

**Soil Carbon Dioxide dynamics and Nitrogen cycling in an Eastern  
Amazonian Rainforest, Caxiuanã, Brazil**

Dissertation

Submitted for the Degree of  
Doctor of Forestry and Forest Ecology  
of Georg-August-University of Göttingen

by

Eleneide Doff Sotta

From Curitiba, Brazil

Göttingen, June 2006

Referee: Prof. Dr. Edzo Veldkamp

Coreferee: Prof. Dr. Gode Gravenhorst

Day of Oral Examination: 11.07.2006

- 4.2** Microbial C, available C, water filled pore space (WFPS) and rates of N<sub>2</sub>O emission.
  
- A1** Soil CO<sub>2</sub> efflux, soil temperature at 0.05 m depth (*T<sub>s</sub>*) and soil water content (*swc*) at 0.3 m depth in sand and clay soil textures
- A2** Soil CO<sub>2</sub> production (*P<sub>CO2</sub>*), soil temperature (*T<sub>s</sub>*) and soil water content (*swc*) in control and throughfall exclusion (TFE) plot

## List of Abbreviations and Symbols

C	carbon
C:N	carbon : nitrogen ratio
CO <sub>2</sub>	carbon dioxide
DNRA	dissimilatory nitrate reduction to ammonia
DOC	dissolved organic carbon
ECEC	effective cation exchange capacity
ENSO	El Nino Southern Oscillation
FDR	frequency domain reflectometry
IRMS	isotope ratio mass spectrometry
LAI	leaf area index
LBA	Large Scale Biosphere Atmosphere Experiment in Amazonia
Mg	Megagrams
MPEG	Museu Paraense Emilio Goeldi
MRT	mean residence time
N	nitrogen
N <sub>2</sub> O	nitrous oxide
NEE	net ecosystem exchange
NH <sub>4</sub> <sup>+</sup>	ammonia
NO <sub>3</sub> <sup>-</sup>	nitrate
NPP	net primary productivity
PAR	photosynthetically active radiation
Pg	Petagrams
SOC	soil organic carbon
T <sub>0</sub>	core extracted 10 minutes after the injection

$T_1$	core extracted 1-2 days after the injection	
TCD	thermal conductivity detector	
TDR	time domain reflectometry	
TFE	through-fall exclusion	
$T_g$	Tones	
WFPS	water filled pore space	
$x$	determined from the relation $a^{2x} + (1-a)^x = 1$	
$y$	exponent usually between 0.6 and 0.8	
$z$	exponent usually between 0.6 and 0.8	
$a$	air-filled porosity	$m^3 m^{-3}$
$a_{100}$	air-filled porosity at -100 cm H <sub>2</sub> O	$m^3 m^{-3}$
$a_{er}$	inter-aggregated air-filled pore space	$m^3 m^{-3}$
$a_{ra}$	intra-aggregated air-filled pore space	$m^3 m^{-3}$
$b$	pore-size distribution	
$D_o$	diffusion coefficient of the same gas in free air	
$D_s$	diffusion coefficient of a gas in soil air	
$\delta_s$	$\delta^{15}N$ value at different depths in the soil profile	‰
$\delta_{so}$	$\delta^{15}N$ value of the input substrate	‰
$E$	soil CO <sub>2</sub> efflux	$\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$
$\varepsilon$	total porosity	$m^3 m^{-3}$
$\varepsilon$	enrichment factor	‰
$\varepsilon_{pe}$	inter-aggregated total pore space	$m^3 m^{-3}$
$\varepsilon_{ap}$	intra-aggregated total pore space	$m^3 m^{-3}$
$f$	remaining fraction of total N	‰

$P_{CO_2}$	soil CO <sub>2</sub> production	$\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$
$\theta$	volumetric water content.	$\text{m}^3 \text{ m}^{-3}$
$swc$	soil water content	$\text{m}^3 \text{ m}^{-3}$
$T_s$	Soil temperature	$^{\circ} \text{C}$
$\Psi$	water potential	kPa
$\delta^{15}\text{N}$	delta <sup>15</sup> N	‰
$k_C$	0.45	
$k_N$	0.68	

# 1. Introduction

## 1.1. Problem analysis

At the present, there is no doubt that the composition of the atmosphere and reactions among atmospheric constituents are changing as a result of human activities (Schlesinger 1997). Atmospheric concentrations of greenhouse gases have grown significantly since pre-industrial time (IPCC 1992). The concentration of CO<sub>2</sub> has increased from about 280 to almost 360 ppmv and N<sub>2</sub>O from about 275 to about 310 ppbv. These trends can be attributed largely to human activities, mostly fossil fuel use, manufacturing and industrial processes, such as production of iron, steel, aluminium, ammonia, cement and other materials, land use change and agriculture (IPCC 1997). This increase of greenhouse gas concentrations leads to an additional warming of the atmosphere and the Earth's surface, and consequently a likely global rise in soil temperature. As a response to the higher soil temperature, soil respiration is expected to increase, in a rate of about 2.0 per 10° C rise in temperature (Schimel et al. 1994, McGuire et al. 1995). However, the effect of the higher temperature in the soil biochemical dynamics is yet not clear and it may differ between temperate and tropical areas.

The global carbon cycle is closely linked with climate, the water cycle, nutrient cycles, and the production of biomass through photosynthesis on land and in the oceans. Soil carbon is a major component of the terrestrial carbon cycle. Nearly all models of global climate change predict a loss of carbon from soils as a result of global warming (Schimel et al. 1994, McGuire et al. 1995). Global soil organic carbon storage in the top 3 m of soil is 2344 Pg C (Jobaggy and Jackson 2000), which is three times the amount of carbon in the atmosphere and five times the carbon stored in vegetation (Schlesinger et al. 2000). Thus small increases or decreases in the amount of carbon in soils could have a large impact on the atmospheric CO<sub>2</sub> concentration (Trumbore 2000). Soil CO<sub>2</sub> efflux is the major path by which carbon is lost

from the soil system. Soil CO<sub>2</sub> flux is a major flux in the global C cycle (60 Pg C yr<sup>-1</sup>), second in magnitude to the fixation of carbon by land plants (120 Pg C yr<sup>-1</sup>; Schlesinger et al. 2000). As a result of burning of fossil fuels (6 Pg C yr<sup>-1</sup>) and deforestation (2 Pg C yr<sup>-1</sup>) there is currently an anthropogenic input to the atmosphere of about 8 Pg of carbon each year as CO<sub>2</sub> (IPCC 2000). Of the 8 Pg C yr<sup>-1</sup> emitted, only about 3 Pg of carbon remains in the atmosphere. The remaining carbon is dissolved in the ocean or taken up by photosynthesis and sequestered as biomass or organic matter in soil.

Additionally to the unknown soil C feedbacks to the increase of global temperature, the increase in N deposition may also affect soil CO<sub>2</sub> emissions (Brumme and Beese 1992, Gallardo and Schlesinger 1994). Apart from the influence on CO<sub>2</sub> emissions, N deposition may also have an effect on N<sub>2</sub>O emissions. Current rates of atmospheric N deposition are in some cases large enough to saturate the biological demand for N within many ecosystems over time (Aber et al. 1995, Dise and Wright 1995) resulting in losses of N as soil gases.

N deposition has been of great concern, already for some time, in the industrialized world, primarily associated with N-oxide and ammonia emissions from combustion processes and agricultural activity (Hall and Matson 2003). However, the intensification of fossil fuel use and agricultural practices worldwide, including many tropical areas, has raised the concern of N deposition also in the developing world (Galloway et al. 1994, Matson et al. 1999). As well as in carbon cycle, nitrogen cycle is also linked to the rate of net primary production on land and in the sea (Vitousek and Howarth 1991). About 240 Tg of newly fixed N is delivered from the atmosphere to the Earth's land surface each year, 40 % by natural and 60 % by human-derived sources. Each year rivers carry about 36 Tg N from land to the sea (Wollast 1993), and humans additions of fixed nitrogen to the terrestrial biosphere have also resulted in marked increases in the nitrogen content of groundwater, especially in many agricultural areas (Spalding and Exner 1993). The remaining nitrogen is assumed to be lost by

denitrification in terrestrial soils and in wetlands, and during forest fires. Estimates of global denitrification in terrestrial ecosystems range from 13 to 233 Tg N yr<sup>-1</sup> (Bowden 1986). Most of the loss occurs as N<sub>2</sub>, but the small fraction that is lost as N<sub>2</sub>O during nitrification and denitrification contributes significantly to the global budget of this gas.

N<sub>2</sub>O is an effective greenhouse gas, and its concentration in the atmosphere is increasing by 0.25 % yr<sup>-1</sup> due to human activity (IPCC 1996). This long-lived greenhouse gas has a per molecule radiative forcing strength 200-300 times greater than CO<sub>2</sub> (Shine et al. 1990, 1995, Prather and Ehalt 2001). N<sub>2</sub>O also contributes to stratospheric ozone destruction (Cicerone 1987). Recent estimates suggest that soil emissions of N<sub>2</sub>O from humid tropical forests account for 20-50 % of all global sources of atmospheric N<sub>2</sub>O (Prather et al. 1995, Potter et al. 1996). As these ecosystems are generally N saturated the N availability may exceed biological demand very rapidly and the excess of N will possibly result in even larger and more immediate losses of N (Verchot et al. 1999, Hall and Matson 2003).

Natural systems and biogeochemical cycles have historically maintained their pools in dynamic equilibrium. However with the current anthropogenic activities it is already possible to observe large shifts among terrestrial, oceanic and atmospheric pools (IPCC 1995). The disruption of the global C and N cycle by human activity in both developed and developing countries is one of the key environmental issues facing human populations as we move into the 21st century (Rustad et al. 2000).

## 1.2. Future projections

### *Intensification of ENSO in the Amazon region*

Many global climate change models (Foley et al. 1996, Cramer et al. 2001) suggest strong reductions in precipitation in some tropical regions, particularly in Amazonia (Prentice

et al. 2000). As a result of the lower recirculation of water between the deforested biosphere and the atmosphere, the regional climate in the Amazon Basin may become drier (Shukla et al. 1990, Nobre et al. 1991, Costa and Foley 2000, Werth and Avisar 2002) with consequent reduction in forest area and net primary productivity (NPP). Added to that the development in the Amazon region has been accompanied by increasing forest fragmentation and poorly managed logging activities. Both fragmentation and logging increase the likelihood of fire escaping from managed systems into forest, especially during dry years often associated with El Niño (Keller et al. 2004). El Niño Southern Oscillation (ENSO) is responsible for a large part of the climate variability at interannual scales in Latin America (Foley et al. 2002). ENSO-related drought can desiccate large areas of Amazonian forest, creating the potential for large-scale forest fires. Such episodes are increasing in frequency and intensity, possibly in response to the accumulation of greenhouse gases in the atmosphere (Nepstad et al. 1999, Timmermann et al. 1999).

Changes in precipitation could also affect emissions of carbon dioxide (CO<sub>2</sub>) from the remaining forested soils (Davidson et al. 2004). However, besides the precipitation, changes in CO<sub>2</sub> concentration and soil temperature also play important roles in finding the equilibrium on the soil C pool. The full consequences of these changes are not yet well known. Increasing temperature may cause a net loss of soil organic carbon, increasing CO<sub>2</sub> concentration can stimulate NPP, thus adding extra carbon to the system and increasing total soil carbon storage (e.g. Kirschbaum 1993, King et al. 1997). Model results point to the existence of a positive feedback from warming to increased CO<sub>2</sub> concentration on decade to century time scales that to some extent counteracts the negative feedback due to the physiological effects of CO<sub>2</sub> (Prentice et al. 2000). Increased storage of carbon in soils could help offset further anthropogenic emissions of CO<sub>2</sub>, whereas a release could significantly exacerbate the atmospheric increases (Eswaran et al. 1993).

Ecosystem models which include soil carbon and nitrogen cycling predict carbon turnover times of less than a decade for most of the carbon in the upper 20 to 30 cm of moist tropical forest soils (Potter et al. 1993, Schimel et al. 1994). It is also expected that increased flux of CO<sub>2</sub> from soils resultant from disturbance or global warming will largely derive from labile pools with the fastest turnover times. Hence, the greatest losses of soil carbon will probably be seen in tropical regions (Trumbore et al. 1996). This is of concern as the amount of carbon stored in the upper meter of tropical soils is estimated to be 13-17 % of global soil carbon storage (Sombroek et al. 1993), and the Amazon forest in Brazil alone contains ~210 Pg of this carbon (Houghton et al. 2001).

#### *Increase in N<sub>2</sub>O emissions to the atmosphere from Amazon soils*

Nitrogen availability is especially high in clay-rich, weathered tropical soils where N does not limit plant growth (Martinelli et al. 1999). The rapid cycling on nitrogen supports large emissions of the greenhouse gas nitrous oxide (N<sub>2</sub>O) (Keller et al. 2004). Emissions of N<sub>2</sub>O from the forests of the Amazon Basin account for ~0.8-1.3 Tg N yr<sup>-1</sup>, or nearly 10-15 %, of the global natural emissions of that gas (Melillo et al. 2001). Because increased anthropogenic N deposition (as is projected for large areas in the tropics) may result in larger and more immediate losses of N as soil gases (nitrous oxide, nitric oxide, dinitrogen) or as NO<sub>3</sub><sup>-</sup> in solution (Hall and Matson 2003), perturbations of the Amazon tropical forest may be expected to have a major impact on global concentrations of N<sub>2</sub>O, with consequent effects on the chemistry of the stratosphere and on the heat budget of the atmosphere (Myers 1980, Fearnside 1986, Keller et al. 1988).

However, mechanisms of soil N retention may exert a strong influence on the size and timing of these losses. Despite the high denitrification potential of humid tropical forests, N retention may be favoured in the presence of high C-to-NO<sub>3</sub><sup>-</sup> ratio (Silver et al. 2005). The

relative balance between  $\text{NO}_3^-$  reduction to  $\text{NH}_4^+$  via dissimilatory nitrate reduction to ammonia (DNRA) and losses via  $\text{N}_2\text{O}$  emissions is likely to be sensitive to a variety of ecosystem properties, particularly soil redox status and soil C and  $\text{NO}_3^-$  pools (Silver et al. 2005). Hence, the predicted loss of C from soils with the change in climate may also have unknown feedbacks in the N cycle in the soil of these ecosystems.

### 1.3. Objectives of the study

The significance of climate changes to the interaction of both carbon and nitrogen cycles in tropical soils is still unknown and deserves more attention. For that, it is important to identify individual processes and their consequences to changes in the climate. The overall goal of this study was to quantify spatial and seasonal variation in soil  $\text{CO}_2$  dynamics as a function of soil properties and climate variability as well as to determine the effectiveness of N retention mechanism in the main soil types in the Amazon basin.

This main goal was subdivided in several objectives:

- to quantify and compare the soil  $\text{CO}_2$  efflux rates in two soil textures from the dominant soil type in the eastern Amazon.
- to estimate  $\text{CO}_2$  production rates as a function of depth
- to evaluate how soil and environmental factors control  $\text{CO}_2$  production and soil  $\text{CO}_2$  efflux
- to investigate how an artificially imposed drought affects depth and amount of soil  $\text{CO}_2$  production and transport
- to quantify the gross rates of mineralization, nitrification, and microbial and abiotic N immobilization in a low N availability and a high N availability tropical forest soil.

#### 1.4. Site description

##### *Characteristics of Amazon forest soils, vegetation and climate*

All studies were conducted in the National Reserve of Caxiuanã (1°43'3.5''S, 51°27'36''W), approximately 400 km west of the city of Belem, Para, Brazil (Lisboa 1997). The site is administered by the Ferreira Penna Scientific Station which belongs to Museu Paraense Emilio Goeldi (MPEG). Caxiuanã Tropical Forest is located in the north-eastern Brazilian Amazon. The terrain around Caxiuanã site consists mainly of Cretaceous sedimentary rocks (Alter do Chao Formation of the Amazon basin) geomorphologically remodelled in various periods during Pleistocene (Kern 1996). These sediments were deeply weathered giving rise to lateritic profiles which extend deeply down to the saprolite, locally exposing fine kaolinite zones. Near and at the surface, the lateritic profiles have been converted into Oxisols (Yellow Latosols in the Basilian classification), which are widespread over the region. These Oxisols have clay to sand texture, are deep, acidic and oligotrophic (Almeida et al. 1993). Topography is gentle to steep and the additional erosion and leaching has reduced even further the fertility of the soils of these terraces.

The climate of the region is classified as humid tropic of the type Am (at Köppen classification; Moraes et al. 1997). Annual mean precipitation is about 2200 mm, with the peak of the rainy period registering on average 300 mm month<sup>-1</sup> occurring from February to April. The period with least precipitation is September to November, and less than 100 mm of rain are received on average per month (Lourdes Pinheiro Ruivo et al. 2002). Based on monthly rainfall observed during the study period (November 2001 – November 2003; Caxiuanã Meteorological Station), two seasons were distinguished. Months with more than 100 mm rainfall were assigned to the wet season (December to June), and the dry season consists of the period of months with less than 100 mm rainfall (July to November). Mean annual incoming short wave radiation is around 350 W m<sup>-2</sup> and mean annual temperature is

25.7 °C. Average daily minimum temperatures remains the same (23.0-23.1°C), but maximum temperature is higher in the dry season (31.2 °C) than the wet season (29.6 °C) (Fisher et al. in review a). The height of the canopy is about 35 meters, and the aboveground biomass is 200 m<sup>3</sup> ha<sup>-1</sup> (Lisboa 1997, Lisboa and Ferraz 1999). The forest presents considerable diversity and big trees, as *Dinizia excelsa* (angelim-vermelho), *Marmaroxylon racemosum* (Angelim-rajado), *Couratari guianensis* (tauari), *Bucheniavia grandis* (tanimbuca), *Swartzia racemosa* (pitaica), *Dipteryx odorata* (cumaru), among others (Almeida et al. 1993).

### *General design of the study*

This thesis presents an analysis including the CO<sub>2</sub> dynamics and the nitrogen cycle in two different soil textures analyzing the potential feedback mechanisms in these soils generated by the climate change. Data on the throughfall exclusion experiment in Caxiuanã is part of the Large Scale Biosphere Atmosphere Experiment in Amazonia (LBA) project. The objective of the LBA project is to understand the changes in the water recirculation, solar energy, carbon and nutrients with local changes of the vegetation and global climate changes (Avisar and Nobre 2002). Two experimental rainfall manipulations were implemented by LBA project (Avisar and Nobre 2002) in order to investigate the role of drought in constraining forest gas exchange. Two sites, Santarém and Caxiuanã, were selected in Eastern Amazonia, the area most at risk from reduced rainfall (Cox et al. 2000, 2004). At both sites, a system of plastic panels and guttering intercepts the rainfall at 2 m height, and channels the intercepted water away from the plot, thereby reducing the quantity of water hitting the soil by ~ 50 % (Fisher et al. 2006).

## 1.5. Overview of the thesis

This thesis is divided into 5 chapters, according to the different objectives. Chapter 2 deals with the quantification of soil CO<sub>2</sub> efflux, in particular the spatial and temporal variation of CO<sub>2</sub> emissions in different soil types, landscape and litter input together with climatic controls. In Chapter 3, the estimates of CO<sub>2</sub> productions rates are presented and the effects of an induced drought on soil CO<sub>2</sub> production and soil CO<sub>2</sub> efflux are discussed. Diffusion coefficients, which are needed to calculate the CO<sub>2</sub> production rates, are derived from empirical formulas and validated using radon measurements. In addition, two years data on soil air CO<sub>2</sub> concentration, soil temperature and soil water content are shown and compared with a similar throughfall exclusion experiment results. Chapter 4 focuses on the quantification of gross rates of mineralization, nitrification, and microbial and abiotic N immobilization in a tropical forest soil with low N availability and one with high N availability. Measurement of gross rates of N mineralization and nitrification were made using <sup>15</sup>N pool dilution technique, as well as estimates of NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> immobilization rates using chloroform fumigation extraction technique and the characterization of soil physical and chemical properties. These rates were used to evaluate if the mechanisms of soil N retention (biotic and abiotic immobilization and DNRA) are more effective in tropical rain forest soils with a low N availability than in tropical rain forest soils with a high N availability. All results are compiled in Chapter 5 to reach some general conclusions.

## **2. Landscape and climatic controls on spatial and temporal variation in soil CO<sub>2</sub> efflux in an Eastern Amazonian Rainforest, Caxiuanã, Brazil.**

### 2.1. Introduction

In recent years, the recognition that old-growth forests of Amazonia play an important role in the global carbon cycle, has led to the establishment of several sites across the Amazon basin where net ecosystem exchange (NEE) of CO<sub>2</sub> is measured (Grace et al. 1995a, Malhi and Grace 2000, Saleska et al. 2003). In the absence of fire, NEE is the net result of CO<sub>2</sub> uptake through photosynthesis and CO<sub>2</sub> losses through autotrophic and heterotrophic respiration. A major part of the respired CO<sub>2</sub> originates from the soil and quantifying the size and variation of this CO<sub>2</sub> source is critical for the correct interpretation of NEE measurements.

In contrast to tower-based NEE measurements, there are no standard methods to measure soil CO<sub>2</sub> efflux (or soil respiration) over larger areas; chambers which normally cover only a fraction of a square meter are used. At the same time, soil CO<sub>2</sub> efflux is highly variable, both spatially and temporally (Hanson et al. 1993, Xu and Qi 2001). As a result, estimates of the mean soil CO<sub>2</sub> efflux, even within homogeneous vegetation are uncertain. Spatial variability of soil CO<sub>2</sub> efflux, typically caused by variations in landscape, soils and vegetation (Xu and Qi 2001, Schwendenmann et al. 2003) introduces a considerable level of uncertainty in modelling soil respiration at landscape and larger regional scales (Gough and Seiler 2004). Temporal variability, mainly caused by climatic variables (Davidson et al. 2000a), is a major source of error when estimating the cumulative annual soil CO<sub>2</sub> efflux (Janssens et al. 2000, Gough and Seiler 2004).

Although the vast majority of soils in Amazonia have in common that they are heavily weathered, there is considerable spatial heterogeneity in soil texture both at local and regional

scales (Sombroek 1966, Jordan 1985) and along topographic gradients (e.g. Silver et al. 2000). Furthermore, topographically induced microclimates and variations in soil water content can also cause spatial heterogeneity by affecting the ability to retain carbon, water, and nutrients (Running et al. 1987, Kang et al. 2000). Apart from soil texture and topography, the litter layer may also contribute to spatial and temporal variation of soil CO<sub>2</sub> efflux. Although litter input and turnover are frequently studied, the influence of the litter layer on temporal variation of soil CO<sub>2</sub> efflux has to our knowledge not been studied for tropical forests.

Because NEE measurements are done at high frequency and later integrated for longer time periods (hours to days), there is an increasing tendency to also collect soil CO<sub>2</sub> efflux at high frequency, with a limited amount of (automated) chambers (e.g. Goulden and Crill 1997, Drewitt et al. 2002). While this approach leads to an excellent characterization of temporal variation, spatial variation can only be quantified between the few deployed chambers. As a result, soil CO<sub>2</sub> efflux is normally modelled using climatic parameters as input (most often soil temperature and sometimes soil moisture) thereby ignoring landscape variations in soil CO<sub>2</sub> efflux. This may lead to serious errors because the ‘footprint’ of tower-based measurements is normally large enough to cover considerable variation in landscape and soils (Grace et al. 1995b). An additional problem may be that soil temperature and soil moisture co-vary, even in tropical forest ecosystems, making it impossible to separate their effect on soil CO<sub>2</sub> efflux (Davidson et al. 2000a, Schwendenmann et al. 2003).

Our goal was to quantify the spatial and seasonal variation in soil CO<sub>2</sub> efflux and its environmental controls in the old-growth forest of Caxiuanã in the eastern Amazon. Using manually deployed flux chambers, we monitored soil CO<sub>2</sub> efflux from two Oxisol sites with contrasting soil texture over the course of two years. Furthermore we aimed to quantify the contribution of the litter layer to soil CO<sub>2</sub> efflux and to evaluate the effect of landscape

position on CO<sub>2</sub> efflux. As the climate of the eastern Amazon is characterized by small fluctuations in temperature throughout the year, we expected that changes in soil water content would control the seasonal variation in soil CO<sub>2</sub> efflux.

## 2.2. Materials and Methods

### *Study site*

The experimental site was located in Caxiuanã National Forest, Pará, Brazil, (1°43'3.5''S, 51° 27'36''W). The forest is a lowland *terra firme* rainforest. Mean annual temperature is 25.7 °C. Mean annual rainfall is 2272 mm (± 193 mm), with a dry season when only 555 mm (± 116 mm) of rainfall occurs on average (Fisher et al. 2006). Months with more than 100 mm rainfall were assigned to the wet season (December to June), and the dry season consisted of the period of months with less than 100 mm rainfall (July to November).

