generated utilising two different knockout strategies for obtaining *Vti1a* deficient mice. Two embryonic stem cell clones carrying a constitutively mutated *Vti1a* gene copy were selected and used for obtaining chimeric mice.

Acknowledgements

I would like to express my gratitude to Prof. Dr. K.von Figura for his excellent supervision, helpful tips, advices and comments which led to successful experiments and important data.

I am grateful to Prof Dr. G. Gottschalk for co-reference.

A special acknowledgment to Dr. G. Fischer von Mollard for giving me the opportunity to do this work. This has been an exciting project for me and I thank her for guiding me. I have also benefitted from the stimulating discussions and her excellent supervision. I acknowledge her for the critical reading of the thesis.

Thanks also go to Eeva-Liisa Eskelinen, who did the electron microscopic studies of hepatocytes.

I acknowledge all employees and research workers of the Department of Biochemistry II for their cooperation. I gratefully acknowledge Dr. Peter Schu and Dr. Paul Saftig for their helpful advices and support.

I thank Elizabeth Munk and other workers of the animal house for their active support.

I thank Anna-Lena Illert for teaching me the art of liver perfusion.

I acknowledge Mike Dilcher, Beate Köhler and Nina Müllers for creating a healthy working atmosphere in our laboratory, with supportive advices, help, good spirits and humour.

I thank Vera Kreykenbohm for helping me to gain technical skills in handling Adobe Illustrator and for helping me with the graphics of the thesis.

Finally, I owe a debt to my parents who supported me honourably all these years.

Curriculum vitae

I was born on 9th August 1973 as first child of Ekaterina Aleksandrovna Atlachkine (nee Belokopytova) and Vladimir Ivanovitch Atlachkine in Kvitok (Tayshetsky district, Irkutsk region of Russia).

From 1980 till 1983 I had my elementary education in a school in Sosnovoborsk (Krasnoyarsky region, Russia). In 1984 I joined a high school in Sosnovoborsk and successfully completed in 1990 with school-leaving certificate.

In the winter semester 1990 I started to study biology at the State University of Krasnoyarsk where I joined the department of ichthyology in 1992 for specialisation. I started my diploma thesis in summer 1994. In June 1995 I submitted my diploma thesis entitled “Ecological and morphological characteristics of fish of lakes Arachley and Shaksha (Chita region of Russia)” followed by an oral diploma examination.

In August 1995 I joined the ichthyology department of the Limnological Institute of Siberian Branch Russian Academy of Sciences (Irkutsk, Russia) was joined for labrotation. In June 1996 I joined the molecular biology laboratory of the same institute was joined for labrotation, which I successfully finished in September 1997. From September 1997 till June 1998 I was working as research assistant in a project on “Phylogenetic relationships of picoplanktonic green algae of the lake Baikal” in the molecular biology laboratory of the Limnological Institute.

From June 1998 till January 1999 I was holding a scholarship of the fund SATW (Swiss Academy of Technical Sciences) – Branco-Weiss. In that time I worked as a trainee at the Ecotoxicology laboratory for non-target arthropods (Novartis Crop Protection AG, Basel, Switzerland).

In February of 1999 I moved to Germany and started the PhD thesis presented here with the title “Characterisation of Vti1b and Vti1a proteins and generation of knock-out mice” at the Georg-August University of Göttingen in the department of Prof. Dr. K. von Figura under the supervision of Dr. G. Fischer von Mollard.