Most soils (65 % of the experimental site, Costa 2002) are yellow Oxisols (Brazilian classification Latossolo), but there are large differences in texture. Our study was on two Oxisols with contrasting soil texture: clay and sand (Table 2.1). Both soils have a broken laterite layer (0.3-0.4 m thick) at 3-4 m depth. The texture of the top 0.5 m of the sand is 75 % sand and 25 % clay + silt, while the topsoil of the clay had 31 % sand and 69 % clay + silt (Ruivo and Cunha 2003). Mineralogy of both soils is mainly kaolinite in the clay fraction and quartz in the sand fraction (Ruivo and Cunha 2003). The sites are located about 15 m above river level, and the water table has occasionally been observed at a depth of 10 m during the wet season (Fisher et al. in review b). The forest structure does not vary much among soil types: 419 trees ha<sup>-1</sup> with a basal area of 25.1 m<sup>2</sup> ha<sup>-1</sup> and leaf area index (LAI) of 5.5 m<sup>2</sup>m<sup>-2</sup> on the clay soil and 434 trees ha<sup>-1</sup>, a basal area of 23.9 m<sup>2</sup> ha<sup>-1</sup> and LAI of 5.2 m<sup>2</sup>m<sup>-2</sup> for the sand site (unpublished data. D. Metcalfe). The height of the canopy is about 35 meters, and

the aboveground biomass is 200 m<sup>3</sup> ha<sup>-1</sup> (Lisboa et al. 1997). The forest presents considerable diversity, with species like *Dinizia excelsa* (angelim-vermelho), *Marmaroxylon racemosum* (Angelim-rajado), *Couratari guianensis* (tauari), *Bucheniavia grandis* (tanimbuca), *Swartzia racemosa* (pitaíca), *Dipteryx odorata* (cumaru), among others (Almeida et al. 1993).

Table 2.1 - Characterization of chemical and physical properties of the soil of our study area in Caxiuanã, Para, Brazil.

Texture/ Depth	Clay (%)	Silt (%)	Sand (%)	pH (H <sub>2</sub> O)	ECEC (cmol dm <sup>-3</sup> )	Total P (mg kg <sup>-1</sup> )	Total C (g kg <sup>-1</sup> )	Total N (g kg <sup>-1</sup> )	SOC (g kg <sup>-1</sup> )	Bulk density (Mg m <sup>-3</sup> )
<b>Sand</b>										
0-10cm	14	10	77	4.5	3.1	3.4	9.6	0.40	9.5	1.49
10-100cm	23	7	70	4.4	2.2	1.2	4.3	0.38	4.8	1.53
<b>Clay</b>

10-100cm	56	20	24	4.2	2.4	2.0	6.7	0.68	5.9	1.22

#### *Design of experiment to measure effect of soil texture*

Using a systematic design, 16 chambers were deployed on a 1 ha plot at the sand site, and 8 chambers on a 0.5 ha plot at the clay site. While 8 chambers was enough to get a good estimate of soil CO<sub>2</sub> efflux, we used more chambers on the sand site because of an additional throughfall exclusion experiment which is not described here (Fisher et al. 2006). In June 2001, PVC rings (0.296 m in diameter, 0.20 m tall) were inserted to a depth of 0.02 m into the soil. Once inserted, the rings were left in place throughout the period of measurements. Chambers were kept free of seedlings. Each of the two sites was sampled every two weeks from December 2001 to November 2002 and monthly from December 2002 to November 2003. It took two days to measure all sites, and all measurements were made between 8 AM and 2 PM local time.

### *Design of experiment to measure effect of topography*

In February 2002, we installed chambers along four topographic transects which were between 30 and 40m apart. Average slope length was  $108 \pm 11$  m and average inclination was  $5.4^\circ \pm 0.2^\circ$ . At each transect three chambers were installed at four different positions: plateau, upper slope, lower slope and valley. The chambers in the valley were installed about 0.5 m above the flood plain level. Measurements were made every three months from April 2002 to July 2003.

### *Design of experiment to measure contribution of litter layer*

Adjacent to the sandy site twelve chambers were systematically installed within an area of  $36 \text{ m}^2$  to minimize spatial variation. The following three treatments were imposed on four replicated chambers each: in treatment one ('no litter'), the chamber was placed directly on the mineral soil and litter was removed, and a small litter trap of 0.40 by 0.40 m was placed directly above each chamber. In treatment two ('normal litter'), the litter was not manipulated (it was used as control treatment). In the third treatment ('double litter'), the litter collected from treatment one was deposited in the chambers every two weeks. Measurements of  $\text{CO}_2$  efflux were made every three months from July 2002 to October 2003. Contribution of litter layer was the average of the difference between 'double litter' and 'no litter' soil  $\text{CO}_2$  efflux, and 'normal litter' and 'no litter' soil  $\text{CO}_2$  efflux. Soil water content and soil temperature from 'no litter' and 'double litter' treatment did not differ from control ('normal litter').

### *Measurements of soil CO<sub>2</sub> efflux*

Dynamic, closed chambers were used to determine soil CO<sub>2</sub> efflux (Parkinson 1981). Flux chambers were closed for about 5 minutes using a PVC cover. The volume of the chamber was about 13 L. Air was circulated at a flow rate of 0.8 L min<sup>-1</sup> between an infrared CO<sub>2</sub> gas analyzer (LI-6262, Li-Cor, Inc., Lincoln, Nebraska, USA) and the flux chambers. To prevent pressure differences between the chamber and the atmosphere, the chamber was vented to the atmosphere through a 0.25 m long stainless steel tube (3.2 mm outer diameter). CO<sub>2</sub> concentrations were recorded at 5 second intervals with a datalogger (Campbell CR10X, Campbell Scientific, Inc., Logan, Utah, USA). CO<sub>2</sub> flux (μmol CO<sub>2</sub> m<sup>-2</sup> s<sup>-1</sup>) was calculated from linear regression of CO<sub>2</sub> concentration within the chamber versus time, usually between 2 and 4 min after placing the cover over the ring. The coefficient of determination ( $r^2$ ) of the regression was typically greater than 0.99. The infrared gas analyzer was calibrated in the laboratory using a loop with a column containing CO<sub>2</sub> scrubber (Soda Lime indicating 4-8 mesh) as zero-standard and a secondary CO<sub>2</sub> standard (510 ppm). The secondary standard was calibrated against primary standards from the Large Scale Biosphere-Atmosphere Experiment in Amazon (LBA) project.

### *Complementary measurements*

Three replicates of mineral soil were collected for total C, N analysis to support our measurements of the soil CO<sub>2</sub> efflux. Bulk density was determined using soil core method. Particle size distribution was analyzed with the pipette method using pyrophosphate as a dispersing agent. Soil pH was measured from a saturated paste mixture (1:1 ratio of soil to H<sub>2</sub>O and to 1 M KCl). ECEC was determined from air-dried, 2-mm sieved samples, percolated with unbuffered 1 M NH<sub>4</sub>Cl, and the percolates analyzed for exchangeable cations

using Flame-Atomic Absorption Spectrometer (Varian, Darmstadt, Germany). Total P was analyzed from air-dried, ground samples, digested under high pressure in concentrated HNO<sub>3</sub>, and the digests were analyzed using Inductively Coupled Plasma-Atomic Emission Spectrometer (Spectro Analytical Instruments, Kleve, Germany)

In October 2001, 20 litterfall collectors were placed randomly at the sand site. The collectors were made of 2 mm mesh nylon net, had an area of 1 m<sup>2</sup>, and were placed about 30 cm above the forest floor. From November 2001 to November 2003, litter was collected monthly, put in paper bags and dried in a ventilated oven at 80 °C for 48 hours. The material was separated in three fractions: a) leaves, b) twigs and c) reproductive organs (flower, fruit and seeds); and weighed.

Soil temperature (*T<sub>s</sub>*) was measured adjacent to each flux chamber at approximately 0.05 m depth from soil surface (litter layer was normally insignificant) using a thermocouple T-probe and a handheld thermocouple meter (HI 93551, Hanna Instruments, Ann Arbor, MI, USA). Soil water content (*swc*) was determined using frequency domain reflectometry (FDR). The probe (CS 615, Campbell Scientific Ltd, Loughborough, UK) consists of 0.3 m long stainless steel rods that were placed vertically into the soil. The sensor output was converted to estimates of volumetric soil water content (m<sup>3</sup> m<sup>-3</sup>) using the standard calibration curve from the sensor. For the sand soil, the *swc* values were corrected by the calibration equation from Fisher et al. (in review a). Soil temperature and soil water content probes were inserted into the soil each time. Half-hourly meteorology data was measured by a tower-based automatic weather station in the vicinity of the study site (Carswell et al. 2002). This weather station provided measurements for wet and dry bulb temperature, incoming and outgoing short-wave radiation, photosynthetically active radiation (PAR), and long-wave radiation, wind speed and direction and rainfall (unpublished data from Y. Malhi).

### *Calculations and Statistical analyses*

For each of the sites, the average CO<sub>2</sub> efflux rate was calculated from the chamber flux measurements. Daily mean soil efflux was calculated by averaging the sampling dates for each site in both years. Coefficient of variation was the standard deviation of all chambers in each measurement date divided by the average soil CO<sub>2</sub> efflux of the given measurement for each site in both years.

Spatial (between soil types and treatments) and temporal differences as well as differences in topography were analysed by repeated measure ANOVA. Progressive decrease in soil CO<sub>2</sub> efflux was evaluated by testing (t-test) the average of the beginning (for the wet season from December to March, and for the dry season from July to September) and the end (for the wet season April to June, and for the dry season from October to November) of each season. Multiple regression analysis was used to examine relationships between soil CO<sub>2</sub> efflux, soil water content, soil temperature and other factors. Significant effects were determined at  $P < 0.05$ . All statistical analyses used STATISTICA 6 software package (StatSoft Inc., Tulsa, OK, USA).

## 2.3. Results

### *Variation in soil CO<sub>2</sub> efflux caused by differences in soil texture*

Spatial variation, for both sites, among soil chambers within the two-year measurements ranged from 13 to 52 % and was on average 23 % for the sand soil and 25 % for the clay soil. The two-year average CO<sub>2</sub> efflux rates were 21 % higher ( $P < 0.001$ ) for the sand ( $3.9 \pm 0.1 \mu\text{mol CO}_2 \text{ m}^{-2}\text{s}^{-1}$ ) than for the clay ( $3.1 \pm 0.1 \mu\text{mol CO}_2 \text{ m}^{-2}\text{s}^{-1}$ ). No difference was detected for soil temperature between sites ( $24.1 \pm 0.1 \text{ }^\circ\text{C}$  for sand and  $24.2 \pm 0.1 \text{ }^\circ\text{C}$  for

clay;  $P < 0.05$ ), while soil water content in sandy soil ( $23.2 \pm 0.3$  %) was much lower ( $P < 0.001$ ) than the clay soil ( $34.5 \pm 1.0$  %), for the two-year period.

Temporal variation ranged from 16.4 to 30.7 % and with an average coefficient of variation (CV) of 16.4 % for sand and 21.8 % for clay soil. Soil CO<sub>2</sub> efflux decreased progressively during the first wet season ( $P < 0.05$ ,  $n = 6$ ) in both sites. Towards the transition from the wet to the dry season, soil CO<sub>2</sub> efflux increased, followed by a progressive decrease observed during the dry season. Soil CO<sub>2</sub> efflux recovered with the onset of heavy rainfalls at the beginning of the wet season (Fig. 2.1). There was no difference in soil CO<sub>2</sub> efflux between the two years of measurement for both soils ( $P > 0.05$ ). The magnitude of soil CO<sub>2</sub> efflux on both soils did not differ significantly between dry season ( $4.0 \pm 0.1$  for sand and  $3.1 \pm 0.1$   $\mu\text{mol CO}_2 \text{ m}^{-2}\text{s}^{-1}$  for clay) and wet season ( $3.9 \pm 0.1$  for sand and  $3.1 \pm 0.1$   $\mu\text{mol CO}_2 \text{ m}^{-2}\text{s}^{-1}$  for clay), probably due to the within season variation.. Soil temperature and water content did differ between seasons on both sites ( $P < 0.001$ ).

#### *Spatial variation in soil CO<sub>2</sub> efflux caused by topography*

Coefficient of variation among landscape position and soil chambers ranged from 17.2 to 32.8 % and were on average 26.3 %. On average, soil CO<sub>2</sub> efflux did not differ between the plateau, valley and upper and lower slope positions. Time of the year and the interaction between time and position did however have a significant effect on CO<sub>2</sub> efflux ( $P < 0.01$ ). April (peak wet season) was generally the month with lowest CO<sub>2</sub> efflux while July and January (transition months) were the months with highest efflux rates, independent of topographic position (Fig. 2.2). Soil water content and soil temperature differed as a function of topographical position.

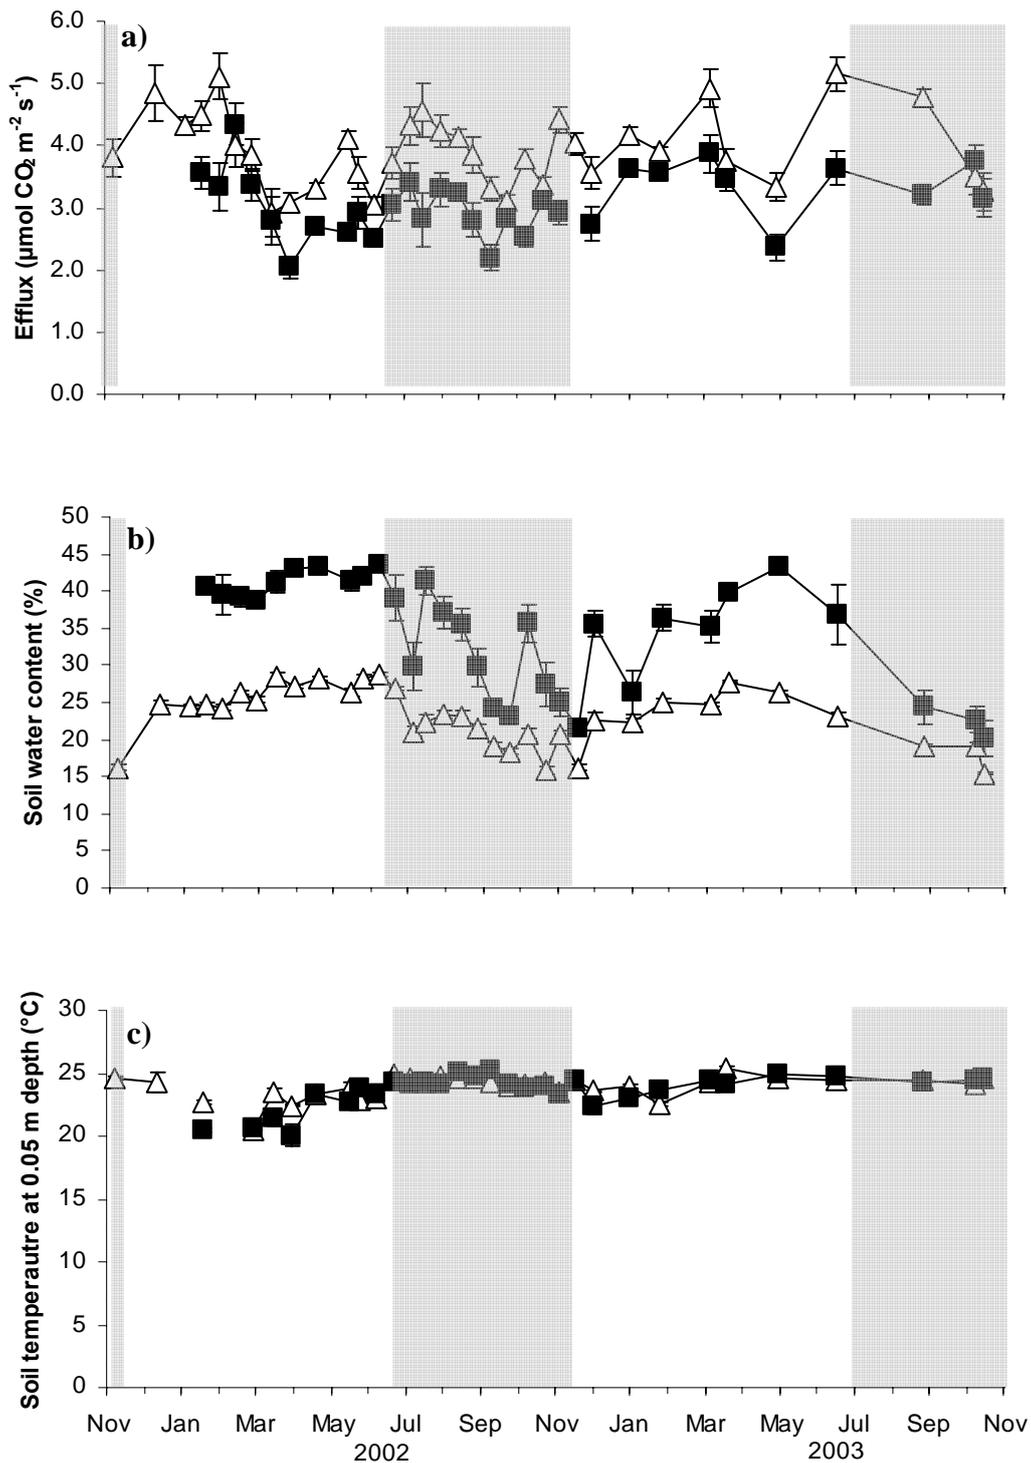

Figure 2.1 - Soil CO<sub>2</sub> efflux (a) , soil water content (b) and soil temperature (c) from November 2002 to November 2003 in sandy (-△-) and clay (-■-) sites. Shaded area mark the dry season; white background indicates the wet season. Each point is the mean of sixteen chambers for sand and eight chambers for clay. Error bars represent ± standard error of the mean.

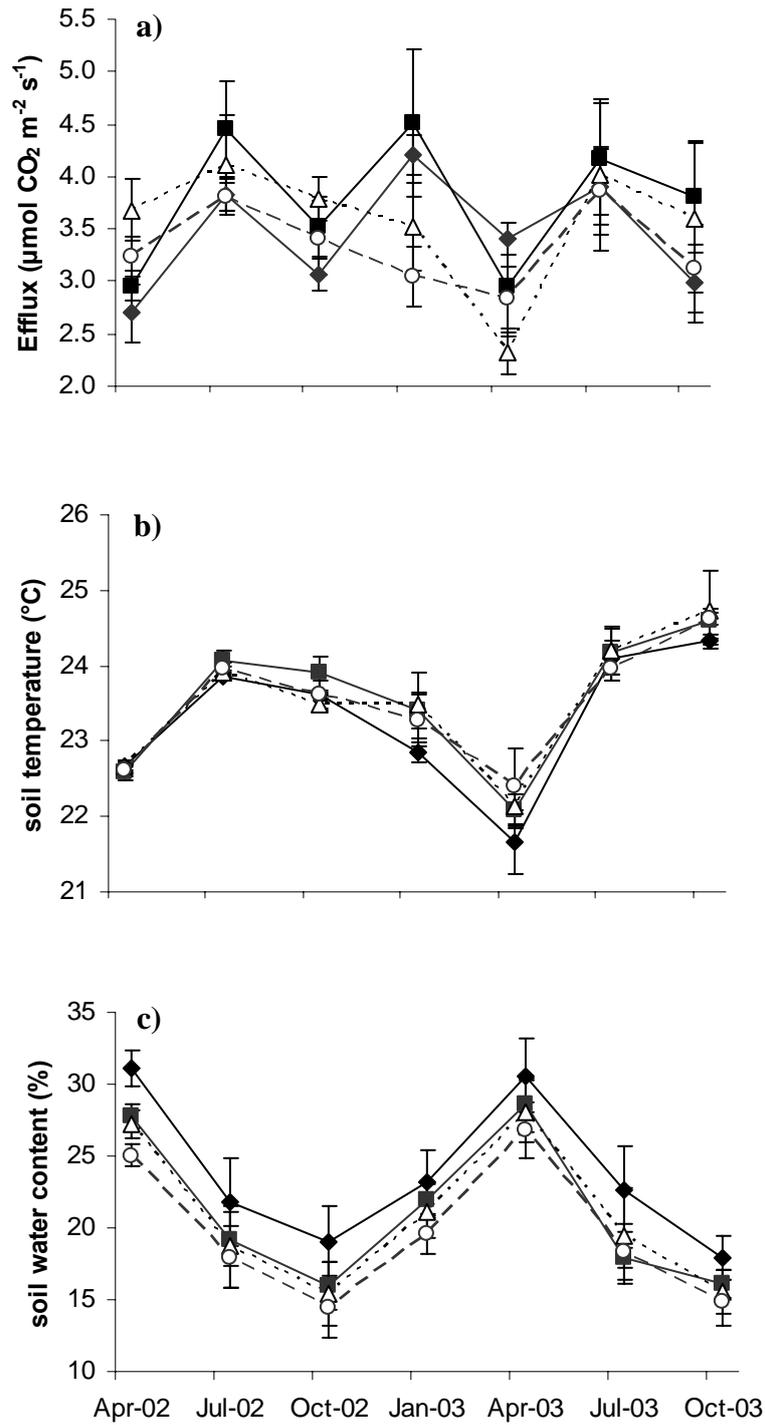

Figure 2.2 - Measurements of (a) soil CO<sub>2</sub> efflux, (b) soil temperature at 0.05 m depth and (c) soil water content at 0.30 m depth in the valley (—◆—), low slope (—■—), upper slope (···△···) and plateau (- -○- -). Each point is the mean of four sites (with three chambers measurements at each site). Error bars represent  $\pm$  standard error of the mean.

### Temporal variation in soil CO<sub>2</sub> efflux caused by the litter layer

Throughout the year the contribution of the litter layer to CO<sub>2</sub> efflux was about 20 %, varying from 25 % to almost zero depending on the seasonal conditions. In the wet season (Jan-03) the higher rates of soil CO<sub>2</sub> efflux ( $6.1 \pm 0.6 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ,  $P < 0.05$ ,  $n = 4$ ) were measured in the double litter treatment, while at the onset of the dry season (July) soil CO<sub>2</sub> efflux rates were similar in all treatments (Fig. 2.3). Total litterfall was higher during the end (May and Jun) of the wet season and lower at the peak (Jan-Feb) of the wet season (data not shown). Soil temperature and soil water content did not differ among treatments ( $P > 0.05$ ).

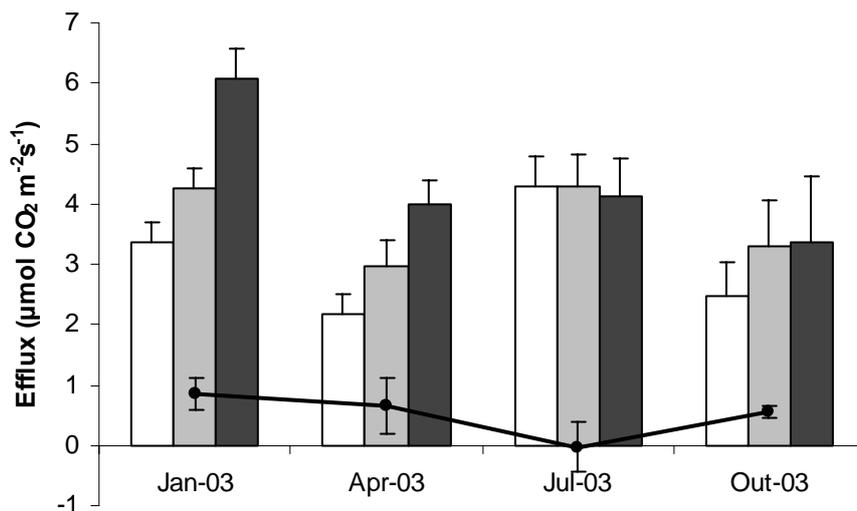

Figure 2.3 - Soil CO<sub>2</sub> efflux from forest floor without litter (white background), with normal amount of litter (gray background) and double the normal amount of litter (black background) at different time of the year, and the estimates of average seasonal contribution of the litter layer (—●—) to soil CO<sub>2</sub> efflux. Each point is the mean of four chambers. Error bars represent ± standard error of the mean.

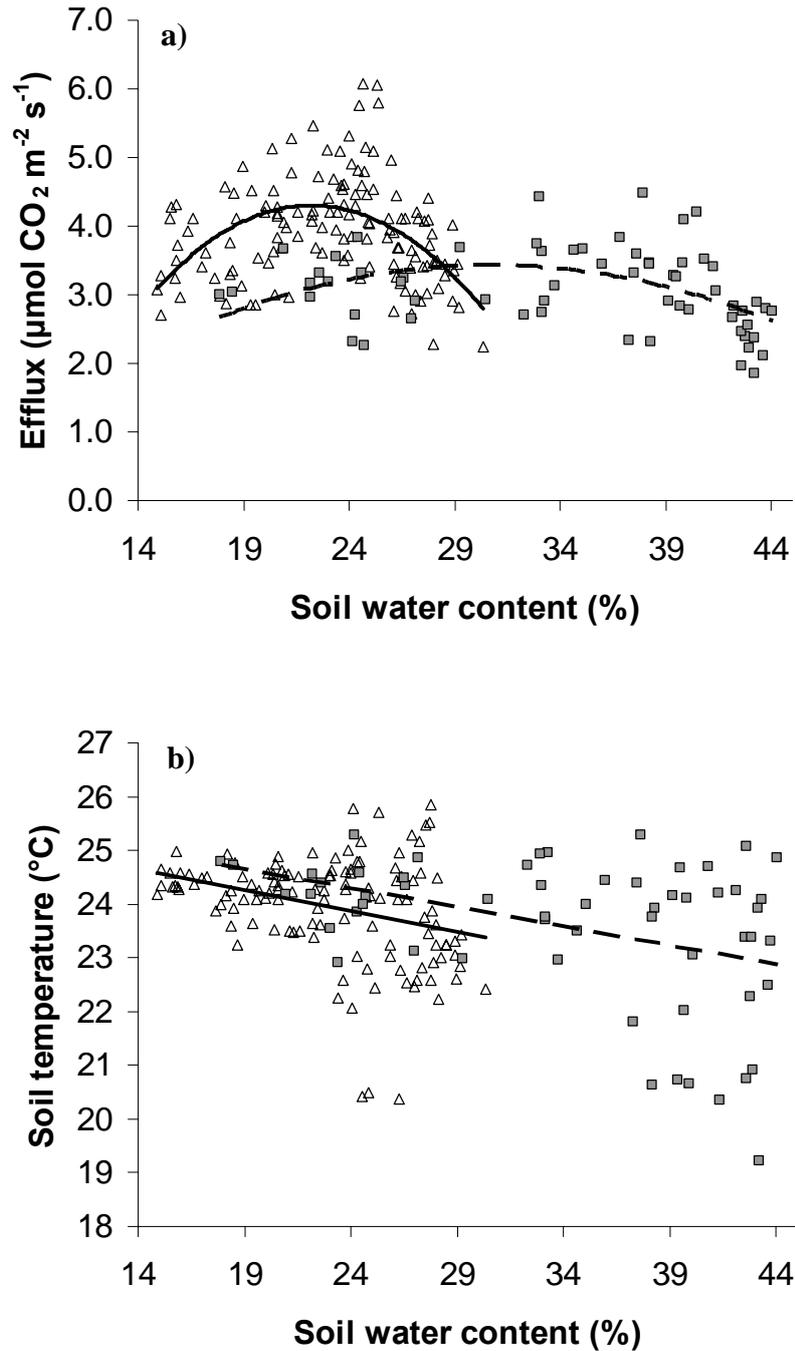

Figure 2.4 - Relationship between (a) soil water content (*swc*) and soil CO<sub>2</sub> efflux (*E*) and (b) between soil water content and soil temperature at 0.05 m depth (*T<sub>s</sub>*) in sand (△) and clay (■) soil texture. The regression curves in (a) are for sand (solid line)  $E_{sand} = -0.0226(swc)^2 + 1.0053(swc) - 6.8602$ ,  $r^2 = 0.23$  and for clay (dashed line)  $E_{clay} = -0.0046(swc)^2 + 0.2842(swc) - 0.9443$ ,  $r^2 = 0.18$ . The regression lines in (b) are for sand  $T_s = -0.0771(swc) + 25.718$ ,  $r^2 = 0.10$  and for clay  $T_s = -0.0708(swc) + 25.984$ ,  $r^2 = 0.16$ .

### *Correlations with environmental factors*

Soil CO<sub>2</sub> efflux was correlated with soil moisture and temperature but did not correlate with any other environmental factor (Table 2.2). As expected, soil temperature was positively correlated with air temperature and radiation and negatively correlated with rainfall. For both soils, the relationship between soil water content and soil CO<sub>2</sub> efflux could be described with a quadratic function ( $r^2 = 0.23$  for sand and  $r^2 = 0.18$  for clay soil,  $P < 0.01$ ). The optimal soil water content, at which CO<sub>2</sub> efflux was highest, was greater for the clay than for the sand (Fig. 2.4a). A multiple regression for soil water content including both soil textures explained 22 % of the soil CO<sub>2</sub> efflux ( $P < 0.001$ ; not shown). Soil water content and soil temperature co-varied in both soil types ( $r^2 = 0.09$  for sand and  $r^2 = 0.16$  for clay,  $P < 0.001$ , Fig. 2.4b).

Table 2.2 - Correlation among sites, seasons, CO<sub>2</sub> efflux and environmental factors using Spearman  $r$  coefficient ( $n = 18$ ). Bold values are significant at  $P < 0.05$ .

	<b>Soil CO<sub>2</sub> efflux</b>	<b>Soil temperature</b>	<b>Soil water content</b>	<b>Air temperature</b>	<b>Solar radiation</b>
<b>Soil temperature</b>	<b>0.5</b>				
<b>Soil water content</b>	<b>-0.5</b>	0.1			
<b>Air temperature</b>	0.1	<b>0.3</b>	-0.2		
<b>Solar radiation</b>	0.1	<b>0.4</b>	-0.1	<b>0.8</b>	
<b>Rainfall</b>	-0.1	<b>-0.4</b>	0.3	<b>-0.7</b>	<b>-0.7</b>

Monthly average, across all chambers and both soil types, was used for soil CO<sub>2</sub> efflux, soil temperature and soil water content. Monthly average was also used for air temperature and solar radiation, while for rainfall was used the monthly sum.

## 2.4. Discussion

### *Magnitude of CO<sub>2</sub> efflux and spatial variation*

Our annual CO<sub>2</sub> effluxes are similar to those reported for clay Oxisols in Manaus, Santarém and Costa Rica (Chambers et al. 2004, Davidson et al. 2004, Schwendenmann et al.

2003). However, higher CO<sub>2</sub> effluxes have been reported for a clay Oxisol in Paragominas (Davidson et al. 2000a) and Manaus (Sotta et al. 2004). The lower CO<sub>2</sub> efflux from the clay soil, compared to the sand soil may have different causes. The lower water holding capacity and capacity to retain nutrients (Table 2.1) of the sandy Oxisol may stimulate this forest to invest more in roots, reflected in a higher root respiration. In Santarém, it was shown that forest on a sandy soil had a higher fine root biomass and total root biomass than an adjacent forest on clay (Silver et al. 2000). Additionally, during the wet season the soil water content of the clay was frequently close to or at saturation level (estimated at ~40 %) which may have prevented diffusion of CO<sub>2</sub> out of the soil. This effect is illustrated by the low soil CO<sub>2</sub> efflux that we measured at high soil water contents which has also been shown for Oxisols in Costa Rica (Schwendenmann et al. 2003).

Although the effect of topographic position was not significant on a year basis, the significant interaction of topographic position and time shows that soil CO<sub>2</sub> efflux from different topographic positions have different seasonal variations (Fig. 2.2). These variations may be caused by water redistribution in the landscape and by different amounts of litter and soil organic matter at different positions. That water redistribution takes place is likely given the systematic difference in soil water content along the topographical gradient (Fig. 2.2c). A study on the effect of topographical position on soil CO<sub>2</sub> efflux in a forest close to Manaus also reported a high soil CO<sub>2</sub> efflux from the slope and a low value from the plateau and valley (Souza 2004). Although variations in topography are relatively small, spatial variation in soil CO<sub>2</sub> efflux due to topography was comparable to temporal variation in soil CO<sub>2</sub> efflux, illustrating its importance.

### *Temporal variation in CO<sub>2</sub> efflux*

Temporal variability of soil CO<sub>2</sub> efflux was comparable to other studies, and depended mainly of soil water content (Davidson et al. 2000a, Schwendenmann et al. 2003). The quadratic function fitted to the plot of soil water content against soil CO<sub>2</sub> efflux is comparable to the influence of soil moisture detected in a tropical wet forest of Costa Rica (Schwendenmann et al. 2003). As was the case in Costa Rica, in our study soil temperature could not explain additional variation of soil CO<sub>2</sub> efflux beyond soil moisture alone. The weak positive correlation that we found between soil CO<sub>2</sub> efflux and soil temperature we therefore explain by the covariance of soil temperature and soil moisture (Fig. 2.4b) combined with the small variations in temperature that occur throughout the year (Fig. 2.1). Covariation of temperature and soil moisture has been detected in several ecosystems, including tropical rainforests (Davidson et al. 2000a, Schwendenmann et al. 2003).

Seasonal variation in the contribution of the litter layer to CO<sub>2</sub> efflux (Fig. 2.4) may be caused by variations in the amount of decomposing litter on the forest floor and in conditions influencing litter decomposition. Our results show that in July during the dry season the contribution of the litter layer to CO<sub>2</sub> emissions was negligible, even though in May and June the peak of litter production occurs (data not shown). The low moisture content of litter is probably responsible for this small contribution (Toledo 2002). The highest contribution was measured in January, about one month after the onset of the rainy season when there is both a considerable amount of litter on the forest floor and a high moisture content of litter. Although our results cannot be used to calculate the contribution of the litter layer to total soil CO<sub>2</sub> efflux (due to the relatively low frequency of measurements), they do illustrate that the dynamics of litter production and litter decomposition exert quite a strong influence on the observed temporal variation in soil CO<sub>2</sub> efflux.

Although we measured some seasonal variation in soil temperature and soil water content, the seasonality of the soil CO<sub>2</sub> efflux was not strong (Fig. 2.1). A drought mediated reduction in CO<sub>2</sub> produced from microbial respiration in the topsoil and litter layer may be (partly) compensated by higher CO<sub>2</sub> production from deeper root activity (Liu et al. 2004) which may explain the weak seasonality. Under normal rainfall conditions, Amazonian forests are able to sustain high evapotranspiration rates throughout the majority of the dry season (Nepstad et al. 1994, Davidson et al. 2004, Fisher et al. in review b) and water stress is not strong enough to affect root respiration. The somewhat lower fluxes for the dry season may also be related to a reduction in leaf area index and ecosystem photosynthetic capacity (Meir and Grace 2005), because of the peak in litterfall associated with the onset of the dry season (Chambers et al. 2004). Seasonality of soil CO<sub>2</sub> efflux in a Costa Rican rain forest was also minimal; however the dry season in this forest was much shorter compared to many areas in the Amazon Basin (Schwendenmann et al. 2003).

#### *Estimating annual landscape scale CO<sub>2</sub> efflux*

To illustrate how extrapolation methods affect estimates of annual soil CO<sub>2</sub> efflux we use an area of 581 ha in Caxiuanã which includes the area where the tower based NEE measurements are being done. In the first approach we used measurements done at the base of the tower to scale up the results for the whole area during one year. This approach is often found in literature using monthly or less frequent measurements (e.g. Fan et al. 1990, Chambers et al. 2004). We calculated the monthly mean plus or minus one standard error and added the results to an annual soil CO<sub>2</sub> efflux which was then calculated for the whole area. The result of this approach was 6953 ( $\pm$  623) Mg C yr<sup>-1</sup>. In the second approach, we first stratified the area in the different landscape unit. Contribution of the different landscape units were: valley: 14 %; lower slope: 15 %; upper slope: 15 %; plateau with sand: 20 % and

plateau with clay: 36 %. For each of these units we calculated the annual soil CO<sub>2</sub> efflux plus or minus one standard error, including the seasonal variation and this value was multiplied with the area of the landscape unit. Finally the total soil CO<sub>2</sub> efflux was calculated by adding the contributions of the different landscape units. This approach resulted in an annual soil CO<sub>2</sub> efflux of 7594 (± 621) Mg C yr<sup>-1</sup> which was almost 10 % higher than the first estimate.

The results of our study illustrate that successful extrapolation of soil CO<sub>2</sub> efflux for larger areas needs inclusion of complex spatial and temporal controls. Soil temperature and moisture are important drivers of temporal variations in soil CO<sub>2</sub> efflux at a specific location, however to detect non-linear relationships (like we found e.g. between soil moisture and soil respiration) it is necessary to do measurements under a wide range of conditions. Had we limited our measurements to the wettest part of the wet season and the driest part of the dry season only, we would not have detected the non-linearity between soil water and soil CO<sub>2</sub> efflux. Furthermore, our extrapolation example shows that soil texture, litter stocks and the significant interaction of topographical position and time make it necessary to include some of the complexity of landscapes when extrapolating soil CO<sub>2</sub> efflux over landscapes.

### **3. Effects of an induced drought on the soil CO<sub>2</sub> production and soil CO<sub>2</sub> efflux in an Eastern Amazonian Rainforest, Brazil.**

#### 3.1. Introduction

In the next few decades, climate of the Amazon basin is expected to change, as a result of regional deforestation and rising global temperatures (Nobre et al. 1991, Costa and Foley 2000, Werth and Avisar 2002). Several climate scenarios predict a warming trend of 1.5 – 2.5 °C in annual mean temperature for a large part of the tropics (Cox et al. 2000, Hulme and Viner 1998) and some of these scenarios predict more frequent occurrence of ENSO droughts of increasing severity (Timmermann et al. 1999) induced by global warming. These changes in climate may lead to feedback mechanisms in global biogeochemical cycles that are presently unknown. For example climate changes may affect C stocks in vegetation as well as shifts in total soil C and belowground C allocation (Davidson et al. 2004).

One third of the global soil carbon storage (to 3 m depth) is in the upper meter of tropical soils (Jobbagy and Jackson, 2000). Moreover, a large portion of the soil organic carbon (SOC) in tropical soils has a short residence time (Amundson 2001), which implies a high potential for rapid changes in soil carbon stocks (Trumbore et al. 1995). Increasing temperature may therefore lead to additional CO<sub>2</sub> release, especially in the tropics (Trumbore et al. 1996). Until the early 1990's carbon fluxes in soil below 1 m depth were often thought to be insignificant compared to C fluxes in the upper meter (e.g. Sombroek et al. 1993). However, many forest soils in the Brazilian Amazon are very deep, strongly weathered and contain significant live-root biomass below 1 m depth (Nepstad et al. 1994). For these Amazonian ecosystems (but also e.g. for deeply weathered forest soils in Costa Rica) it has been shown that the deep part of the soil contributes considerable amounts to the CO<sub>2</sub> efflux (Davidson and Trumbore 1995, Schwendenmann and Veldkamp 2006).

Given the expected intensification of ENSO events, which will probably lead to an increasing frequency of droughts and higher temperatures, an experiment was set up in which throughfall was experimentally reduced to create an artificial drought (Fisher et al. 2006). This experiment was part of the Large Scale Biosphere Atmosphere Experiment in Amazon (LBA). Using this throughfall exclusion experiment, our goal was to study how an artificially imposed drought affects depth and amount of soil CO<sub>2</sub> production and transport in a deeply weathered soil of the Eastern Amazon. Our hypothesis is that soils with lower capacity to maintain water in the root zone will be more promptly affected by the reduced precipitation. A similar experimental rainfall manipulation was implemented in another site in Eastern Amazon, Santarém (Nepstad et al. 2002, Stokstad 2005). In this replicate the throughfall exclusion of three rain seasons did not lead to significant differences in soil CO<sub>2</sub> efflux (Davidson et al. 2004). However, Amazon region has high variability in soil and vegetation and different responses to drought may be expected. Over the course of two years, we monitored soil CO<sub>2</sub> efflux and soil CO<sub>2</sub> concentrations, soil temperature and soil moisture in pits down to 3 m depth in a sandy Oxisol. Using a simple one-dimensional gas diffusion model which was calibrated using naturally occurring <sup>222</sup>Rn profiles, we calculate CO<sub>2</sub> production with depth and we relate this to a range of environmental controls that can potentially affect the production and emission of CO<sub>2</sub> in the soil.

### 3.2. Materials and Methods

#### *Study site*

The experimental site was located in Caxiuanã National Forest, Para, Brazil, (1° 43' 3.5''S, 51° 27' 36''W). The forest is a lowland *terra firme* rainforest. Mean annual rainfall is 2272 mm, with a pronounced dry season between July and December, when on average only

555 mm of rainfall occurs (Fisher et al. 2006). Months with more than 100 mm rainfall were assigned to the wet season (December to June), and the dry season consisted of the period of months with less than 100 mm rainfall (July to November).

The studied soil is a yellow Oxisol (Brazilian classification: Latosol), which has a broken ironstone layer (0.3-0.4 m thick) at 3-4 m depth. On average, the top 0.5 m of the soil contains 75 % sand, 15 % clay and 10 % silt (Table 3.1). Mineralogy of the clay fraction is dominantly Kaolinite while the sand fraction consists mainly of quartz (Ruivo and Cunha 2003). The location of the experiment is about 15 m above river level, and during wet season, the water table has been observed at a depth of 10 m (Fisher et al. 2006). The forest structure is formed by 434 trees ha<sup>-1</sup>, a basal area of 23.9 m<sup>2</sup> ha<sup>-1</sup> and leaf area index (LAI) of 5.2 m<sup>2</sup>m<sup>-2</sup> (unpublished data. D. Metcalfe). The height of the canopy is about 35 meters, and the aboveground biomass is 200 m<sup>3</sup> ha<sup>-1</sup> (Lisboa et al. 1997).

### *Experimental design*

The experiment consists of two plots of 1 ha (100m x 100m), one control plot and one experimental throughfall exclusion (TFE) plot. Both plots are located about 800 m north of the research station. In the TFE plot, a roof of transparent plastic sheeting and wooden guttering was installed at approx. 2 m height above the soil, with the purpose of displacing part of the throughfall from the plot to impose an artificial drought. Both control plot and the TFE plot were trenched to a depth of 1 m around their borders to reduce the lateral flow of water in roots and soil across plot boundaries. Throughfall exclusion started in January 2002, ~ 50 % of the rainfall was excluded from the soil of the TFE plot. During the peak dry season (from mid September to mid November) only 50 % of the plastic panels were left on the TFE plot in order to have a better aeration under the covered area. At each plot four pits (0.8 m by 1.8 m with 5 m depth) were established at randomly chosen locations. The plots were further divided into four quadrants in order to facilitate the systematic placement of soil CO<sub>2</sub> efflux chambers.

### *Measurements of soil CO<sub>2</sub> efflux*

Sixteen respiration chambers were deployed systematically forming a cross in the TFE and control plot of the drought experiment, four at each quadrant. Systematic sampling was chosen to cover the plots uniformly, which allows a better overview of the soil CO<sub>2</sub> efflux spatial variation. In June 2001, PVC rings (0.296 m in diameter, 0.20 m tall) were inserted to a depth of about 0.02 m into the soil. Once inserted, the rings were left in place throughout the time investigated. Chambers were kept free of seedlings throughout the whole study period. Dynamic, closed chambers were used to determine soil CO<sub>2</sub> efflux (Parkinson 1981, Norman et al. 1992). Average chamber volume was about 13 L. Flux chambers were closed with a PVC cover for about 5 minutes. Air was circulated at a flow rate of about 0.8 L min<sup>-1</sup> between

an infrared CO<sub>2</sub> gas analyzer (LI-6262, Li-Cor, Inc., Lincoln, Nebraska, USA) and the flux chambers. To prevent pressure differences between chamber and atmosphere, chambers were vented to the atmosphere through a 0.25 m long stainless steel tube (3.2 mm outer diameter). CO<sub>2</sub> concentrations were recorded at 5 second intervals with a datalogger (Campbell CR10X, Campbell Scientific, Inc., Logan, Utah, USA). CO<sub>2</sub> flux ( $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ) was calculated from the linear change in CO<sub>2</sub> concentration multiplied by the density of air and the ratio of chamber volume to soil surface area. Air density was adjusted for air temperature measured at the time of sampling. A linear increase in CO<sub>2</sub> concentration usually occurred between 2 and 4 min after placing the cover over the ring. The coefficient of determination ( $r^2$ ) of the regression was typically better than 0.99. The infrared gas analyzer was calibrated in the lab using a loop with a column with CO<sub>2</sub> scrubber (Soda Lime indicating 4-8 mesh) as zero-standard and a secondary CO<sub>2</sub> standard (510 ppm). The secondary CO<sub>2</sub> standard was calibrated against primary standards from the LBA project.

Each plot was measured every two weeks from December 2001 to November 2002 and monthly from December 2002 to November 2003. It took two days to measure both plots. All measurements were conducted between 8 AM to 2 PM local time. For each plot, the average CO<sub>2</sub> efflux rate was calculated from the sixteen chamber flux measurements on a sampling day. Daily mean soil efflux for each plot was calculated by linear interpolation between sampling dates. Daily CO<sub>2</sub> flux rates were then summed up to estimate annual flux rates. Soil temperature at 0.05 m depth was measured with a thermocouple probe (HI 93551, Hanna Instruments, Ann Arbor, MI, USA) and soil water content was measured with a soil moisture probe (CS 615, Campbell Scientific Ltd, Loughborough, UK).

### *Measurements of CO<sub>2</sub> concentration profiles*

In December 2001, all eight pits were instrumented for sampling of soil air. Stainless steel gas sampling tubes (3.2 mm outer diameter) were inserted horizontally at 0.10, 0.25, 0.50, 1.00, 2.00 and 3.00 m depth. The tubes were perforated at one end and closed with a septum holder with septum at the other end to allow sampling of soil air (Davidson and Trumbore 1995). Tubes at depths of 0.10 m to 1.00 m were 0.90 m long; tubes at greater depth were 1.80 m long. Samples at 0.05 m depth were collected using a 0.10 m stainless steel tubing adapted to a syringe, which was vertically inserted in the top soil every sampling date. Soil air samples were collected in polypropylene syringes which were closed with a three-way stopcock. Before a sample was taken, 10 to 20 ml of soil air was withdrawn and discarded.

Gas samples were analyzed for CO<sub>2</sub> concentration in the lab within 8 hours using a gas chromatograph (GC 11, Delsi Instruments, France) with a thermal conductivity detector (TCD). Soil air CO<sub>2</sub> concentration was calculated by comparison of integrated peak areas of samples with standard gases (0.051 % and 3 % CO<sub>2</sub>), which were used to make a two point calibration. The coefficient of variation for replicate injections of standard gases was < 1 %. Storage tests indicated that on average 9-12 % of CO<sub>2</sub> was lost between time of sampling and analysis. Soil CO<sub>2</sub> concentration measurements were made in all pits every two weeks in 2002 and monthly in 2003.

### *Measurements of soil radon activity and radon production*

To validate the gas diffusion model we measured <sup>222</sup>Rn activity and <sup>222</sup>Rn production rates as described by Mathieu et al. (1988) and Davidson and Trumbore (1995). Soil air samples were withdrawn from the stainless steel gas sampling probes to determine soil air <sup>222</sup>Rn concentration (also called radon activity). Soil air (90 to 120 mL) was dried using a CaCl<sub>2</sub> column and introduced into pre-evacuated 150 mL scintillation cells (110A Lucas Cell,

Pylon Electronics Inc., Ottawa, ON, Canada). Impulses were measured using a Pylon AB-5 radiation monitor (Pylon Electronics Inc., Ottawa, ON, Canada). Radon production rates were measured for each site and depth interval individually, for both dry and wet conditions following the procedure described by Davidson and Trumbore (1995).

### *Calculation of CO<sub>2</sub> production*

The diffusive properties of a soil media are usually characterized by means of relative diffusion coefficient  $D_s/D_o$ .  $D_s$  is the diffusion coefficient of a gas in soil air and  $D_o$  is the diffusion coefficient of the same gas in free air at standard conditions, e.g.  $0.158 \text{ cm}^2 \text{ s}^{-1}$  for CO<sub>2</sub> at 20 °C and standard pressure of 1013 hPa (Mason and Monchick 1962). The gas diffusion coefficient in soil ( $D_s$ ) is a fraction of the gas diffusion coefficient in free air ( $D_o$ ), as diffusivity depends not only on gas pressure and temperature but also on the amount of air-filled pores and on their continuity and shape. The relationship between  $D_s/D_o$ , and soil properties have been investigated in multiple studies and several empirical formulas have been developed to describe soil gas diffusivity. In our experiment we tested the gas diffusion models with three different approaches:

a) the model described by Millington and Quirk (1961) for non-aggregated media,

$$\frac{D_s}{D_o} = a^{2x} \left( \frac{a}{\varepsilon} \right)^2; \quad (1)$$

where:

$a$	air-filled porosity	$\text{m}^3 \text{m}^{-3}$
$\varepsilon$	total porosity	$\text{m}^3 \text{m}^{-3}$

b) the model developed by Millington and Shearer (1971) for aggregated media,

$$\frac{D_s}{D_o} = \frac{\left[ \left( \frac{a_{ra}}{\varepsilon_{ra}} \right)^2 \left( \frac{a_{ra}}{1 - \varepsilon_{er}} \right)^{2x} (1 - \varepsilon_{er}^{2y}) (a_{er} - a_{er}^{2z}) \right]}{\left[ \left( \frac{a_{ra}}{\varepsilon_{ra}} \right)^2 \left( \frac{a_{ra}}{1 - \varepsilon_{er}} \right)^{2x} (1 - \varepsilon_{er}^{2y}) + (a_{er} - a_{er}^{2z}) \right]} + \left[ a_{er}^{2z} \left( \frac{a_{er}}{\varepsilon_{er}} \right)^2 \right]; \quad (2)$$

where:

$a_{ra}$	intra-aggregated air-filled pore space	$\text{m}^3 \text{m}^{-3}$
$\varepsilon_{ra}$	intra-aggregated total pore space ( $\varepsilon_{ra} = \theta_W$ at field capacity)	$\text{m}^3 \text{m}^{-3}$
$a_{er}$	inter-aggregated air-filled pore space	$\text{m}^3 \text{m}^{-3}$
$\varepsilon_{er}$	inter-aggregated total pore space ( $\varepsilon_{er} = \varepsilon - \varepsilon_{ra}$ )	$\text{m}^3 \text{m}^{-3}$
$x$	determined from the relation $a^{2x} + (1-a)^x = 1$	
$y$	exponent usually between 0.6 and 0.8	
$z$	exponent usually between 0.6 and 0.8	

and c) the model described by Moldrup et al. (2000) based on the soil water characteristic curve,

$$\frac{D_s}{D_o} = (2a_{100}^3 + 0.04a_{100}) \left( \frac{a}{a_{100}} \right)^{2+3b} \quad (3)$$

where:

$a_{100}$	air-filled porosity at -100 cm H <sub>2</sub> O (porosity with the soil tension at -10 kPa)	$\text{m}^3 \text{m}^{-3}$
$b$	pore-size distribution characterized by the slope of the line determined from the water retention curve, which is: $\log - \psi = a + b\theta$ where $\psi$ is the water potential and $\theta$ is volumetric water content.	

To calculate diffusivity we estimated total porosity ( $\varepsilon$ ) from measurements of bulk density and an assumed particle density of 2.65 Mg m<sup>-3</sup>. Air-filled porosity ( $a$ ) was calculated by the difference between total porosity and water-filled porosity ( $\theta$ ). Water-filled porosity is the volumetric soil water content determined from the TDR probes on a given sampling date.

For the aggregated soil model the pore space is divided into intra-aggregated porosity (estimated from volumetric water content at field capacity) and inter-aggregated porosity (calculated as the difference between total porosity and volumetric water content at field capacity).

A 1-dimensional model developed by Schwendenmann and Veldkamp (2006) was used to predict  $^{222}\text{Rn}$  activity throughout the soil profile. Input parameters are measured radon production rates and the diffusion coefficient calculated by the three approaches. These predicted values were compared with measured  $^{222}\text{Rn}$  activities from the profile to test the diffusion models for their applicability. The estimated diffusion values from the Millington and Quirk (1961) soil model (M&Q) provided better agreement with the observed  $^{222}\text{Rn}$  activities (Fig. 3.1). Millington and Shearer (1971) model overestimated diffusivity resulting in an underestimation of  $^{222}\text{Rn}$  activities, while Moldrup et al. (2000) model underestimated diffusivity which resulted in an overestimation of  $^{222}\text{Rn}$  activities. We thus decided to use M&Q model to estimate the diffusion coefficients for Caxiuanã soils. Fluxes of  $\text{CO}_2$  were estimated at each sampling depth, based on Fick's law (Trumbore et al. 1990, Uchida et al. 1997).

Because a uniform diffusion coefficient in the soil is unlikely, a multi-box model was used (De Jong and Schapert 1972, Davidson and Trumbore 1995) to calculate soil  $\text{CO}_2$  production ( $P_{\text{CO}_2}$ ).  $\text{CO}_2$  production was calculated for each 0.1 m layer, but as the  $P_{\text{CO}_2}$  rate for these individual layers may not be reliable, we summed the  $P_{\text{CO}_2}$  estimates for larger depth intervals (0.6 – 1.0, 1.0 – 2.0, 2.0 – 3.0 m; Schwendenmann and Veldkamp 2006). For the topsoil (0-0.5 m depth)  $\text{CO}_2$  production was estimated as the difference between the measured soil  $\text{CO}_2$  efflux and the sum of the  $\text{CO}_2$  production rates for all individual 0.1 m layers between 0.6 and 3.0 m (subsoil) on a given date. This approach avoids negative production

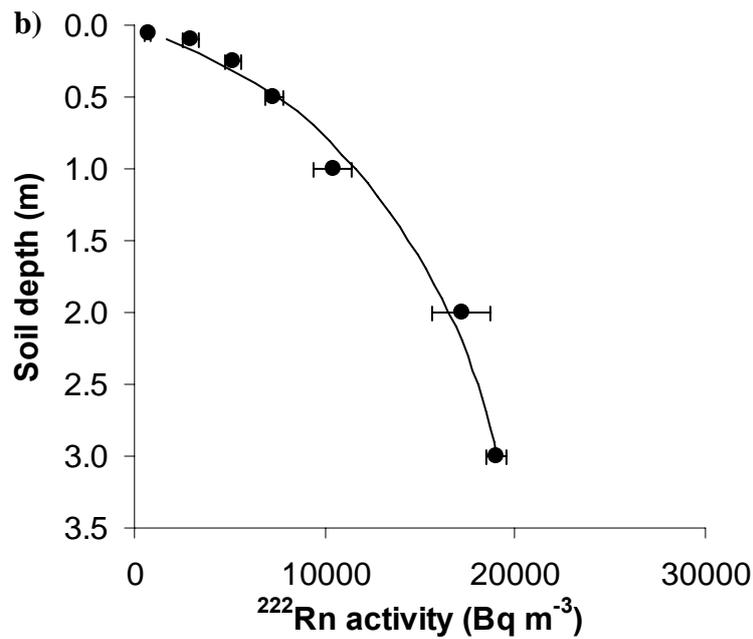

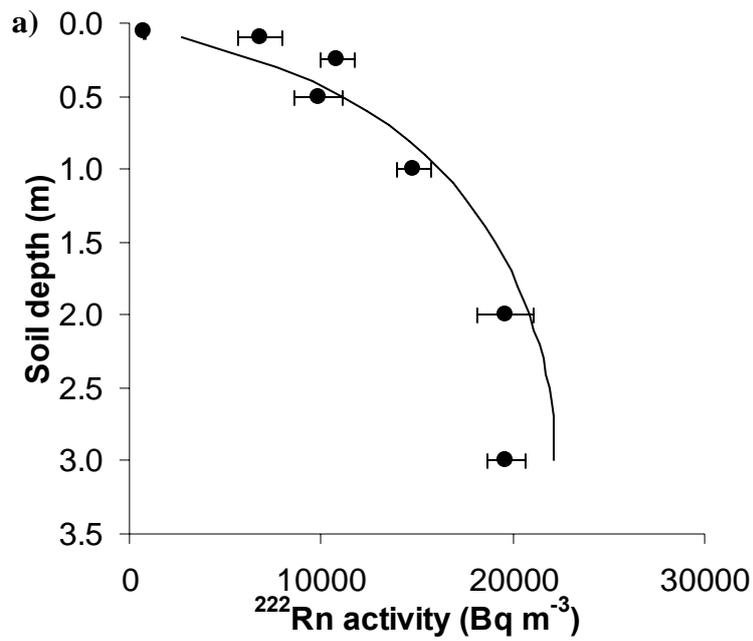

Figure 3.1 - Depth profiles of simulated and measured radon activity in (a) control and (b) TFE plots. Solid lines (—) show the calculated values using the Millington and Quirk (1961) model. The closed circles (●) are the measured radon activity, where each point is the mean ( $\pm$  standard error) of four profiles.

values, in case soil constituents are not uniformly distributed and the soil CO<sub>2</sub> gradient near the surface is not smooth (Davidson and Trumbore 1995).

### *Environmental measurements*

Thermocouple T-probes were installed at the same depths attached to the end of the stainless steel tubes inserted in the soil for sampling CO<sub>2</sub> concentration. Soil temperature was measured with a handheld thermometer (HI 93551 Microprocessor K, J, T-Type Thermocouple Thermometer, Hanna Instruments Deutschland GmbH, Kehl/Rhein, Germany). At 0.05 m depth the temperature was measured with a T-type thermocouple penetration tip probe (HI 766 Thermocouple probe, Hanna Instruments GmbH, Kehl/Rhein, Germany).

For soil moisture monitoring, Time Domain Reflectometry (TDR) sensors (Soil Moisture Corp, Santa Barbara, CA, USA) were installed vertically at the soil surface (0-0.30 m depth) and horizontally at 0.50, 1.00, 2.00 and 3.00 m depth (Fisher et al. in review b). TDR were inserted 1.5 m into the walls, with connections sticking out of the re-packed soil wall. Measurements were made at the same time as CO<sub>2</sub> concentration. Water retention curves of intact soil cores were determined on pressure plates by Dr E. J. M. Carvalho in the soil physics laboratory of Embrapa Amazonia Oriental in Belém, Brazil. The water retention curve for each plot was then used to transform soil water content in soil water potential ( $\Psi$ ). Half-hourly meteorology data was measured by a tower-based automatic weather station in the vicinity of the study site (Carswell et al. 2002). This weather station provided measurements for wet and dry bulb temperature, incoming and outgoing short-wave radiation, photosynthetically active radiation (PAR), and long-wave radiation, wind speed and direction and rainfall (unpublished data from Y. Malhi).

From November 2001 to November 2003, litter was collected monthly, put in paper bags and dried in a ventilated oven for 48 hours at 80° C. The material was separated into three fractions: a) leaves, b) twigs and c) reproductive organs (flower, fruit and seeds); and weighted.

In October 2002 (nine month after the start of the throughfall exclusion), 12 pits of 0.40 x 0.40 x 0.50 m depth were excavated in control and in TFE plot (24 holes in total). All roots were sieved and separated by layers (0-0.05, 0.05-0.10, 0.10-0.25 and 0.25-0.50 m depth). Roots were than separated into two classes: fine (< 5 mm diameter) and coarse (> 5 mm diameter) roots.

### *Statistical analyses*

Repeated measure ANOVA was used to examine differences in season and treatment. Regression analysis was used to examine relationships between CO<sub>2</sub> production rates and environmental variables. Significant effects were determined at  $P < 0.05$ . All statistical analyses were carried out using the STATISTICA 6 software package (StatSoft Inc., Tulsa, Oklahoma, USA).

## 3.3. Results

### *Magnitude and seasonality of soil CO<sub>2</sub> efflux and CO<sub>2</sub> production*

The coefficient of variation among soil chambers within plots was on average 23 % for control plot and 26 % for TFE plot, and typically ranged from 13 to 40 %. The two-year average CO<sub>2</sub> efflux rates were higher ( $P < 0.01$ ,  $n = 32$ ) for the control plot ( $4.3 \pm 0.1 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ) than the TFE ( $3.2 \pm 0.1 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ; Fig. 3.2). Although we detected seasonal changes in soil CO<sub>2</sub> efflux, the CO<sub>2</sub> efflux of the control plot did not differ

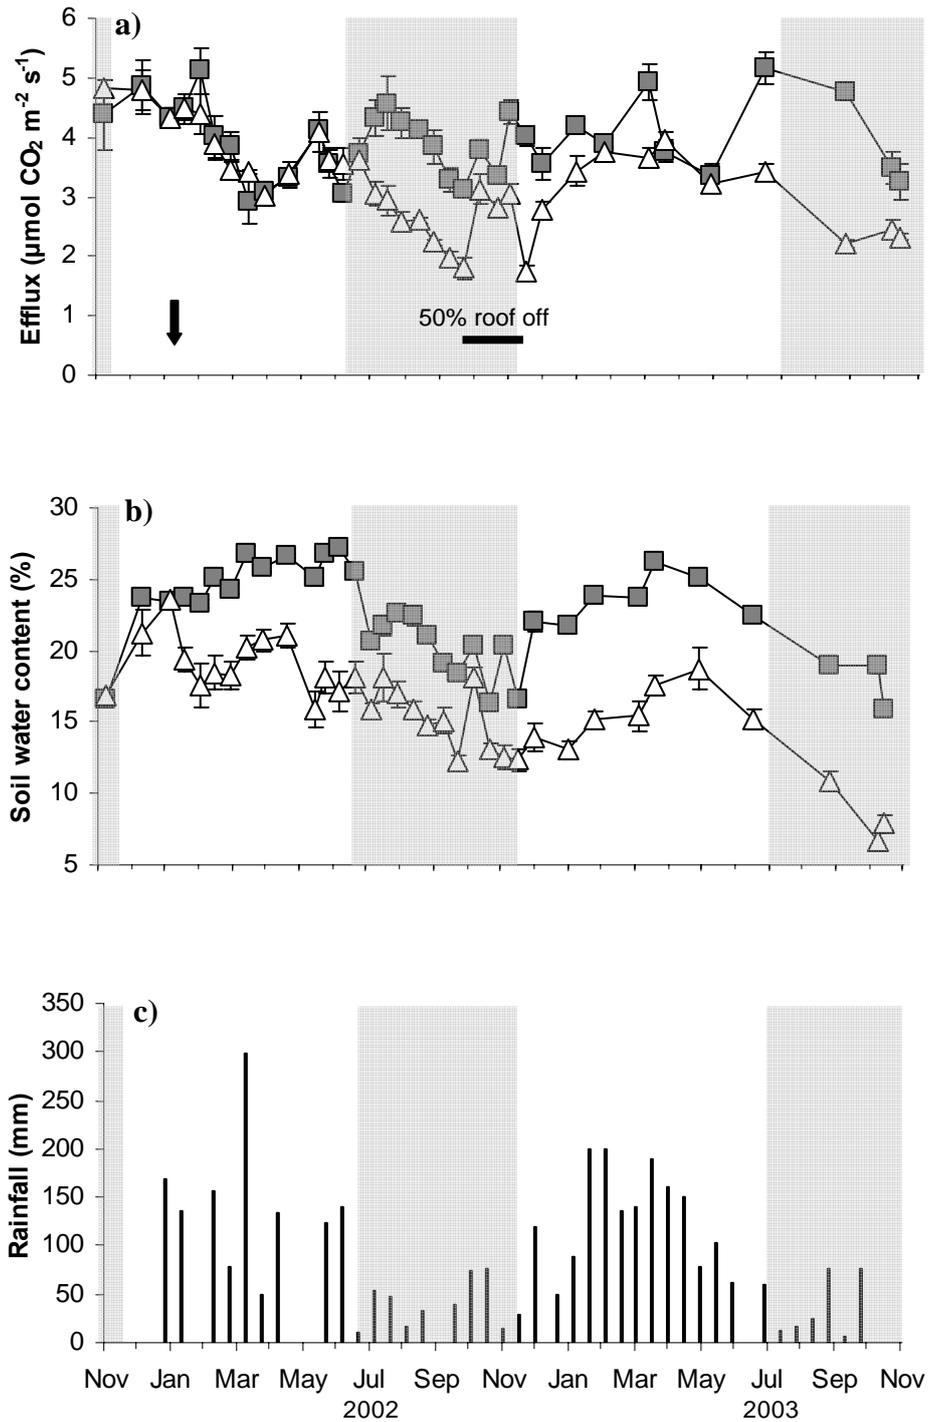

Figure 3.2 – Temporal variation of (a) soil CO<sub>2</sub> efflux, (b) soil water content (VWC) at 0.3 m depth in control (—■—) and TFE (—△—) plots and (c) bi-weekly rainfall from November 2002 to November 2003. Each point is the mean ( $\pm$  standard error) of 16 chambers per treatment. Shaded area mark the dry season and white background indicates wet season. The arrow shows when the throughfall exclusion began.

significantly between wet season ( $4.2 \pm 0.2 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ) and dry ( $4.5 \pm 0.1 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ) season. During the wet season the TFE ( $3.7 \pm 0.1 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ) did not differ ( $P > 0.05$ ) from the control plot, however during the dry season  $\text{CO}_2$  efflux from the TFE was lower ( $2.6 \pm 0.1 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ) than the control ( $P < 0.01$ ).  $\text{CO}_2$  efflux in the TFE plot significantly differ between wet and dry season ( $P < 0.001$ ).

The importance of the topsoil (0-0.5 m) for soil  $\text{CO}_2$  production ( $P_{\text{CO}_2}$ ) is illustrated by the following numbers: between 71 % and 73 % of soil  $\text{CO}_2$  production in both plots occurred within the top 0.5 m of the soil including the forest litter layer. In the topsoil (0-0.5 m including litter layer) the TFE ( $2.3 \pm 0.1 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ) had a significantly lower  $\text{CO}_2$  production than the control plot ( $3.1 \pm 0.1 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ; Fig. 3.3a). At the onset of the dry season in July 2002  $\text{CO}_2$  production at 0-0.5 m decreased by approximately  $0.8 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ . The  $\text{CO}_2$  production in this layer dropped by another  $0.8 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$  between Sep-Nov 2002.

The production of  $\text{CO}_2$  in the subsoil (0.6-3.0 m depth) in both plots was on average  $0.8 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ . But during the first two months of throughfall exclusion (Feb-Mar 2002) the  $P_{\text{CO}_2}$  from 0.6-2.0 m layer was significantly higher in the TFE plot as compared to the control plot ( $P < 0.05$ ; Fig. 3.3b). The higher  $P_{\text{CO}_2}$  was also observed in the 2.1-3.0 m layer of the TFE plot in the subsequent months (May-Jun 2002; Fig. 3.3c). During the dry season there was no difference in  $P_{\text{CO}_2}$  between plots at the subsoil (0.6-3.0 m depth).

In the control plot, soil  $\text{CO}_2$  production at 0-0.5 m depth was negatively correlated ( $r = -0.45$ ,  $P < 0.01$ ) to 0.6-3.0 m  $\text{CO}_2$  production for the whole experiment, which was not observed for the TFE plot. Nonetheless the  $P_{\text{CO}_2}$  at 2.1-3.0 m depth in the TFE plot did have a negative correlation ( $r = -0.70$ ,  $P < 0.000$ ) with the  $P_{\text{CO}_2}$  of the top 0.5 m. The contribution of subsoil (0.6-3.0 m) to the total soil  $\text{CO}_2$  efflux was higher in the TFE plot (28 %) compared to the control plot (17 %,  $P < 0.000$ ; Table 3.2), and it did not differ between seasons and years.

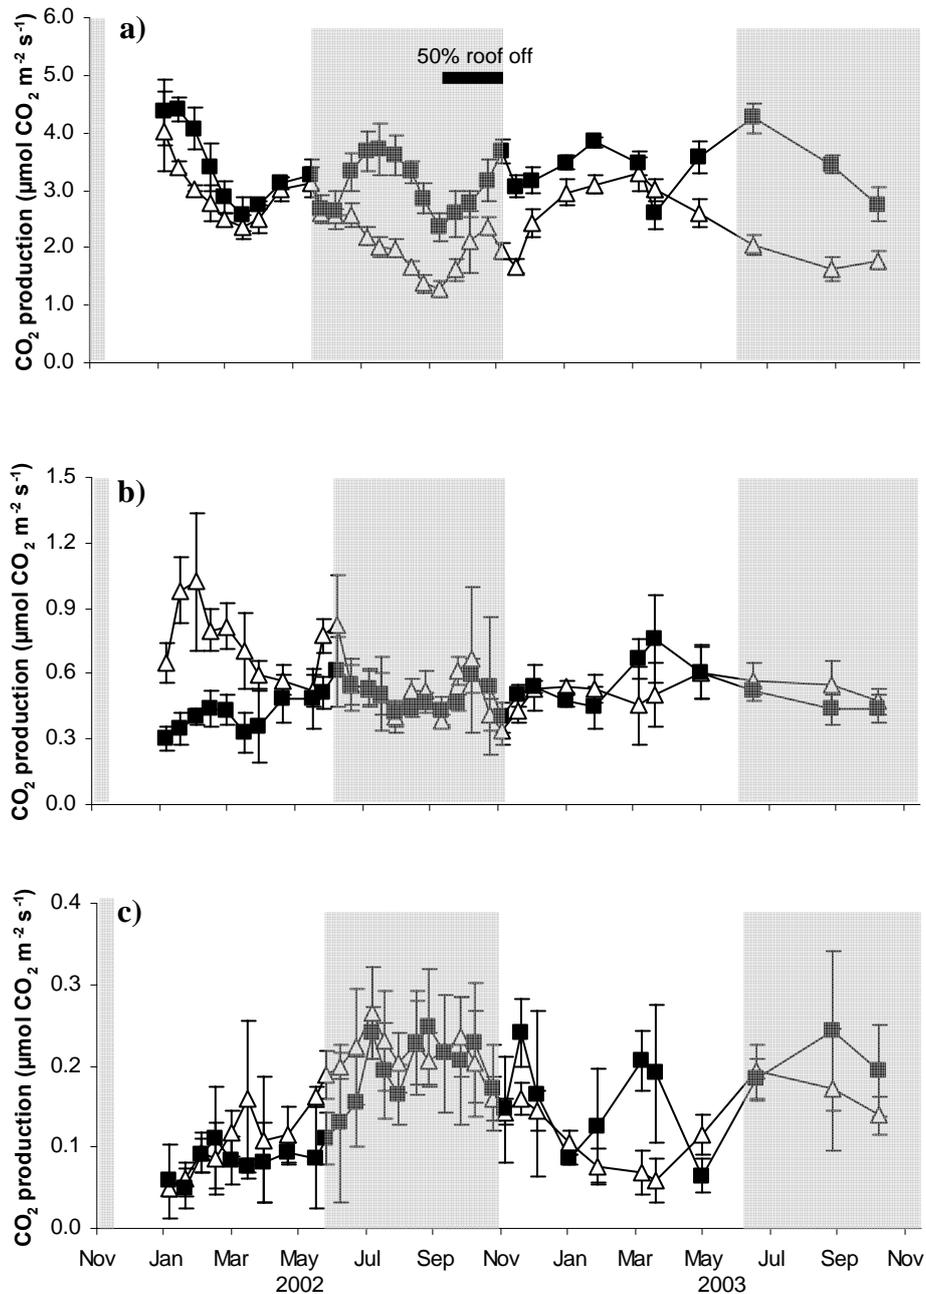

Figure 3.3 - Temporal variation in CO<sub>2</sub> production rates from January 2002 to November 2003 in both control (—■—) and TFE (—△—) plot. (a) CO<sub>2</sub> production of the 0-0.5 m layer; (b) CO<sub>2</sub> production of the 0.6-2.0 m layer; and (c) CO<sub>2</sub> production of the 2.1-3.0 m layer. Each point is the average ( $\pm$  standard error) of four profiles. Shaded area mark the dry season and white background indicates wet season. The arrow shows when the throughfall exclusion began.

Table 3.2 - Contribution of the subsoil (0.6-3.0 m depth) to the total CO<sub>2</sub> production by seasons for both plots. Letters indicate difference between treatments (ANOVA,  $P < 0.05$ ).

Relative contribution of deep soil (%)	2002		2003	
	Wet season	Dry season	Wet season	Dry season
Control plot	16 A	19 A	19	17 A
TFE plot	27 B	32 B	20	31 B

### *Soil CO<sub>2</sub> concentrations*

Soil CO<sub>2</sub> concentration profiles (at 0-3.0 m depth) changed with season in both plots. CO<sub>2</sub> concentrations increased over the course of the wet season and decreased soon after the beginning of the dry season (Fig 3.4a, b). Up to 2 % CO<sub>2</sub> were measured in the upper layers (0.05 m and 0.10 m depth) of control plot during periods of high precipitation and high soil water contents. This observation corroborates with our observations of soil CO<sub>2</sub> efflux which tends to be lower towards the end of the wet season (Fig. 3.2a). During the two-year period the average soil CO<sub>2</sub> concentration measured in the control plot (3.2 %) was higher than the concentration in the TFE (1.0 %).

### *Environmental parameters*

Soil water content at 0-0.3 m depth differed significantly between plots ( $P < 0.01$ ). The two year average for the control plot was  $22.4 \pm 0.6$  % and for TFE was  $16.2 \pm 0.6$  % (Fig. 3.2b) with the correspondent soil water potential of  $-47 \pm 8$  kPa and  $-201 \pm 29$  kPa respectively. In the control, soil water potential reached a maximum of -184 kPa in the dry season and a minimum of -8 kPa in the wet season, while in the TFE plot soil water potential varied between -744 kPa in the dry and -22 kPa in the wet season. Soil water content was also significantly different for control and TFE at all depths in the soil profile and in dry and wet

period. We did not measure differences in soil temperature at 0.05 m depth between control ( $23.9 \pm 0.2$  °C) and TFE plot ( $24.0 \pm 0.2$  °C), nor at greater depth in the soil profile.

Total fine root biomass (<5 mm diameter) in the 0-0.50 m layer recorded in Oct 2002 (after nine months of throughfall exclusion) was not different between control ( $13.9 \pm 1.3$  Mg ha<sup>-1</sup>) and TFE plot ( $15.2 \pm 2.1$  Mg ha<sup>-1</sup>).

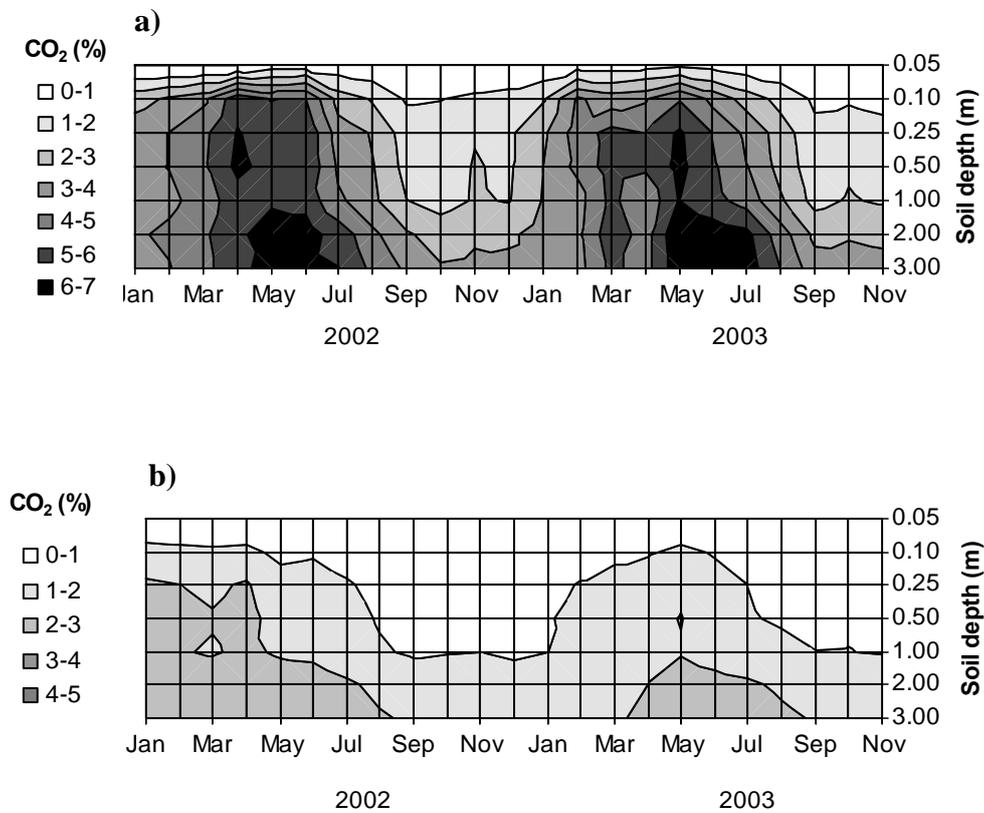

Figure 3.4 - Isopleths of CO<sub>2</sub> concentration in soil air as a function of soil depth and time in (a) control and (b) TFE plot. Each measurement is the mean of four profiles per plot.

### *Effects of environmental parameters on soil CO<sub>2</sub> efflux and on CO<sub>2</sub> production*

For both control and TFE plot, the relationship between soil CO<sub>2</sub> efflux and soil water potential (at 0-30 cm depth) could be described with a parabolic function ( $r^2 = 0.43$ ,  $P < 0.001$ ). The shape of the curves from both plots was complementary (Fig. 3.5a) with the higher water potential from the TFE plot and lower from the control. Taking only the values from the TFE plot we observed a linear relationship between soil water potential and CO<sub>2</sub> efflux ( $r^2 = 0.36$ ,  $P < 0.001$ ). We did not find any significant effect of temperature on soil CO<sub>2</sub> efflux, but there was a positive covariation between soil temperature and soil water potential ( $r^2 = 0.07$ ,  $P < 0.05$ ; Fig. 3.5b).

Total litter biomass for both plots had a significant polynomial relationship with soil CO<sub>2</sub> efflux ( $r^2 = 0.13$ ,  $P < 0.05$ ) which is probably explained by the positive linear relationship between total litter and soil water content ( $r^2 = 0.25$ ,  $P < 0.001$ ). The reproductive part of the litter (~15 % of total litter biomass) also had a high relationship with soil CO<sub>2</sub> efflux and co-varied with soil water content. A positive linear relationship was found between reproductive part of the litter and soil water content for the TFE plot ( $r^2 = 0.35$ ,  $P < 0.01$ ), but for the control plot the linear relationship was negative and only marginally significant ( $r^2 = 0.16$ ,  $P = 0.05$ ).

For the control plot at 0-0.5 m and 0.6-1.0 m depth there was no correlation with P<sub>CO<sub>2</sub></sub>. At 1.1-2.0 m depth soil temperature correlated positively with P<sub>CO<sub>2</sub></sub> ( $r = +0.41$ ), while at 2.1-3.0 m depth soil water content ( $r = -0.52$ ), soil temperature ( $r = +0.41$ ) and PAR ( $r = +0.46$ ) correlated with P<sub>CO<sub>2</sub></sub>. For the TFE plot at 0-0.5 m depth soil water content ( $r = +0.63$ ) and soil temperature ( $r = -0.35$ ) correlated with P<sub>CO<sub>2</sub></sub>. At 0.6-1.0 m soil water content ( $r = +0.41$ ), soil temperature ( $r = -0.44$ ) and air temperature ( $r = -0.56$ ) also had significant correlations. There was no significant correlation at 1.1-2.0 m depth with P<sub>CO<sub>2</sub></sub> rate but at 2.1-3.0 m depth soil water content ( $r = -0.48$ ) and PAR ( $r = +0.47$ ) correlated with P<sub>CO<sub>2</sub></sub> rate.

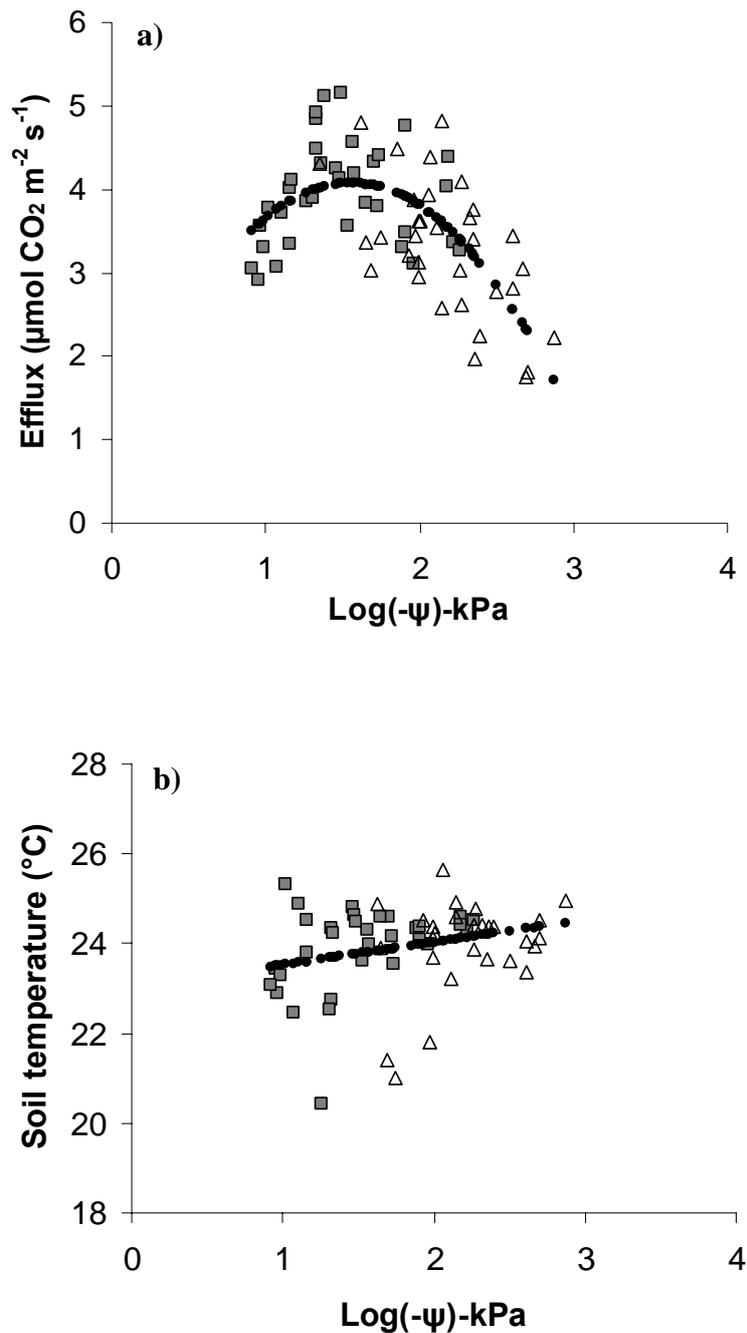

Figure 3.5 - Relationship between (a) soil water potential and soil CO<sub>2</sub> efflux and (b) between soil water potential and soil temperature with data from both control (■) and TFE (△) plot. The regression equation for (a) is  $\text{Efflux} = -1.3664 (\log \psi)^2 + 4.2622 (\log \psi) + 0.7486$  ( $r^2 = 0.43$ ,  $P < 0.001$ ) and for (b) is  $\text{Soil temperature} = 0.5051(\log \psi) + 23.008$  ( $r^2 = 0.07$ ,  $P < 0.05$ ).

### 3.4. Discussion

#### *Effects of seasonality on soil CO<sub>2</sub> production and emission*

Soil CO<sub>2</sub> efflux in the control plot was strongly affected by seasonality. Although on average no difference was detected in soil CO<sub>2</sub> efflux between dry and wet season, this masks the strong seasonal response that we observed as a result of changes in soil moisture content (Fig. 3.2). At the onset of the rainy season, soil CO<sub>2</sub> efflux was high, and tended to decrease during the course of the wet season when soil water content increased. This was especially clear during the first year. The low soil CO<sub>2</sub> efflux at the end of the wet season corresponded with high CO<sub>2</sub> concentrations in the topsoil (Fig. 3.4) which suggests that low gas diffusivity may have contributed to the low soil CO<sub>2</sub> efflux. A similar pattern in soil CO<sub>2</sub> efflux during the wet season in Costa Rica was also explained with reduced gas diffusivity (Schwendenmann et al. 2003). However, as was the case in Costa Rica, this cannot be the only explanation as soil CO<sub>2</sub> *production* rates (calculated with the gas diffusion model) in the top 0.5 m of our study were also reduced at the end of the wet season (Fig. 3.3). The high water content at the end of the wet season may have reduced microbial activity and root activity which may have resulted in lower CO<sub>2</sub> production. Reduced soil CO<sub>2</sub> efflux from an Amazonian forest during the wet season has also been attributed to lower solar flux rates, which could affect photosynthesis rates and indirectly also root respiration (Wofsy et al. 1988).

At the beginning of the dry season the observed increase in soil CO<sub>2</sub> efflux corresponded with a strong decrease in CO<sub>2</sub> concentrations (Fig. 3.2a a 3.4). A similar increase in CO<sub>2</sub> efflux has been observed in a study in Paragominas (Davidson et al. 2000a) and in Costa Rica (Schwendenmann et al. 2003). The increase may be the result of CO<sub>2</sub> diffusing out of the soil that had accumulated during the wet season. However, the transition of wet to dry season may also have caused high root growth as has been observed e.g. in a

Panamanian rainforest (Cavelier et al. 1999). The decrease in soil CO<sub>2</sub> efflux during the dry season we attribute to water stress which may have reduced root respiration as well as heterotrophic respiration. Such a decrease has been observed in the forest in Paragominas which has also a strong dry season (Davidson et al. 2000a) but not in Costa Rica, which has a very weak dry season (Schwendenmann et al. 2003). A strong increase in CO<sub>2</sub> production after some rainstorms at the beginning of the wet season was probably caused by the effect of rewetting. During rewetting normally a CO<sub>2</sub> production peak occurs which depends on the size of decomposable soil organic carbon (Franzluebbers et al. 2000). Field experiments in temperate forests have shown that this CO<sub>2</sub> peak occurs within minutes of rewetting and strongly depends on the amount of rain added to the ecosystem (Borken et al. 2003).

#### *Effects of throughfall exclusion on soil CO<sub>2</sub> efflux and CO<sub>2</sub> production*

During the first year we were able to distinguish three phases in the TFE experiment. The first phase started with a reduction in soil CO<sub>2</sub> production in the 0.0-0.5 m depth interval shortly after throughfall was excluded (Fig. 3.3a) which was accompanied by an increase in the depth interval 0.5-2.0 m until May 2002 (Fig. 3.3b) and in the depth interval 2.0-3.0 m depth from March until July 2002 (Fig. 3.3c). These features can be explained by a translocation of water uptake (and accompanying root activity) to deeper layers in the TFE plot. Roots are expected to respond to reduced water availability in the topsoil by searching for water deeper in the soil profile (Joslin et al. 2000, Norby and Jackson 2000). This is furthermore supported by the lack of difference between total soil CO<sub>2</sub> efflux between TFE and control in this period (Fig. 3.2a) which suggests that there was not yet enough water stress to affect microbial activity and/or total root respiration. A similar translocation of root activity to deeper layers has been observed in a Costa Rican rain forest even though the dry season in this forest is very weak (Schwendenmann and Veldkamp 2006). It should be mentioned here

that in our method to derive CO<sub>2</sub> production in the top 0.5 m, CO<sub>2</sub> production in topsoil and subsoil were not completely independent so these results should be interpreted with care.

The second phase of the drying started at the onset of the dry season (July 2002; Fig. 3.3a). The observed reduction in total soil CO<sub>2</sub> efflux and soil CO<sub>2</sub> production (0-0.5 m) in the TFE plot compared to the control was probably related to a reduction of the activity of soil- and litter decomposers, which are sensitive to water stress (Lavine et al. 2004, Li et al. 2005). At this moment a reduction in total root respiration did not yet occur because sap flow measurements from this period in the TFE plot did not show a reduction either suggesting that water stress was not yet severe enough to affect photosynthesis (Fisher et al. in review b). Further support comes from an ancillary experiment where we showed that during the wet season about 25 % of the soil CO<sub>2</sub> efflux originated from the litter layer, a contribution which became negligible during the dry season (Sotta et al. in review). Bacterial activity declines sharply as water potential falls from -50 to -300 kPa and is negligible at -1500 kPa (Wong and Griffin 1976). In our experiment, the decrease in soil CO<sub>2</sub> efflux in July 2002 was accompanied with a drop in soil water potential from -100 to -200 kPa. The lag between the start of the TFE and the reduction in soil CO<sub>2</sub> production and CO<sub>2</sub> efflux was probably related to the time necessary for the litter to dry out. In a temperate forest Salamanca et al. (2003) showed that after 12 months of partial throughfall exclusion, litter mass loss was not different from the control. However, three months of total exclusion resulted in lower litter mass loss, lower CO<sub>2</sub> efflux and lower microbial biomass of decomposing forest litter.

The third phase of drying was characterized by a continuing decrease in soil CO<sub>2</sub> production between Sep. and Nov. 2002 which was probably dominated by a water stress-induced decrease in total root respiration when soil water potential dropped from -250 to -500 kPa. This is supported by a decline in sap flow which was probably caused by the reduced stomatal conductance due to the low soil-to-leaf water supply (Fisher et al. in review b). The

reduction in stomatal conductance caused a decrease in estimated GPP suggesting a reduction in the photosynthetic supply (Fisher et al. in review b). This may also explain the high observed correlation between the reproductive parts of the litter and CO<sub>2</sub> efflux.

*Comparison with the drought experiment in Santarém and consequences for drought sensitivity*

In the control plot (no TFE) the annual estimate of soil CO<sub>2</sub> efflux in Santarém was about 30 % lower (10 Mg C ha<sup>-1</sup> yr<sup>-1</sup>, Davidson et al. 2004) than the estimate for Caxiuanã (15 Mg C ha<sup>-1</sup> yr<sup>-1</sup>). The higher soil CO<sub>2</sub> efflux in the control of Caxiuanã is probably related to soil texture as the soil CO<sub>2</sub> efflux from an Oxisol with a clay texture in Caxiuanã was also lower compared to the sand (Sotta et al. in review). Apart from soil texture, also rooting depth probably differs between the two sites (at least 12 m rooting depth in Santarém (Davidson et al. 2004); 10 m rooting depth in Caxiuanã with very low root density under 5 m because of coarse sands (Fisher et al. in review b)). In contrast to our results, three years of throughfall exclusion in Santarém led to a marginal increase of about 9 % (11 Mg C ha<sup>-1</sup> yr<sup>-1</sup>) in the annual soil CO<sub>2</sub> efflux while in Caxiuanã already the first year of throughfall exclusion led to a decrease of 22 % (12 Mg C ha<sup>-1</sup> yr<sup>-1</sup>) in annual soil CO<sub>2</sub> efflux. These different reactions of soil CO<sub>2</sub> efflux to throughfall exclusion are probably related to the time needed to reach a matrix potential where decomposition and photosynthesis are strongly reduced because of water stress. While with the clay texture and deep rooting zone in Santarém three years of throughfall exclusion did not reach this matrix potential, the sandy texture and less available soil water at depth, caused that this critical matrix potential was already reached in the first dry season following throughfall exclusion in Caxiuanã. This completely different effect of soil CO<sub>2</sub> efflux to throughfall exclusion illustrates that soil characteristics (especially soil texture, related soil water retention and rooting depth) will strongly influence the resilience of

Amazonian forests to prolonged dry periods. The more drought-sensitive ecosystems are the ones located on soils with coarse textures which cannot compensate the relatively low water holding capacity with water stored in deeper soil layers.

## **4. Mechanisms of soil N retention in an Eastern Amazonian Rainforest, Caxiuanã, Brazil.**

### 4.1. Introduction

High nitrogen (N) deposition is an environmental problem recognized until recently mainly in the economically developed regions of Europe and North America (Matson et al. 1999). Projections are that rates of N deposition in the tropics will increase by several hundred percent due to demands for food and energy by a growing population with increasing per capita use of N (Galloway et al. 2002). Presently, Latin America is a region where both enhanced and low inputs of reactive N occur, and a rapid increase is predicted for this region (Galloway et al. 2004) as a consequence of continued increase in fertilizer use, fossil fuel consumption (Matson et al. 1999), and biomass burning (Cochrane 2003, Fabian et al. 2005).

European and North American studies on responses of forest ecosystems to elevated N inputs have reported forest destabilization, increased  $\text{NO}_3^-$  pollution to ground and surface water (Aber et al. 1998, Schulze 1989), increased soil acidity (Van Breemen et al. 1982), increased losses of soil nutrients that are important for long-term fertility of soils, increased emissions of  $\text{N}_2\text{O}$  (a potent greenhouse gas) and other N-oxides which drive the formation of photochemical smog (Vitousek et al. 1997), and loss of biodiversity (Bobbink et al. 1998). A condition in which N availability exceeds the capacity of plants, soil biotic and abiotic processes to accumulate N is termed as N saturation (e.g., Aber et al. 1998). The results of European and North American studies have been summarized by Aber et al. (1998) into a conceptual model of N saturation, which depicts that the rate at which a forest ecosystem moves towards N saturation is regulated by two main factors: the rate of N input and the inherent N status of the system (the latter being determined by soil type, forest types, and land-use history). The only experiment in tropical forest in which environmental

consequences of elevated N input have been investigated (in Hawaii; Vitousek and Farrington 1997) reported that N additions were processed differently in N-limited forests and forests with high N-availability, depending on the relative strength of the pathways of N-retention versus N-loss (such as leaching losses (Hedin et al. 2003) and N trace gases emissions (Hall and Matson 2003)). In contrast to N-limited forests, high-N availability forests responded to N additions with large and immediate losses of N<sub>2</sub>O and other N-oxides (Hall and Matson 2003). This study and those from temperate forests made clear that the soil N status is the key to analyze effects of increasing anthropogenic N deposition on forest ecosystem processes.

At present, our knowledge on the N status of tropical forests is based on indirect evidence, e.g., N contents in leaves and litter (Vitousek 1984), extractable inorganic N, net rates of soil N cycling and related N oxide emissions (Matson and Vitousek 1987, Riley and Vitousek 1995, Davidson et al. 2000b), and <sup>15</sup>N isotope signals in leaves and soils (Martinelli et al. 1999). While net rates of soil N cycling provide information on N availability for plants, they do not reveal the N retention processes which are important indicators of how a forest ecosystem reacts to changes in N input. An alternative way to assess the soil N status of tropical forest is identification and quantification of pathways of N-retention versus N-production. So far there are only few studies in tropical forest soils which quantified gross rates of soil N cycling, revealing rates of N production and consumption (i.e., Puerto Rico: Silver et al. 2001; Hawaii: Hall and Matson 2003; Costa Rica: Silver et al. 2005; Indonesia: Corre et al. 2006; and only one study in the Brazilian Amazon (Rondonia): Neill et al. 1999).

From indirect evidence of the N status of tropical forests, lowland forests have higher litterfall N contents, lower dry mass/N ratios (Vitousek 1984), higher net mineralization rates and N trace gas emissions (Matson and Vitousek 1987, Riley and Vitousek 1995, Davidson et al. 2000b), and heavier  $\delta^{15}\text{N}$  signals in leaves and soils (Martinelli et al. 1999) than montane forests, supporting the speculation that N in lowland forests is in relative excess. However,

within the lowland forests of Amazon basin, there is substantial evidence that soil texture influences soil  $\text{NH}_4^+$  and  $\text{NO}_3^-$  concentrations, water and other nutrient ions availability, decomposition, soil C retention and net primary production, particularly in highly-weathered soils (Silver et al. 2000, Luizão et al. 2004). For example, Silver et al. (2000) reported that Amazonian lowland forests on clay soils have higher  $\text{NO}_3^-$  and lower  $\text{NH}_4^+$  concentrations than those on sandy soils. Sites where extractable  $\text{NO}_3^-$  dominates over  $\text{NH}_4^+$  have been characterized as having a ‘leaky’ or relative excess of N (i.e. N losses through  $\text{NO}_3^-$  leaching or gas emissions are relatively high compared to the amount of N cycling), while sites where  $\text{NH}_4^+$  dominates have been interpreted as N-limited or having a ‘closed’ N cycle (Davidson et al. 2000b). Our investigation was therefore based on two contrasting soil texture on highly-weathered soil (Oxisol) in an Eastern Amazon forest. Our objectives were: 1) to assess the soil N status of a sandy and clayey, lowland forest soils by quantifying gross rates of N-production processes (N mineralization and nitrification), and 2) to evaluate their differences in N-retention processes by measuring the microbial N immobilization, dissimilatory  $\text{NO}_3^-$  reduction to  $\text{NH}_4^+$ , and abiotic N immobilization. Direct quantification of the inherent soil N status of tropical forests and processes of N retention will provide much-needed baseline information for tropical forests, which may hint how such ecosystems will react to predicted increase in N deposition.

## 4.2. Methods

### *Site Description*

The experimental site was located in Caxiuanã National Forest, Pará, Brazil (1°43’3.5’’S, 51° 27’36’’W). The forest is an old-growth lowland *terra firme* rainforest. Mean annual temperature is 25.7 °C. Mean annual rainfall is 2272 mm, with a pronounced dry

season between July and December, when on average only 555 mm of rainfall occurs (Fisher et al. 2006). The plateau of the Caxiuanã region belongs to Alter do Chão Formation (Costa and Kern 1999), which contains sedimentary rocks with texture varying from sand to clay. Soils of Caxiuanã are predominantly Oxisols (Brazilian classification Latosol), with large differences in texture (Kern 1996). Our study was conducted on two Oxisols with contrasting soil texture: clay and sand (Table 4.1). Both soils have a broken laterite layer (0.3-0.4 m thick) at 3-4 m depth. The texture of the top 0.5 m of the sand is 75 % sand and 25 % clay + silt, while the topsoil of the clay has 31 % sand and 69 % clay + silt. Mineralogy of both soils is mainly kaolinite in the clay fraction and quartz in the sand fraction (Ruivo and Cunha 2003).

#### *Sampling design*

Soil samples were collected from the sand and clay sites once during the dry (August 2004) and once during the wet (April 2005) season. From a randomly selected central transect four sampling points spaced 20 m apart were sampled. A 20-m sampling distance was selected because this ensured spatial independence between sampling points (see *Statistical Analyses*). At each sampling point, 5 undisturbed samples of the topsoil (0-0.05 m) were taken within a 0.30 m x 0.30 m area using stainless steel cores of 0.08 m diameter. Furthermore, soil, litter and green leaf samples were taken at each site for analysis of supporting parameters.

\* Leaf sampling was one composite sample ( $n = 1$ ) made of three subsamples

Soil cores were put in cases with built-in fittings to maintain their integrity and packed with blue ice during transport. They were transported from Caxiuana, Brazil to the Institute of Soil Science and Forest Nutrition, Göttingen, Germany, where the N cycling measurements

were conducted. Samples were kept cool during the whole duration of the transport. The duration between field sampling and the start of laboratory assay was 2 weeks. Prior to measurements, the soil cores were allowed to acclimatize in the laboratory for 2 days at 24 °C (average soil temperature of the site).

#### *<sup>15</sup>N pool dilution for measurement of gross rates of N mineralization and nitrification*

We used the <sup>15</sup>N pool dilution technique to estimate gross rates of soil N cycling (Davidson et al. 1991, Hart et al. 1994a). From 4 core samples at each sampling point, 2 were injected with (<sup>15</sup>NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> solution (for gross N mineralization) and 2 with K<sup>15</sup>NO<sub>3</sub> solution (for gross nitrification), using 18 gauge side-port spinal needles. Each core received five 1-mL injections of the solutions, containing 30 μg N mL<sup>-1</sup> with 98 % <sup>15</sup>N enrichment. This was equivalent to a rate of 1.0-1.7 μg <sup>15</sup>N g<sup>-1</sup> for the sandy soil and 1.4-2.4 μg <sup>15</sup>N g<sup>-1</sup> for the clayey soil. One core of each labelled pair was immediately broken up, mixed well in a plastic bag, and subsampled for extraction with 0.5 mol L<sup>-1</sup> K<sub>2</sub>SO<sub>4</sub> (approx. 5:1 ratio of solution to dry mass soil). Time elapsed between injection and extraction was 10 minutes (T<sub>0</sub> cores). Not all of the added <sup>15</sup>NH<sub>4</sub> and <sup>15</sup>NO<sub>3</sub> were recovered in the labelled pool at T<sub>0</sub>. The T<sub>0</sub> cores were used to correct for reactions that occur immediately after injection of <sup>15</sup>NH<sub>4</sub> and <sup>15</sup>NO<sub>3</sub>, as recommended by Davidson et al. (1991) and Hart et al. (1994a). In the second measurement of soil N cycling rates (wet season, April 2005), we identified the fates of added <sup>15</sup>N at T<sub>0</sub> by measuring <sup>15</sup>N recoveries in K<sub>2</sub>SO<sub>4</sub>-extractable mineral N and organic N pools (by Persulfate digestion; see below *N concentration and <sup>15</sup>N analyses*) and in the total N pool (by submitting freeze-dried subsamples directly for isotope ratio mass spectrometry (IRMS)). The <sup>15</sup>N recovery in the insoluble (non-extractable) organic N pool was calculated from the difference between <sup>15</sup>N recoveries in the total N pool and in K<sub>2</sub>SO<sub>4</sub>-extractable N pools (NH<sub>4</sub><sup>+</sup> + NO<sub>3</sub><sup>-</sup> + soluble organic N).

The other pair of labelled cores was incubated for 1 day (except for the  $^{15}\text{NO}_3^-$  injected cores from wet-season sampling that were incubated for 2 days) in the dark at 24 °C ( $T_1$  cores). The  $^{15}\text{NO}_3^-$ -labelled wet-season cores were incubated for 2 days because our measurements in August 2004 showed very minimal change in  $^{15}\text{NO}_3^-$  enrichment and  $\text{NO}_3^-$  concentration within 1 day of incubation. The  $T_1$  cores were then extracted with 0.5 mol L<sup>-1</sup>  $\text{K}_2\text{SO}_4$ . Extraction was done by shaking the samples for 1 hour and filtering the extracts through  $\text{K}_2\text{SO}_4$ -rinsed filter paper. From each core sample, gravimetric moisture content was measured in order to express gross rates on a soil dry mass basis.

Gross N mineralization and nitrification rates were estimated from cores that received  $^{15}\text{NH}_4^+$  and  $^{15}\text{NO}_3^-$ , respectively, using the modified calculation procedure of Davidson et al. (1991) from the Kirkham and Bartholomew (1954) model. For gross nitrification rates, the method we used does not distinguish between autotrophic and heterotrophic nitrification; results presented include both these processes.

#### *N concentration and $^{15}\text{N}$ analyses*

$\text{NH}_4^+$  and  $\text{NO}_3^-$  contents of extracts were analyzed using continuous flow injection colorimetry (Cenco/Skalar Instruments, Breda, Netherlands), where  $\text{NH}_4^+$  was determined using the Berthelot reaction method (Skalar Method 155-000) and  $\text{NO}_3^-$  was measured using the copper-cadmium reduction method (Skalar Method 461-000). Detection limits were 150  $\mu\text{g N L}^{-1}$  for  $\text{NO}_3^-$  and  $\text{NH}_4^+$ . The organic N content of extracts was determined by Persulfate digestion (Cabrera and Beare 1993, Stark and Hart 1996), which involves oxidation of  $\text{NH}_4^+$  and organic N to  $\text{NO}_3^-$  while  $\text{NO}_3^-$  remains the same. We conducted an ancillary experiment to test this method and results showed complete oxidation of  $\text{NH}_4^+$  and organic N and no losses of  $\text{NO}_3^-$ . In short, 10 mL extract was added with 10 mL oxidizing reagent (consisting of 50 g  $\text{K}_2\text{S}_2\text{O}_8$ , 30 g  $\text{H}_3\text{BO}_3$ , and 100 mL of 3.75 mol L<sup>-1</sup>  $\text{NaOH}$  per 1-L solution) and was

autoclaved for 1 hour at 120 °C; distilled-deionized water was added to a final volume of 100 mL and the N concentration was analyzed by colorimetry. Extractable organic N was calculated as the difference between Persulfate-N (i.e, total N) and  $\text{NH}_4^+$  +  $\text{NO}_3^-$  concentrations.

For  $^{15}\text{N}$  analysis from the extracts, the diffusion procedure described in detail by Corre et al. (2003) and Corre and Lamersdorf (2004) was followed. We used 5-cm wide Teflon (polytetrafluoroethylene) tape to encase the acidified filter disks (2 disks of 7-mm diameter cut from glass fiber filter paper and acidified with 20  $\mu\text{L}$  of 2.5 mol  $\text{L}^{-1}$   $\text{KHSO}_4$  solution), and this Teflon-encased acid trap was placed on the mouth of the diffusion bottle. The wide Teflon tape covered the mouth of the diffusion bottle which helped fastening the lid tightly.

For the  $T_0$  cores, part of the extracts was used for serial diffusion of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  and part was used for Persulfate digestion for determination of  $^{15}\text{N}$  enrichment in extractable organic N pool (Stark and Hart 1996). This allowed us to detect which extractable N pools of the unrecovered portion of the added  $^{15}\text{N}$  was converted at  $T_0$ . For  $\text{NH}_4^+$  diffusion, 50 mL of the  $\text{K}_2\text{SO}_4$  extract was placed in a 150-mL glass bottle.  $\text{MgO}$  was added to make the extract solution alkaline and drive off  $\text{NH}_3$ ; the Teflon-encased acid trap was immediately placed on the mouth of the bottle and the lid fastened. Diffusion proceeded for 6 days in 22 °C room, during which periodic mixing of the solution was done by swirling the bottles. The bottles were left open for 5 days before diffusion of  $\text{NO}_3^-$  to completely eliminate residual  $\text{NH}_4^+$ , if any. For  $\text{NO}_3^-$  diffusion, new  $\text{MgO}$  and Devarda's alloy were added to convert  $\text{NO}_3^-$  to  $\text{NH}_3$ . For  $^{15}\text{N}$  determination in the extractable organic N pool, 2 mL of 10 mol  $\text{L}^{-1}$   $\text{NaOH}$  was added to 50 mL of the Persulfate digest (raising the pH to > 13) and left open for 5 days to eliminate any residual  $\text{NH}_4^+$ . Diffusion of Persulfate-N ( $\text{NO}_3^-$  form) proceeded by adding another 2 mL of 10 mol  $\text{L}^{-1}$   $\text{NaOH}$  (maintaining the pH at >13) and Devarda's alloy, similar to the methods of Stark and Hart (1996). We calculated the  $^{15}\text{N}$  enrichment of the extractable organic N pool

based on isotope mixing equations using the difference in  $^{15}\text{N}$  enrichments and N concentrations between the Persulfate-N (i.e, total N) and  $\text{NH}_4^+ + \text{NO}_3^-$  pools. Our ancillary test of the Persulfate-N diffusion method, similar to the test of Stark and Hart (1996), showed that  $^{15}\text{N}$  enrichment from extractable organic N was accurately measured. For the  $T_1$ -core extracts, only  $\text{NH}_4^+$  was diffused from the  $^{15}\text{NH}_4^+$ -labeled cores (for gross N mineralization), and  $\text{NH}_4^+$  and  $\text{NO}_3^-$  were sequentially diffused from the  $^{15}\text{NO}_3^-$ -labeled cores (for gross nitrification and dissimilatory nitrate reduction to ammonium (see below)). Part of the  $T_1$ -core extracts was reserved for the microbial N immobilization assay (see below). Blank correction, calculated by isotopic dilution, was carried out as recommended by Stark and Hart (1996).  $^{15}\text{N}$  was analyzed using IRMS (Finigan MAT, Bremen, Germany).

#### *Dissimilatory nitrate reduction to ammonium (DNRA)*

We calculated rates of DNRA, using the  $^{15}\text{NO}_3^-$ -injected cores, as the difference in the  $^{15}\text{NH}_4^+$  atom % between  $T_0$  and  $T_1$ , multiplied by the mean  $\text{NH}_4$  pool size during the incubation period, and corrected for isotopic composition of  $^{15}\text{NO}_3^-$  source pool over the incubation interval (Silver et al. 2001, 2005). This was also corrected for any  $\text{NH}_4^+$  transported out of the  $\text{NH}_4^+$  pool (i.e., mean residence time of  $\text{NH}_4^+$ ) over the incubation period.

#### *$\text{NH}_4^+$ and $\text{NO}_3^-$ immobilization rates and microbial biomass C and N by chloroform fumigation*

We used the  $T_1$   $^{15}\text{NH}_4^+$ - and  $^{15}\text{NO}_3^-$ -labeled cores to assess  $\text{NH}_4^+$  and  $\text{NO}_3^-$  immobilization rates, respectively, as described in detail by Davidson et al. (1991). About 25 g fresh samples were placed in a desiccator containing a beaker of purified  $\text{CHCl}_3$  with

several boiling chips. The desiccator was evacuated and flushed with air several times to distribute  $\text{CHCl}_3$  vapor, and during the final evacuation it was closed after letting the  $\text{CHCl}_3$  bubble for 3 minutes. After 5 days of fumigation, the desiccator was flushed with air several times to remove  $\text{CHCl}_3$  vapor, and the samples were extracted with  $0.5 \text{ mol L}^{-1} \text{ K}_2\text{SO}_4$  (approx. 5:1 ratio of solution to dry mass soil).

From these fumigated  $T_1$ -core extracts and the corresponding unfumigated  $T_1$ -core extracts, extractable organic N was determined using Persulfate digestion described earlier. The  $^{15}\text{N}$  in the Persulfate digests was determined following the diffusion procedures mentioned above. The  $^{15}\text{N}$  recovered in fumigated samples was subtracted with the  $^{15}\text{N}$  recovered in corresponding unfumigated samples to estimate the  $^{15}\text{N}$  released (presumably from microbial biomass) by fumigation.  $\text{NH}_4^+$  and  $\text{NO}_3^-$  immobilization rates were calculated using the non-linear model described by Davidson et al. (1991), which is based on the ratio between the  $^{15}\text{N}$  appearance in the  $\text{CHCl}_3$ -labile pool and the change of  $^{15}\text{N}$  enrichments and mineral N concentrations from  $T_0$  to  $T_1$ .

Microbial biomass C and N were determined from samples taken from the same sampling point, acclimatized at the same temperature and period as the cores used for microbial N cycling measurements. We used the fumigation-extraction method (Brookes et al. 1985, Davidson et al. 1989) for determining microbial biomass. Two 25-g fresh subsamples were taken. One pair of the subsamples was immediately extracted with  $0.5 \text{ M K}_2\text{SO}_4$  (approx. 5:1 ratio of solution to dry mass soil) and the other pair was fumigated for 5 days and then extracted. Organic C from the extracts was analyzed by UV-enhanced persulfate oxidation using a Dohrmann DC-80 Carbon Analyzer with an infrared detector (Rosemount Analytical Division, CA, U.S.A.). Organic N was determined using Persulfate digestion described earlier. The differences in organic C and Persulfate-N extracted between the fumigated and unfumigated soils (C and N flushes) are assumed to represent the C and N

released from lysed soil microbes. The C and N flushes were converted to microbial biomass C and N, respectively, using  $k_C = 0.45$  (Joergensen 1996) and  $k_N = 0.68$  for 5-day fumigated samples (Shen et al. 1984, Brookes et al. 1985).

#### *Calculation of mean residence time (MRT)*

The MRT indicates the average length of time an N atom resides in a given pool; a lower MRT indicates a faster pool turnover rate and hence a more dynamic pool. The calculation of MRT (N pool  $\div$  flux rate; e.g. microbial  $N_{MRT} = \text{microbial N pool} \div \text{total N immobilization rate}$ ) assumed that the  $\text{NH}_4^+$ ,  $\text{NO}_3^-$ , and microbial biomass N pools were at steady state and that the fluxes were equal to gross rates of N mineralization, nitrification, and total N ( $\text{NH}_4^+ + \text{NO}_3^-$ ) immobilization, respectively.

#### *Other supporting parameters*

Site characteristics were determined at the start of the study and are reported in Table 4.1. We collected samples of leaves, fresh litter and decomposing litter for C, N and  $\delta^{15}\text{N}$  analyses to support our measurements of the soil N dynamics. Leaves from the trees were randomly collected to obtain a composite sample in each site. Three replicates of fresh litter, decomposing litter, and mineral soil (at 0-0.05, 0.05-0.10, 0.10-0.25 and 0.25-0.50 m depths) samples were also collected. All samples were oven-dried, ground and analysed for total organic C and N using CNS Elemental Analyzer (Elementar Vario EL, Hanau, Germany) and for  $^{15}\text{N}$  natural abundance using IRMS. From  $\delta^{15}\text{N}$  profile in each site, the enrichment factor ( $\epsilon$ ) of the soil was calculated following similar procedure employed by Mariotti et al. (1981) using a Rayleigh equation ( $\epsilon = \delta_s - \delta_{s_0} / \ln f$ ).  $\delta_{s_0}$  stands for the  $\delta^{15}\text{N}$  value of the input substrate, here the decomposing litter,  $\delta_s$  for the  $\delta^{15}\text{N}$  value at different depths in the soil

profile and  $f$  for the remaining fraction of total N. This fraction of total N was calculated as the total N at certain depth divided by the total N of the decomposing litter.  $\delta^{15}\text{N}$  signal in forests has been used as indirect indicator of N status (Martinelli et al. 1999), soil N cycling behaviour (Nadelhoffer and Fry 1988),  $\text{NO}_3^-$  losses (Vervaet et al. 2002), and N gaseous emissions (Purbopuspito et al. 2006).

Additional soil characteristics were also measured. Bulk density was determined using soil core method. Particle size distribution was analyzed with the pipette method using pyrophosphate as a dispersing agent. Soil pH was measured from a saturated paste mixture (1:1 ratio of soil to  $\text{H}_2\text{O}$  and to 1 M KCl). Base saturation was calculated as the percentage base cations of the effective cation exchange capacity (ECEC); ECEC was determined from air-dried, 2-mm sieved samples, percolated with unbuffered 1 M  $\text{NH}_4\text{Cl}$ , and the percolates analyzed for exchangeable cations using Flame-Atomic Absorption Spectrometer (Varian, Darmstadt, Germany). Total P was analyzed from air-dried, ground samples, digested under high pressure in concentrated  $\text{HNO}_3$ , and the digests were analyzed using Inductively Coupled Plasma-Atomic Emission Spectrometer (Spectro Analytical Instruments, Kleve, Germany)

$\text{N}_2\text{O}$  and  $\text{CO}_2$  emissions were measured from the  $T_1$  cores used for the measurement of gross rates of soil N cycling. The soil cores were placed for 30 minutes in a 1-L glass incubation vessels with a gas sampling port fitting on the lid, from which gas samples were drawn and analyzed for  $\text{N}_2\text{O}$  and  $\text{CO}_2$  using a gas chromatograph (GC 14A, Shimadzu, Duisburg, Germany) equipped with an electron capture detector (Loftfield et al. 1997). Fluxes were calculated from the increase in  $\text{N}_2\text{O}$  and  $\text{CO}_2$  concentrations during the incubation period minus the background  $\text{N}_2\text{O}$  and  $\text{CO}_2$  concentrations (incubation vessel without a soil core). The  $\text{CO}_2$  evolution was used to calculate total C utilized by microbes ([microbial C:N

ratio x total N immobilization rate] + CO<sub>2</sub>-C evolution rate), which we used as an index of available C similar to that of Schimel (1988) and Hart et al. (1994b).

### *Statistical Analyses*

First, we tested the spatial independence of our sampling points. This test can be carried out when the sampling points have uniform distance. In August 2004 sampling, we selected the sampling points in each soil type at uniform distance of 20 m and tested their spatial independence using the data on gross N mineralization rates. This test was carried out using the rank version of von Neumann's ratio test (Bartels 1982). We found that our sampling points spaced at 20 m apart were spatially independent. Earlier study on gross rates of microbial N cycling in tropical ecosystem (Corre et al. 2006) also showed sampling points at 10 m apart to be spatially independent and hence we considered the sampling points at each site as replicates in the succeeding analyses. Tests for normality using Kolmogorov-Smirnov D statistic (Sokal and Rohlf 1981) was conducted for each of the measured parameters. For parameters that were found to have non-normal distribution, log transformations were used to approximate normal distribution. Analyses were then carried out using two-way analysis of variance, with sites and sampling seasons representing treatments. Multiple comparisons of treatments were conducted using a Least Significant Difference test at  $P \leq 0.05$ . Means and standard errors were reported as measures of central tendency and dispersion, respectively.

### 4.3. Results

#### *<sup>15</sup>N recovery from intact cores 10 minutes (T<sub>0</sub>) after <sup>15</sup>N injection*

On average  $88 \pm 5$  % of the added <sup>15</sup>NH<sub>4</sub><sup>+</sup> was recovered in the form added when intact cores were extracted at T<sub>0</sub> (Fig. 4.1). We detected no difference in <sup>15</sup>NH<sub>4</sub><sup>+</sup> recoveries

between soil types. Recoveries of  $^{15}\text{N}$  in the  $\text{NO}_3^-$  pool were negligible ( $1.0 \pm 0.2 \%$ ) and recoveries in the extractable organic N pool were not detectable (Fig. 4.1).  $^{15}\text{N}$  recovery in the insoluble (not extractable by  $\text{K}_2\text{SO}_4$ ) organic N was only  $10 \pm 3 \%$  of the added  $^{15}\text{NH}_4^+$ , and no difference was detected between soil types.  $^{15}\text{N}$  recoveries in the total N pool showed complete recovery of the injected  $^{15}\text{NH}_4^+$  (Fig. 4.1).

For the  $^{15}\text{NO}_3^-$ -injected cores, on average  $57 \pm 4 \%$  was recovered in the  $\text{NO}_3^-$  pool at  $T_0$ , and there was no difference detected between soil types (Fig. 4.1). We detected no  $^{15}\text{N}$  above background level in the  $^{15}\text{NH}_4^+$  pool, while the recovery of  $^{15}\text{N}$  in the extractable organic N pool was on average  $12 \pm 5 \%$  and did not differ between soil types. Also,  $^{15}\text{N}$  recoveries in the insoluble organic N pool did not differ between soil types and was on average  $25 \pm 6 \%$ . For the sand, higher  $^{15}\text{N}$  recovery was measured in the insoluble organic N than in the extractable organic N, while for the clay similar  $^{15}\text{N}$  recoveries were observed for these pools.  $^{15}\text{N}$  recoveries in the total N pool were not significantly different from 100 % (Fig. 4.1).

#### *Gross rates of $\text{NH}_4^+$ transformation, microbial biomass, and available C*

High gross N mineralization rates were measured in the clay (seasonal average of  $13.5 \pm 3.1 \text{ mg N kg}^{-1} \text{ d}^{-1}$ ), but these did not significantly differ from the rates in the sand (seasonal average of  $6.0 \pm 0.9 \text{ mg N kg}^{-1} \text{ d}^{-1}$ ), because of the high variation. The rates also did not differ between seasons for each soil (Fig. 4.2).  $\text{NH}_4^+$  immobilization rates were similar to gross N mineralization rates in the dry season, but were only about 50 % (sand) to 65 % (clay) in the wet season (Fig. 4.2). In the wet season,  $\text{NH}_4^+$  immobilization rates were lower in the sand than in the clay. Mean residence time (MRT) of the  $\text{NH}_4^+$  pool was on average  $3.2 \pm 1$  days and there was no difference between soil types and seasons, although a noticeably high MRT

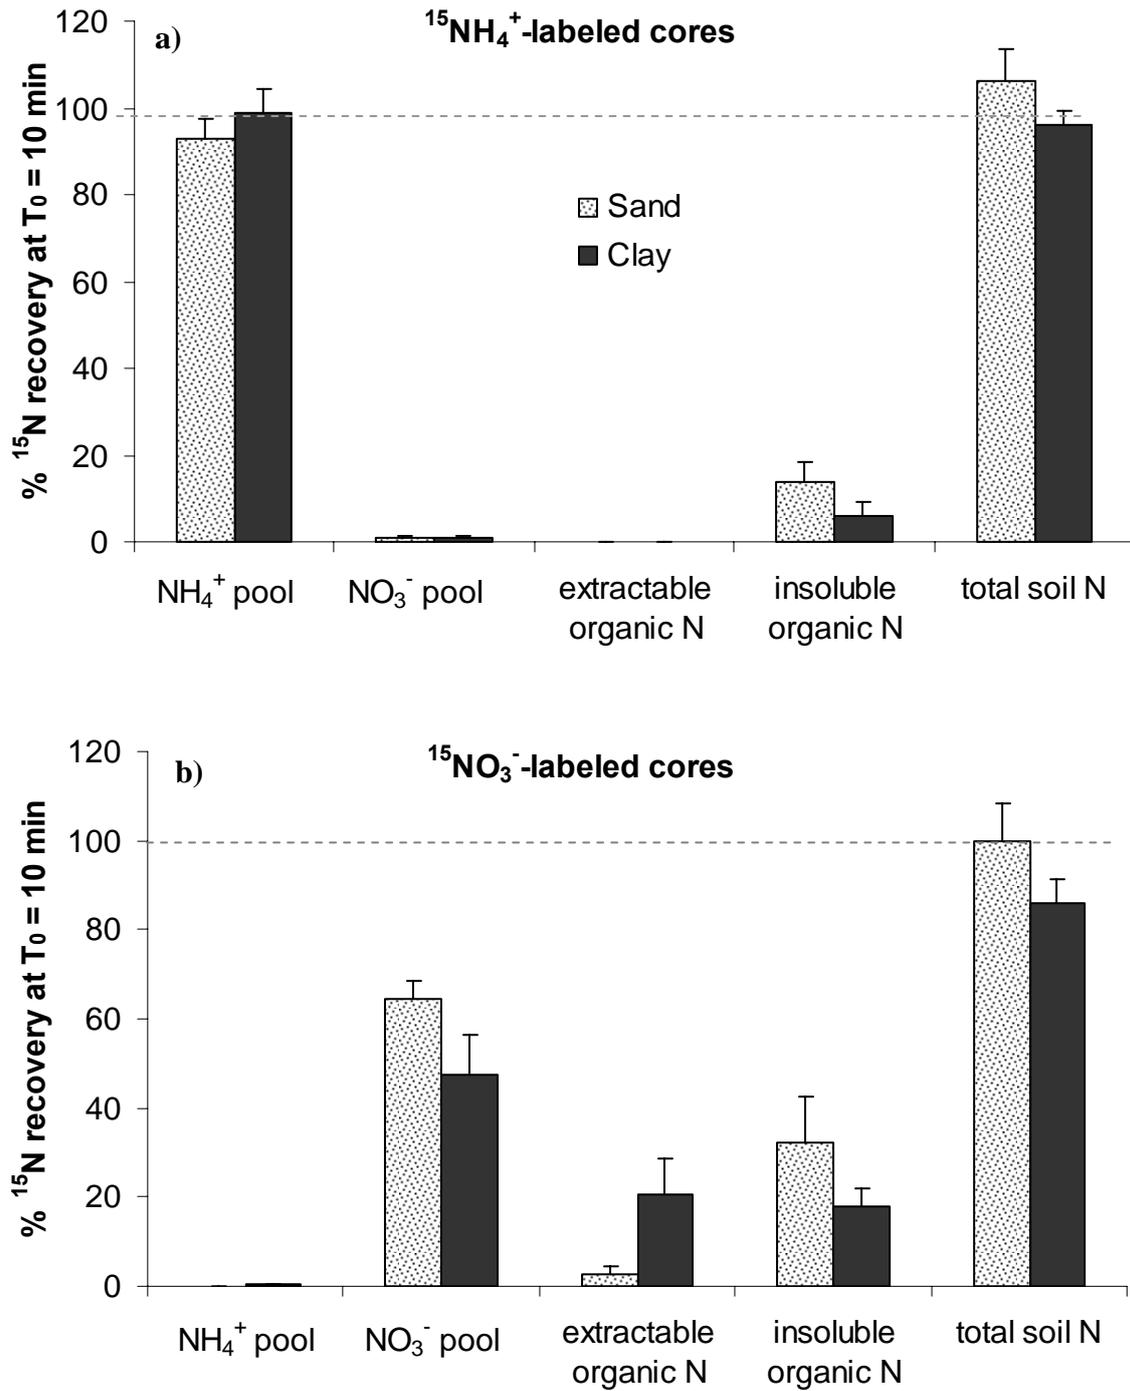

Figure 4.1 - Percent recovery (means  $\pm$  1 SE;  $n = 5$ ) of  $^{15}\text{N}$  in soil N pools after 10 minutes ( $T_0$ ) of  $^{15}\text{N}$  injection into the intact cores during the wet-season sampling (April 2005). (a)  $^{15}\text{NH}_4^+$ -labeled cores; (b)  $^{15}\text{NO}_3^-$ -labeled cores.

(slow turnover rates) occurred in the clayey soil during the wet season (Fig. 4.2). A similar trend was reflected in the size of the  $\text{NH}_4^+$  pool; no difference existed between soil types and seasons, but a large  $\text{NH}_4^+$  pool was apparent in the clayey soil during the wet season.

Microbial biomass N in the clay was more than twice as high as in the sand (Fig. 4.2), and in the sand, it was higher in the dry than in the wet season (Fig. 4.2). The MRT of microbial N pool was on average  $10.1 \pm 2.1$  d, and no difference was observed between soil types and seasons, although a noticeably slow turnover rate was observed for the sandy soil during the wet season (Fig. 4.2). Microbial biomass C was higher in clay than in the sand and did not differ between seasons. Available C was higher in the clay than in the sand and in the clay, it was higher in the wet than in the dry season (Table 4.2).

#### *$\delta^{15}\text{N}$ signals and enrichment factor ( $\epsilon$ )*

In both soils,  $\delta^{15}\text{N}$  signals increased from leaves to litter to soil and with soil depth (Fig. 4.3). On the clay,  $\delta^{15}\text{N}$  values of leaves were on average 2.4 ‰ higher and  $\delta^{15}\text{N}$  values of fresh litter were 1.4 ‰ heavier than on the sand. We calculated the enrichment factor, which considers the  $\delta^{15}\text{N}$  signals from the litter layer down the soil profile, to get an overall measure of the degree of  $^{15}\text{N}$  enrichment for each soil type. A more negative enrichment factor indicates a faster mineralization of isotopically depleted organic N in the upper soil layers and an enrichment of residual soil organic matter in  $^{15}\text{N}$ . Our calculated enrichment factors were higher for the clay than for the sand (Fig. 4.3).

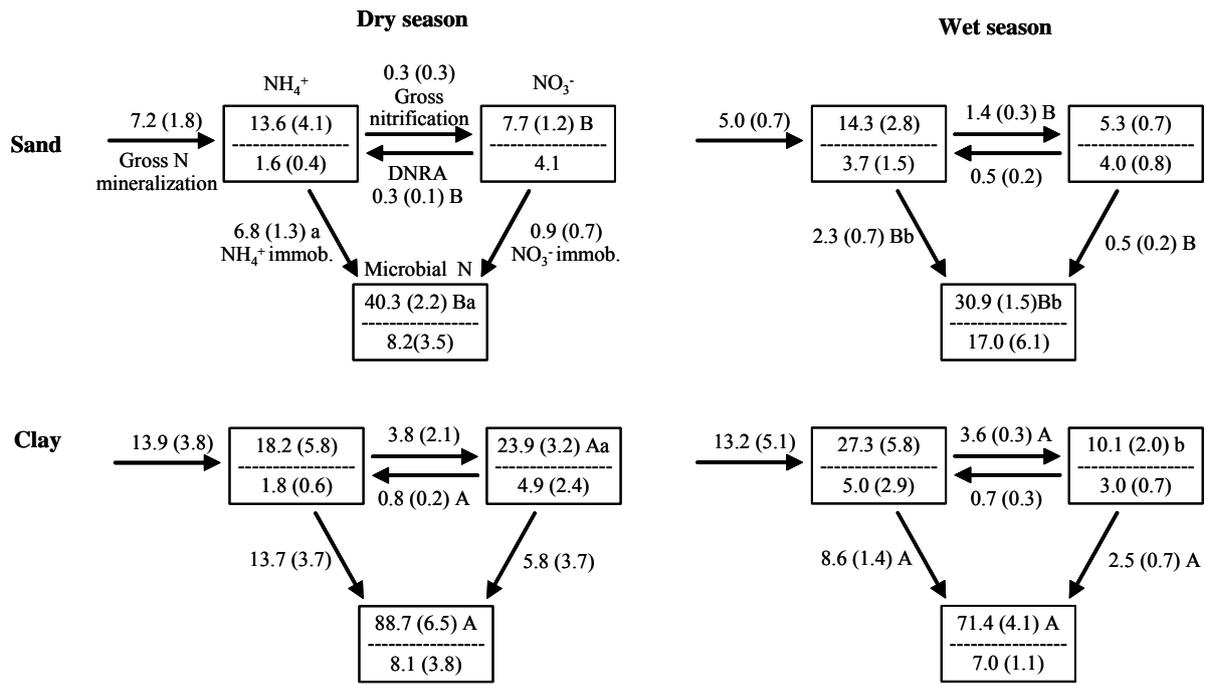

Figure 4.2 - Means  $\pm$  1 SE ( $n = 5$ ) of gross rates of microbial N cycling ( $\text{mg N kg}^{-1} \text{ d}^{-1}$ ), of N pools ( $\text{mg N kg}^{-1}$ ; upper numbers in boxes), and of mean residence time (day; lower numbers in boxes). For each parameter, means with different letters indicate significant differences between soil types at each season (upper case) and between seasons at each soil type (lower case). Arrows in sandy soil, dry season correspond to the same cycling components in clayey soil and both seasons.

Table 4.2. Microbial C, available C, water filled pore space (WFPS) and rates of N<sub>2</sub>O emission for Oxisols with sand and clay texture at Caxiuanã National Forest, Brazil.

	Sand		Clay	
	Mean	SE	Mean	SE
<b>Microbial C (mg kg<sup>-1</sup>)</b>				
dry season	338 B	17	820 A	57
wet season	329 B	5	837 A	42
<b>Available C (mg kg<sup>-1</sup> d<sup>-1</sup>) *</b>

wet season	58 B	3.8	88 Aa	5.9

\*Calculated using a similar index to that of Schimel (1988) and Hart et al. (1994b), where available C = ([microbial C:N ratio x total N immobilization rate] + CO<sub>2</sub>-C evolution rate). Means ± 1 SE (*n* = 5) with different letters indicate significant differences between soil types at each season (upper case) and between seasons at each soil type (lower case) (two-way ANOVA, Least Significant Difference test at *P* ≤ 0.05). There was no significant difference in N<sub>2</sub>O emissions between the T<sub>1</sub> cores injected with <sup>15</sup>NH<sub>4</sub><sup>+</sup> and <sup>15</sup>NO<sub>3</sub><sup>-</sup>; data for each replicate were the average from the two T<sub>1</sub> cores.

*Gross rates of NO<sub>3</sub><sup>-</sup> transformation, dissimilatory nitrate reduction to ammonium (DNRA), and N<sub>2</sub>O emissions*

Gross rates of nitrification and NO<sub>3</sub><sup>-</sup> immobilization were much lower than gross rates of N mineralization and NH<sub>4</sub><sup>+</sup> immobilization in both soil types and seasons (Fig. 4.2). Both gross rates of nitrification and NO<sub>3</sub><sup>-</sup> immobilization were higher in the clay than in the sand; this was particularly detectable in the wet season when the variation (as indicated by the standard

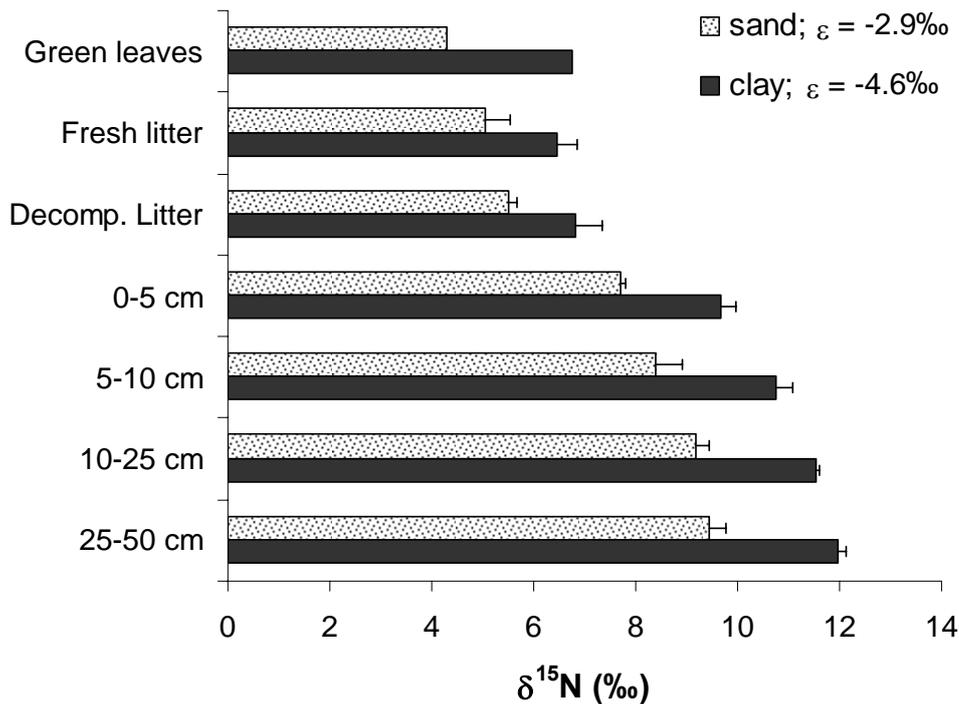

Figure 4.3 - Variation in natural abundance of  $^{15}\text{N}$  ( $\delta^{15}\text{N}$ , ‰) for clayey and sandy soil. One data point represents the average of three samples (means  $\pm$  1 SE).

errors) was less (Fig. 4.2).  $\text{NO}_3^-$  immobilization rates were similar to gross nitrifications rates in the dry season (with high variation), but accounted only about 35 % (sand) to 69 % (clay) in the wet season. The  $\text{NO}_3^-$  pool was larger in the clay than in the sand during the dry season; and in the clay, the  $\text{NO}_3^-$  pool was larger in the dry than in the wet season (Fig. 4.2). MRT of the  $^{15}\text{NO}_3^-$  pool was on average  $3.9 \pm 0.6$  days and tended to be shorter in the clay during the wet season although differences were not significant between soil types or seasons (Fig. 4.2). Rates of DNRA were higher in the clay than in the sand during the dry season, and did not differ between seasons for both soil types (Fig. 4.2). For the sand, DNRA rates were similar to gross nitrification rates in the dry season but this reduced to only about 35 % in the wet season. For the clay, DNRA rates were about 20 % of the gross nitrification rates in both seasons (Fig. 4.2). When comparing their importance for  $\text{NO}_3^-$  retention, rates of DNRA and

$\text{NO}_3^-$  immobilization were similar in the sand, but in the clay DNRA rates were only 14-28 % of  $\text{NO}_3^-$  immobilization rates (Fig. 4.2).  $\text{N}_2\text{O}$  emission rates were higher in the clay than in the sand (Table 4.2). For the sand,  $\text{N}_2\text{O}$  emission rates did not differ between seasons. For the clayey soil, rates were higher in the dry than in the wet season, possibly indicating a further reduction of  $\text{N}_2\text{O}$  to  $\text{N}_2$  because of the more reduced conditions.

#### 4.4. Discussion

##### *Implications of Rapid Reactions of injected $^{15}\text{NH}_4^+$ and $^{15}\text{NO}_3^-$ to organic N*

Our  $^{15}\text{NH}_4^+$  recoveries at  $T_0$  were higher than those reported for mineral soil of N-limited, tropical montane forests in Indonesia (Corre et al. 2006) and in Hawaii (Hall and Matson 1999), but comparable with high-N availability montane forest in Hawaii (Hall and Matson 1999). Our low  $^{15}\text{N}$  recovery in the insoluble organic N pool was comparable with those measured from high N-deposition temperate forests (e.g., 8 % from a German forest with  $34 \text{ kg N ha}^{-1} \text{ yr}^{-1}$  throughfall deposition (Corre and Lamersdorf 2004), and 9 % from U. S. forests with  $11 \text{ kg N ha}^{-1} \text{ yr}^{-1}$  N deposition (Fitzhugh et al. 2003)). The fast reaction of added  $^{15}\text{NH}_4^+$  to organic N pool is usually attributed to abiotic  $\text{NH}_4^+$  immobilization (e.g., physical condensation reactions with phenolic compounds (Nömmik 1970, Nömmik and Vahtras 1982, Johnson et al. 2000), and fixation on clay minerals (Davidson et al. 1991)). The higher  $^{15}\text{NH}_4^+$  recoveries at our sites compared to N-limited, tropical montane forests may indicate lower  $\text{NH}_4^+$ -retention capacity in these soils through rapid, abiotic  $\text{NH}_4^+$  reactions.

Our  $^{15}\text{NO}_3^-$  recoveries at  $T_0$  from both soil types were much higher than those reported for mineral soil of N-limited, tropical montane forests in Indonesia (Corre et al. 2006). There are no other values reported for tropical forests to which we can compare our results. However, from low-N deposition ( $9\text{-}11 \text{ kg N ha}^{-1} \text{ yr}^{-1}$ ) temperate forests, Dail et al. (2001)

reported 30 % recovery of added  $^{15}\text{NO}_3^-$  in the extractable organic N and 5-8 % in the insoluble organic N fractions, while Fitzhugh et al. (2003) reported 7 % in the insoluble organic N fraction. From an N-saturated forest, Corre and Lamersdorf (2004) reported 1 % in the extractable organic N and 49 % in the insoluble organic N fractions. Such fast reaction of  $\text{NO}_3^-$  to organic N has been attributed to abiotic  $\text{NO}_3^-$  immobilization (Berntson and Aber 2000). The hypothesized reaction is that DOC reduces Fe(III) in soil minerals, producing reactive Fe(II) species that reduce  $\text{NO}_3^-$  to  $\text{NO}_2^-$  in anaerobic microsites while Fe(II) is in turn oxidized to Fe(III) (Davidson et al. 2003).  $\text{NO}_2^-$  then reacts readily and abiotically with soil organic matter (Smith and Chalk 1980, Azhar et al. 1986, Van Cleemput and Samater 1996, Thorn and Mikita 2000). The driver of these reactions is DOC, which is needed to reduce metals in the soil. The differences we found between sand and clay may be a reflection of the differences in reactive C between these soils, which may affect whether the  $^{15}\text{N}$  is recovered in soluble or insoluble organic N. In the sand, injected  $^{15}\text{NO}_3^-$  was recovered more in the insoluble organic N pool than the extractable organic N pool, while in the clay  $^{15}\text{N}$  recoveries were similar in both pools. Until now it is however unclear whether the rapid conversion of  $\text{NO}_3^-$  to the organic N pool leads to higher  $\text{NO}_3^-$  retention. The significance of this process and its role in N retention, especially when changes in N deposition in tropical areas occur, deserves more attention.

*Gross rates of  $\text{NH}_4^+$  transformation processes, enrichment factor ( $\epsilon$ ) and implications to soil N status*

Gross N mineralization rates in the sand were comparable to the rates measured for a tropical lowland forest soil in Rondonia, Southern Amazon (with 23-35 % clay, which is intermediate between our sand and clay soils; Neill et al. 1999). These rates were also comparable to those reported for N-limited, tropical montane forests in Hawaii (Hall and

Matson 2003) and in Indonesia (Corre et al. 2006). On the other hand, gross N mineralization rates in the clay were comparable to the rates from a long-term (11 yr) N-fertilized, montane forest in Hawaii (Hall and Matson 2003) and from lowland forest soils (with 68-76 % clay; Veldkamp et al. 2003) in Costa Rica (Silver et al. 2005). These rates were only about half the rates measured from the high-N availability montane forest in Hawaii (Hall and Matson 2003), and much lower (more than 5 times less) than the rates reported for N-saturated temperate forests (e.g., Corre et al. 2003, Corre and Lamersdorf 2004).

The high gross N mineralization rates observed for the clay are coherent with the low C:N ratios in litter and soil, high total soil N (Table 4.1), high microbial N (Fig. 4.2), microbial C, and available C (Table 4.2). Gross N mineralization reflects both the microbial biomass size (presumably active in mineralization, e.g. chemoheterotrophs) and the amount of available substrate (indicated by available C, a similar index used by Hart et al. 1994b). The positive correlations of gross N mineralization to  $\text{NH}_4^+$  immobilization ( $r = 0.67$ ;  $P < 0.05$ ), and  $\text{NH}_4^+$  immobilization to microbial biomass N ( $r = 0.59$ ;  $P < 0.05$ ) attest that the high gross N mineralization rates in the clay provided high available N for microbial assimilation and hence supported a high microbial biomass. On the other hand, the low gross N mineralization rates observed in the sand are probably due to lower litter quality (high C:N ratio; Table 4.1) which was also reflected in the lower available C and microbial biomass (Table 4.2; Fig. 4.2). Lower litter quality was also reported by Silver et al. (2000) for sandy Amazonian forest soil, while nutrient and water limitations have been reported for decomposition (Cuevas and Medina 1986).

$\delta^{15}\text{N}$  signals and the  $^{15}\text{N}$ -enrichment factor reflect the long-term behaviour of soil N cycling of an ecosystem. If N in a forest ecosystem is in relative excess (not limiting), it can be expected to be enriched in  $^{15}\text{N}$  as many of the output pathways of N are discriminating against the heavier  $^{15}\text{N}$  isotope. A heavier  $\delta^{15}\text{N}$  signal in leaves could reflect uptake of a more

$^{15}\text{N}$ -enriched mineral N pool, which in turn indicates high soil N cycling rates with high N losses. Our  $\delta^{15}\text{N}$  values for leaves and soil were within the range reported for Amazonian forest soils (2 to 8 ‰ for leaf litter (Piccolo et al. 1994) and 8 to 23 ‰ for soil (Piccolo et al. 1996)). In our study, the clay that had high gross N mineralization rates also had heavier  $\delta^{15}\text{N}$  in leaves, litter and soil compared to the sand (Fig. 4.3).  $\delta^{15}\text{N}$  signals in litter and soil have been shown to correlate directly to gaseous N losses along a toposequence of montane forest soils in Indonesia (Purbopuspito et al. 2006). In addition, it has been shown in temperate forest soils that net mineralization was the main process of soil N cycle contributing largely to a high (more negative)  $^{15}\text{N}$ -enrichment factor (Nadelhoffer and Fry 1988, Vervaet et al. 2002). Furthermore, temperate forest soils with higher enrichment factors had higher potential net N mineralization rates and higher  $\text{NO}_3^-$  losses (Vervaet et al. 2002). In Amazonian forest soils, the discrimination factor (which has similar meaning as the enrichment factor but only has an opposite sign) generally increased with increasing clay content of the soil (Piccolo et al. 1996). Our study showed that the clay that had high gross rates of N mineralization also had a higher enrichment factor (Fig. 4.3) and higher gaseous losses (i.e.,  $\text{N}_2\text{O}$  emissions; Table 4.2) than the sand.

*Gross rates of  $\text{NO}_3^-$  transformation, dissimilatory nitrate reduction to ammonium (DNRA), and implications for N losses*

Gross rates of nitrification in sand were comparable to those reported for N-limited, montane forest in Hawaii (Hall and Matson 2003) and in Puerto Rico (Silver et al. 2001). These rates were lower than those measured from a lowland forest soil in Rondonia, Southern Amazon (with 23-35 % clay; Neill et al. 1999). However, gross nitrification rates in the clay were higher than this Rondonia site and were comparable to the rates from a lowland forest with heavy clay soil in Costa Rica, characterized by high N availability (Silver et al. 2005)

and large N losses (gaseous N losses, Keller et al. 1993, Keller and Reiners 1994, Veldkamp et al. 1999; and leaching losses, Schwendenmann and Veldkamp 2005).

Despite the high WFPS in the clay during the wet season (Table 4.2), which may limit O<sub>2</sub> diffusion and decrease nitrification (Paul and Clark 1996), higher gross nitrification rates were observed in the clay compared to the sand. This suggests that NH<sub>4</sub><sup>+</sup> availability limits nitrification activity rather than aeration. In the absence of root uptake, mineralized N was assimilated by micro organisms (e.g., heterotrophs) rather than nitrified (Fig. 4.2). Low gross N mineralization rates in the sand may have imposed strong competition for ammonium, resulting in low gross nitrification rates.

The low DNRA rates in the sand were comparable to the rates in lowland forest in Costa Rica (Silver et al. 2005), while the high DNRA rates in the clay were comparable to the montane forest in Puerto Rico (Silver et al. 1999). Contrary to what Silver et al. (2005) found, we did not detect correlations between DNRA rates and total C:NO<sub>3</sub><sup>-</sup> ratios or to any indicators of NO<sub>3</sub><sup>-</sup> availability (e.g., gross nitrification or NO<sub>3</sub><sup>-</sup> pool). Instead we observed a marginal relationship between DNRA and available C ( $r = 0.62$ ,  $P = 0.06$ ), indicating that this NO<sub>3</sub><sup>-</sup> retention process may be in part driven by the availability of C to micro organisms. High DNRA rates in the clay also signified that this process is favoured under a more O<sub>2</sub>-reduced condition (i.e., high WFPS in the clay soil, Table 4.2). In terms of its significance for NO<sub>3</sub><sup>-</sup> retention, only in the sand, where production of NO<sub>3</sub><sup>-</sup> was low, DNRA was as important as NO<sub>3</sub><sup>-</sup> immobilization. In the clay, where gross nitrification rates and NO<sub>3</sub><sup>-</sup> pools were high, DNRA was 3-7 times lower than NO<sub>3</sub><sup>-</sup> immobilization. N<sub>2</sub>O emission rates in the clay (Table 4.2) were also higher than the combined rates of DNRA and NO<sub>3</sub><sup>-</sup> immobilization (Fig. 4.2), while in the sand N<sub>2</sub>O losses were lower than the sum of the rates of these NO<sub>3</sub><sup>-</sup> retention processes. The low N<sub>2</sub>O emissions in the sand reflect the overall low rates of soil N cycling in this soil as well as its low WFPS and C availability. In contrast, the clay typified a system

with relative excess of N - the rates of internal soil N cycling were lower than the rates of N loss (e.g. N<sub>2</sub>O emission).

#### *Mean residence time (MRT) and implication for N losses*

MRT of NH<sub>4</sub><sup>+</sup> during the dry season was similar to the values reported for Rondonia lowland forests (Neill et al. 1999) and for Indonesian montane forests (Corre et al. 2006). We observed fast turnover rates (short MRT) of NH<sub>4</sub><sup>+</sup> in the dry season, when microbial immobilization of NH<sub>4</sub><sup>+</sup> was generally comparable to gross N mineralization (Fig. 4.2). In the wet season NH<sub>4</sub><sup>+</sup> immobilization rates were somewhat lower than gross N mineralization rates, and NH<sub>4</sub><sup>+</sup> tended to have slow turnover rates. Low N immobilization rates in the wet season were also reflected in the small microbial N pool (Fig. 4.2) and a slow turnover rate of microbial N in the sand, (Fig. 4.2). Hart et al. (1994b) have shown that fast turnover of N pools was a response to an increase in C availability that drives the internal soil N cycle. For clay, available C was higher during the wet season, whereas for sand this difference was not significant (Table 4.2). Hence, the slow turnover rates of NH<sub>4</sub><sup>+</sup> and microbial N pools during the wet season were probably not limited by available C but more likely by increased anaerobicity (higher WFPS in the wet season in the clay, Table 4.2).

The MRT of NO<sub>3</sub><sup>-</sup> were comparable to values reported for Rondonia lowland forests (Neill et al. 1999), but higher than those observed from tropical montane forests where NO<sub>3</sub><sup>-</sup> was sometimes even undetectable (Silver et al. 2001, Hall and Matson 2003, Corre et al. 2006). A long MRT of NO<sub>3</sub><sup>-</sup> signals high potential for N losses via leaching and gaseous emissions in times of high soil water content. We do not have estimates of leaching losses from our study area, but estimates of leaching losses from lowland tropical forests were higher than from montane forests (e.g., 10 kg NO<sub>3</sub><sup>-</sup>-N ha<sup>-1</sup> yr<sup>-1</sup> from a, lowland forest in Costa Rica (Schwendenmann and Veldkamp 2005) and a similar amount from a lowland forest in

Paragominas (Klinge et al. 2004) compared to 1-5 kg N ha<sup>-1</sup> yr<sup>-1</sup> from N-limited, montane forest in Indonesia (Dechert et al. 2005)). It has also been shown that N-oxide emissions from most tropical lowland forests (e.g., Costa Rica: Keller et al. 1993, Keller and Reiners 1994, Veldkamp et al. 1999; Brazil: Verchot et al. 1999, Davidson et al. 2000b, Davidson et al. 2004; Australia: Breuer et al. 2000) were higher than from N-limited, tropical montane forests (e.g., Hawaii: Riley and Vitousek 1995; Indonesia: Purbopuspito et al. 2006; Australia: Kiese and Butterbach-Bahl 2002). Furthermore, we observed somewhat comparable NO<sub>3</sub><sup>-</sup> immobilization rates and gross nitrification rates in the dry season while NO<sub>3</sub><sup>-</sup> immobilization rates tended to be lower than gross nitrification in the wet season. However, the MRT of NO<sub>3</sub><sup>-</sup> showed the opposite pattern of NH<sub>4</sub><sup>+</sup>: shorter MRT of NO<sub>3</sub><sup>-</sup> and lower NO<sub>3</sub><sup>-</sup> in the wet than in the dry season for the clay (Fig. 4.2). In the wet season, when the sink of mineral N pool by microbial immobilization was low, NO<sub>3</sub><sup>-</sup> could be more exposed to losses. The fast turnover rate of NO<sub>3</sub><sup>-</sup> in the clay during the wet season could have contributed to high gaseous N losses, which could then result in low NO<sub>3</sub><sup>-</sup> values. The N<sub>2</sub>O emissions we measured do not represent the overall gaseous N losses; in the wet season a significant part of the N<sub>2</sub>O produced was probably reduced further to N<sub>2</sub> and the overall gaseous N losses were thus higher than the N<sub>2</sub>O emissions alone.

#### 4.5. Conclusions

This study shows that large differences exist in N cycling and N retention between heavily weathered tropical forest soils that mainly differ in texture. Our combined results suggest that some Amazonian forest soils have higher N availability than others. While the clay Oxisol in our study had high gross rates of N mineralization and nitrification, and hence high potential for N losses, the sandy Oxisol had low gross rates of N cycling and reacted more like a soil that is N-limited.  $\delta^{15}\text{N}$  signals and the <sup>15</sup>N-enrichment factor, which reflect

the long-term behaviour of soil N cycling of an ecosystem, were also higher in the clay than in the sand. Our findings of faster turnover rates of  $\text{NH}_4^+$  compared to  $\text{NO}_3^-$  signified that  $\text{NH}_4^+$  cycles faster through microorganisms than  $\text{NO}_3^-$ , possibly contributing to better retention of  $\text{NH}_4^+$  than  $\text{NO}_3^-$ . This was opposite to abiotic retention, which showed higher conversion of  $\text{NO}_3^-$  than  $\text{NH}_4^+$  to the organic N pool. How this will affect long-term N retention is presently unknown and cannot be deduced from the present study, which illustrates that the importance of biotic and abiotic retention of N needs further attention. Because of the differences in N cycling and N retention, there is no doubt that the studied soils will react differently to increased anthropogenic N deposition. To make a complete analysis of these effects, however, we have to know better how abiotic and biotic N retention processes contribute to middle and long-term N sequestration and their changes with increasing N deposition in tropical forests.

## 5. Summarizing synthesis

The overall goal of the present study was to evaluate the soil CO<sub>2</sub> dynamics and the N cycle in the old-growth forest of Caxiuanã, Eastern Amazonia. Quantification of temporal and spatial variation of soil CO<sub>2</sub> emissions is essential for an accurate interpretation of tower-based measurements of net ecosystem exchange. This is particularly important now that climate of the Amazon basin is expected to change in the next few decades, as a result of deforestation and rising temperatures which may lead to unknown feedback mechanisms in carbon cycling. Furthermore, changes are also expected in the N cycling from tropical soils with resulting high rates of N<sub>2</sub>O emissions. Nitrogen is in relative excess in heavily weathered lowland tropical forests soils, however within the Amazon basin soil texture may influence soil NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>-</sup> concentrations and hence N availability and retention in the soil.

### 5.1. Landscape and climatic controls on spatial and temporal variation

The chapter 2 had the goal of quantifying the spatial and seasonal variation in soil CO<sub>2</sub> efflux and its environmental controls in the old-growth forest of Caxiuanã, Eastern Amazonia. We measured soil CO<sub>2</sub> efflux from two Oxisol sites with contrasting soil texture and at different landscape positions. Using manually deployed flux chambers, we monitored soil CO<sub>2</sub> efflux every two weeks from the two sites with contrasting soil texture and every three months from the landscape positions, over the course of two years. The CO<sub>2</sub> flux was calculated from the linear regression of increasing CO<sub>2</sub> concentration in the chamber headspace versus time. At the same time soil water content and soil temperature were estimated.

Average CO<sub>2</sub> efflux was 21% higher for sand ( $3.93 \pm 0.06 \mu\text{mol CO}_2 \text{ m}^{-2}\text{s}^{-1}$ ) than for the clay ( $3.08 \pm 0.07 \mu\text{mol CO}_2 \text{ m}^{-2}\text{s}^{-1}$ ). No difference was detected for soil temperature

between sites ( $24.1 \pm 0.13$  °C for sand and  $24.2 \pm 0.15$  °C for clay), while soil water content in sandy soil ( $23.2 \pm 0.33$  %) was much lower than the clay soil ( $34.5 \pm 0.98$  %), for the two-year period. Spatial difference in CO<sub>2</sub> efflux were related to water holding capacity and capacity to retain nutrients of each soil texture, reflecting in different root respiration. Seasonality in soil CO<sub>2</sub> efflux was not detectable and CO<sub>2</sub> efflux did not differ between dry and wet season. However, the interaction between time and topographic position had a significant effect on CO<sub>2</sub> efflux. The variation caused by topography was in the same order of magnitude as temporal variation, indicating the importance of considering this variation while modelling soil CO<sub>2</sub> efflux. Mean contribution of the litter layer to the CO<sub>2</sub> efflux rates was 20 % and varied from 25 % during the wet season to close to 0 % during the dry season. These seasonal variations may be caused by variations in the stock of decomposing litter on the forest floor and by the conditions influencing litter decomposition. Temporal variability of soil CO<sub>2</sub> efflux also depended on climatic variables. The relation between soil water content and soil CO<sub>2</sub> efflux showed an optimum for both soil textures but the shape and optimum of the curves were different. Soil water content explained 23 % of the soil CO<sub>2</sub> efflux in the sand and 18 % in the clay soil texture, and soil temperature co-varied with soil water content in both soil types. The problem of co-variation of temperature and soil moisture has been detected in several ecosystems, including tropical rainforests (Davidson et al. 2000, Schwendenmann et al. 2003). The results of our study show that soil moisture is an important driver of temporal variations in soil CO<sub>2</sub> efflux in this old-growth forest. But when extrapolating soil CO<sub>2</sub> efflux to larger areas, the significant influences of soil texture, litter, and the interaction of topographical position and time illustrate that it is necessary to include some of the complexity of landscapes.

## 5.2. Effects of induced drought on soil CO<sub>2</sub> production and soil CO<sub>2</sub> efflux

Given the expected intensification of ENSO events, which will probably lead to an increasing frequency of droughts and higher temperatures, in Chapter 3, we report how a throughfall exclusion (TFE) experiment affected soil CO<sub>2</sub> production in a deeply weathered sandy Oxisol of Caxiuanã (Eastern Amazon). Over the course of two years, we measured soil CO<sub>2</sub> efflux and soil CO<sub>2</sub> concentrations, soil temperature and moisture in pits down to 3 m depth. TFE reduced soil CO<sub>2</sub> efflux from  $4.3 \pm 0.1 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$  (control) to  $3.2 \pm 0.1 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$  (TFE) and the reduction was already evident on the first year of artificial drought. Over 70 % of soil CO<sub>2</sub> production in both plots occurred within the top 0.5 m of the soil including the forest litter layer, and that was the layer most affected by the soil water stress. The contribution of the subsoil (below 0.5 m depth) to the total soil CO<sub>2</sub> production was higher in the TFE plot (28 %) compared to the control plot (17 %), and it did not differ between years. We distinguished three phases of drying after the TFE was started. The first phase was characterized by a translocation of water uptake (and accompanying root activity) to deeper layers and not enough water stress to affect microbial activity and/or total root respiration. During the second phase a reduction in total soil CO<sub>2</sub> efflux in the TFE plot was related to a reduction of soil- and litter decomposers activity. The third phase of drying, characterized by a continuing decrease in soil CO<sub>2</sub> production was dominated by a water stress-induced decrease in total root respiration. Our results strongly contrast to results of a drought experiment on clay Oxisols which we explain with differences in water holding capacity and depth of rooting zone. We conclude in this chapter, that Amazonian forest ecosystems located on soils with coarse texture are more sensitive to drought than forests located on heavier textures because they cannot compensate the relatively low water holding capacity in the top soil with water stored in deeper soil layers.

### 5.3. Mechanisms of soil N retention

Direct quantification of the inherent soil N status of tropical forests and processes of N retention will provide much-needed baseline information for tropical forests, which may hint how such ecosystems will react to predicted increase in N deposition. Chapter 4 focuses on assessing the soil N status of sand and clay Oxisols, lowland forest soils by quantifying gross rates of N-production processes, and evaluating their differences in N-retention processes by measuring the microbial N immobilization, dissimilatory  $\text{NO}_3^-$  reduction to  $\text{NH}_4^+$ , and abiotic N immobilization. Soil samples were collected from the sand and clay sites once during the dry (August 2004) and once during the wet (April 2005) season. Additional soil, litter and green leaf samples were taken for analysis of other supporting parameters and the measurement of the degree of  $^{15}\text{N}$  enrichment for each soil type. We used the  $^{15}\text{N}$  pool dilution technique to estimate gross rates of soil N cycling (Davidson et al. 1991, Hart et al. 1994a). Gross N mineralization and nitrification rates were estimated from the cores that received  $^{15}\text{NH}_4^+$  and  $^{15}\text{NO}_3^-$ , respectively, using the modified calculation procedure of Davidson et al. (1991) from the Kirkham and Bartholomew (1954) model.

The clay had high gross rates of N mineralization ( $13.5 \pm 3.1 \text{ mg N kg}^{-1} \text{ d}^{-1}$ ), nitrification ( $3.7 \pm 1.1 \text{ mg N kg}^{-1} \text{ d}^{-1}$ ) and  $^{15}\text{N}$  enrichment factor ( $\epsilon = -4.6 \text{ ‰}$ ) and hence high potential for N losses. The sand had low gross rates of N cycling (N mineralization was  $6.0 \pm 0.9 \text{ mg N kg}^{-1} \text{ d}^{-1}$  and nitrification  $0.8 \pm 0.3 \text{ mg N kg}^{-1} \text{ d}^{-1}$ ) and  $^{15}\text{N}$  enrichment factor ( $\epsilon = -2.9 \text{ ‰}$ ), and reacted more like a soil that is N-limited. Faster turnover rates of  $\text{NH}_4^+$  compared to  $\text{NO}_3^-$  signified that  $\text{NH}_4^+$  cycles faster through microorganisms than  $\text{NO}_3^-$ , possibly contributing to better retention of  $\text{NH}_4^+$  than  $\text{NO}_3^-$ . However this was opposite to abiotic retention processes, which showed higher conversion of  $\text{NO}_3^-$  to the organic N pool than  $\text{NH}_4^+$ . Our combined results suggest that some Amazonian forest soils have higher N

availability than others which will have important consequences for soil N cycling and losses when projected increases in anthropogenic N deposition will occur.

#### 5.4. Belowground CO<sub>2</sub> dynamics and N cycling

The use of global climate models has become one of the most powerful tools to estimate changes in natural ecosystems due to climate, but these models are mainly based in meteorological data. Although aboveground components have been successfully modelled using basic climate data, belowground components are not yet satisfactorily assessed. While in many ecosystems temperature has described well the belowground processes (over 80 % of the variation; Janssens et al. 2001), in tropical ecosystems the temperature is not a good predictor. Modelling of belowground processes in tropical areas has therefore been led by the soil water content (Davidson et al. 2006). However, the improvement of these models depends on a better characterization of the belowground processes and their variation within the region. The Amazon region embraces a wide range of soils, vegetation and landscape and this study shows that we should expect different responses within the basin to changes in climate.

Quantification of the contribution of the litter layer, the effect of the interaction of landscape and time, and soil texture on soil CO<sub>2</sub> efflux showed that the inclusion of such variables in the Amazon-wide model analyses, in addition to soil water content and soil temperature, will certainly improve estimates of soil CO<sub>2</sub> efflux for the region. The importance of soil texture has already been pointed by other authors (Silver et al. 2000, Müller and Höper 2004) as well as the importance of the contribution of litter (Luizão and Schubart 1987, Toledo 2002, Chambers et al. 2004), but the quantification of the seasonal litter contribution and topographical variation had been disregarded so far. In these models

Amazon forest is often held as a single ecosystem, which leads to a miscalculation of the effect not only of the soil and vegetation but also of the topography on the fluxes. The topography of the Amazon is quite smooth, however along the seasons the factors influencing soil CO<sub>2</sub> efflux respond differently in each topographic position. The interaction of topographic position in the landscape and time is responsible for a variation of around 30 % in the efflux, and has the same magnitude as the temporal variation.

Predicting whether the soil will be a sink or source of carbon with the expected reduction in precipitation in the Amazon depends not only on the amount of C that is lost from the dried soil but also from the amount of C that is allocated belowground by the plant. This study shows that in the short term, the response to reduced precipitation will mostly depend on the capacity of each soil to supply water to the roots. For example, our sandy Oxisol soil will respond much quicker to low precipitation regime than the clay soil from Santarém (Davidson et al. 2004). The top 0.5 m of soil will be particularly affected by the lower soil water content reducing total soil CO<sub>2</sub> efflux and production, but the deeper soil CO<sub>2</sub> production will mainly depend on the root activity. In the short term, lower CO<sub>2</sub> emissions may signify carbon storage if roots are able to search for water in the soil profile and keep the rates of gross primary productivity (GPP). However, if the soil CO<sub>2</sub> efflux is accompanied by reduction in GPP there may be no change in the net primary productivity (NPP) and thus no change in the allocation of carbon belowground. Declines in GPP and soil CO<sub>2</sub> efflux resulting from soil moisture deficit have been described for temperate European forests (e.g. Ciais et al. 2005) and the processes leading to reduction in both GPP and soil CO<sub>2</sub> efflux seem to be general, though I expect spatial variability in vulnerability to soil moisture stress across the Amazon region.

Accounting for soil diversity along the Amazon basin is also important when predicting the effect of N deposition in the region. The soil with low N availability, as the

sand Oxisols, have lower rates of N cycling, and lower N losses ( $N_2O$  and  $NO$ ), while those with high N availability, as the clay Oxisols, have a high potential for N losses (Figure 5.1). On the other hand, the larger microbial biomass size, available substrate and the higher soil moisture (WFPS) in the clay texture contribute to a higher immobilization of N, hence to a higher N retention in the system. Nevertheless, the mechanisms controlling retention and losses are still not clearly understood.

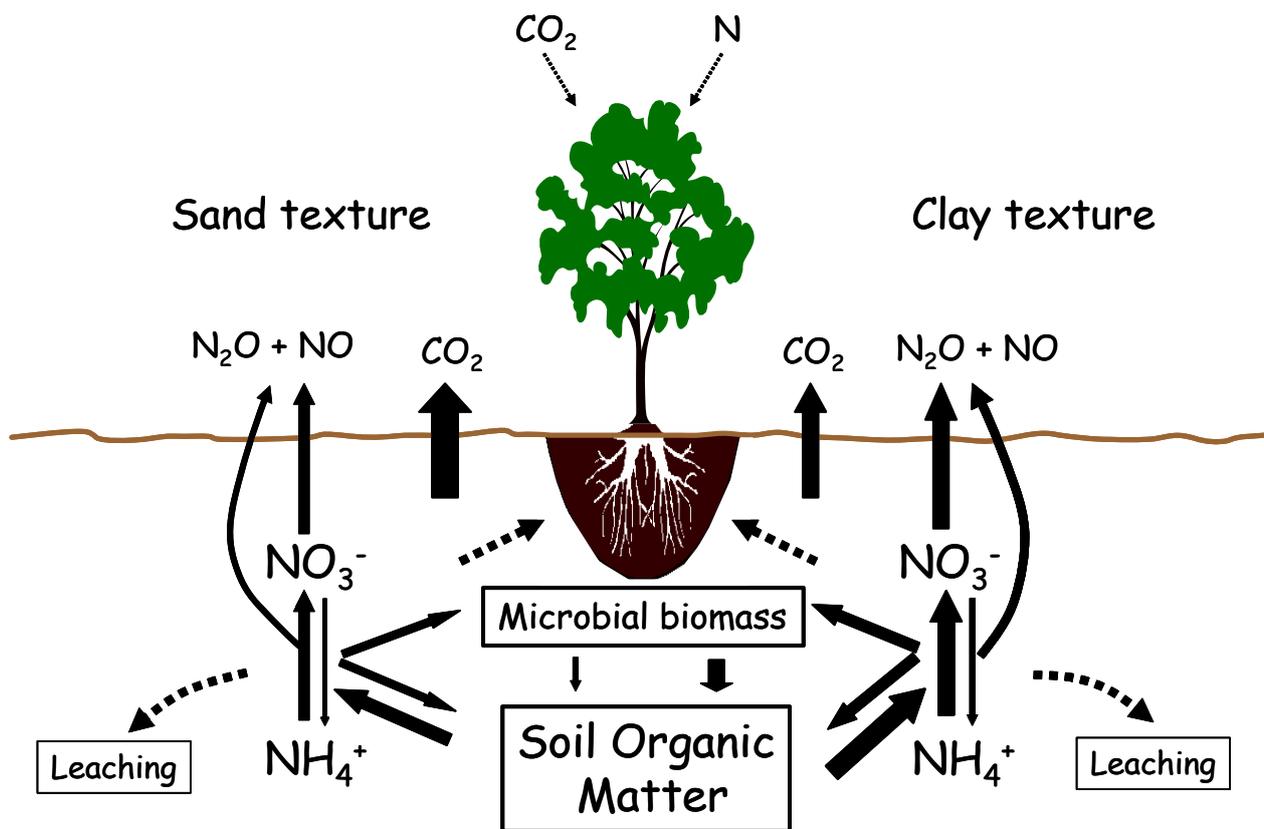

Figure 5.1 - Diagrammatic representation of the carbon and nitrogen cycles, and their interaction in sand and clay soil textures. Line thickness the magnitude of the flux rate and dashed lines fluxes not measured.  $CO_2$  emission is the result of heterotrophic and autotrophic respiration.

With higher soil organic matter and microbial biomass in the clay soil one should expect higher rates of CO<sub>2</sub> efflux resulting from heterotrophic respiration. However, the higher rates of CO<sub>2</sub> efflux were observed in the sand soil. This high rate in sand soil may only be explained by a higher root activity, resultant from the more thorough search for water and nutrients in the coarse soil texture. The larger root biomass in the top 0.3 m of the sand soil (Metcalf et al. in preparation) may indicate a greater root longevity and a mechanism for using more effectively the photosynthetic products. This assumption is corroborated with the linkage between slow root turnover rates and low root tissue N content (Gordon and Jackson 2000).

This study shows that the inclusion of soil and landscape characteristics of the Amazon region in future modelling of global climate change will possibly improve the estimates of C and N belowground processes. That the reduction in soil water will affect some Amazonian forest soils more rapidly than others and that texture will play a big role also on how the forest will react to future N deposition.

## 6. Zusammenfassung

Es ist noch unbekannt, wie sich Klimaänderungen und steigende N-Einträge auf den Kohlenstoff- und Stickstoffkreislauf tropischer Böden auswirken. Deshalb ist es wichtig, individuelle Prozesse und deren Folgen für das Klima zu identifizieren. In dieser Studie bewertete ich die CO<sub>2</sub>-Dynamik im Boden sowie den N-Kreislauf in einem Primärwald in Caxiuana, Ostamazonien. Die Studie gliedert sich in drei Teile: 1) Messung der CO<sub>2</sub> Ausgasungsrate und deren standörtliche Steuergrößen an zwei Oxisol Standorten mit unterschiedlicher Bodentextur und Geländelage, 2) die Untersuchung wie stark sich bei Ausschluss des Bestandesniederschlages (TFE Experiment) die Boden-CO<sub>2</sub> Produktion in einem stark verwitterten sandigen Oxisol in Caxiuana verändert und 3) eine Bewertung des Boden-Stickstoffstatus an zwei stark verwitterten Oxisolen unterschiedlicher Textur (sandig versus tonig). Zwei Jahre lang wurden die Boden-CO<sub>2</sub>-Ausgasungsraten, CO<sub>2</sub>-Konzentrationen, die Bodentemperatur und die Feuchtigkeit der Profile bis in 3 m Tiefe gemessen. Mittels Isotopenverdünnungsanalyse (<sup>15</sup>N pool dilution) wurden für beide Böden die Raten der N-Mineralisierung und der Nitrifikation sowie der N-Retention (mikrobielle N-Festlegung, dissimilatorische NO<sub>3</sub> Reduktion zu NH<sub>4</sub> und abiotische N-Festlegung) gemessen. zusätzlich wurden δ<sup>15</sup>N Werte von der Streu und über das gesamte Profil gemessen, um die <sup>15</sup>N-Anreicherung für jeden Bodentyp zu quantifizieren.

Die wichtigsten Ergebnisse sind:

1) Die durchschnittliche CO<sub>2</sub>-Ausgasungsrate war im Sand ( $3.93 \pm 0.06 \mu\text{mol CO}_2 \text{ m}^{-2}\text{s}^{-1}$ ) 21 % höher als im Ton ( $3.08 \pm 0.07 \mu\text{mol CO}_2 \text{ m}^{-2}\text{s}^{-1}$ ). Keine Unterschiede wurden in der Bodentemperatur zwischen beiden Standorten gemessen, während der Bodenwassergehalt im sandigen Boden ( $23.2 \pm 0.33 \%$ ) geringer war als im tonigen Boden ( $34.5 \pm 0.98 \%$ ). Die Boden-CO<sub>2</sub>-Ausgasungsrate unterschied sich nicht zwischen der Trocken – und Regenzeit,

aber ich fand eine signifikante Wechselwirkung zwischen der Jahreszeit und der topografischen Lage. Die durch die Topografie hervorgerufene Variation war in derselben Größenordnung wie die zeitliche Variation. Der mittlere Beitrag der Streu zur CO<sub>2</sub>-Ausgasungsrate war 20 % und variierte von 25 % innerhalb der Regenzeit bis nahezu 0 % während der Trockenzeit. Die Beziehung zwischen Bodenwassergehalt und Boden-CO<sub>2</sub>-Ausgasungsraten zeigte für beide Bodentexturen ein Optimum aber die Form und das Optimum der Kurve unterschieden sich. Die Ergebnisse unserer Studie zeigen, dass Bodenwasser eine steuernde Größe der zeitlichen Variation der Boden-CO<sub>2</sub>-Ausgasungsraten in diesem Primärwald ist. Bei der Extrapolation der CO<sub>2</sub>-Ausgasungsraten zu größeren Flächen zeigt der signifikante Einfluss von Bodentextur, Streu und Wechselwirkung der topografischen Lage und Zeit, dass es notwendig ist diesen Anteil der Landschaftskomplexität mit zu berücksichtigen.

2) TFE reduzierten den Boden von  $4.3 \pm 0.1 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$  (Kontrolle) zu  $3.2 \pm 0.1 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$  (TFE). Der Beitrag des Unterbodens (unterhalb 0.5 m Tiefe) zur der Gesamtproduktion von CO<sub>2</sub> war in dem TFE Plot größer (28 %) als in dem Kontrollplot (17 %) und er unterschied sich nicht zwischen den Jahren. Ich unterschied drei Phasen der Trocknung nachdem TFE gestartet war. Die erste Phase war durch die Umschichtung der Wasseraufnahme (und begleitender Wurzelaktivität) zu tieferen Schichten und durch einen zu geringen Wasserstress um die mikrobielle Aktivität und /oder die Wurzelatmung zu beeinflussen charakterisiert. Während der zweiten Phase stand die Aktivität von Boden – und Streuzersetzern mit der Reduzierung der gesamten Boden-CO<sub>2</sub>-Ausgasungsrate in dem TFE Plot in Beziehung. Die dritte Trocknungsphase war durch einen kontinuierlichen Abfall der Boden CO<sub>2</sub> Produktion charakterisiert, der durch einen Wasserstress induzierten Abfall in der gesamten Wurzelatmung hervorgerufen wurde. Diese Ergebnisse unterscheiden sich stark von einem Trocknungsexperiment in einem tonigem Oxisol, was ich durch Unterschiede in der

Wasserhaltekapazität und Durchwurzelungstiefe erkläre. Ich folgere, dass Waldökosysteme in Amazonien, die sich auf Böden mit einer groben Textur befinden, sensibler gegenüber Trockenheit sind als Wälder, die sich auf schwereren Böden befinden. Letztere können die relativ geringe Wasserhaltekapazität der Oberböden mit Wasser aus tieferen Bodenschichten kompensieren.

3) Der tonige Oxisol hatte eine große Bruttoreate der N-Mineralisation, Nitrifizierung und des  $^{15}\text{N}$  -Anreicherungsfaktors und somit ein großes Potential für N Verluste. Demgegenüber hatte der sandige Oxisol vergleichsweise niedrige Bruttoreaten und reagierte ähnlich einem Boden der N limitiert ist. Schnellere Umsatzzeiten von  $\text{NH}_4$  im Vergleich zu  $\text{NO}_3$  zeigten an, dass  $\text{NH}_4$  schneller durch Mikroorganismen umgesetzt wird als  $\text{NO}_3$ , möglicherweise führt dies zu einer besseren Retention von  $\text{NH}_4$  im Vergleich zu  $\text{NO}_3$ . Jedoch war dieser Prozess bei abiotischen Retentionsprozessen umgekehrt, welcher für  $\text{NO}_3$  höhere Umwandlung zum organischen N Pool zeigte als  $\text{NH}_4$ . Die verknüpften Ergebnisse zeigen, dass einige Waldböden in Amazonien höhere N-Verfügbarkeit als andere haben, was entscheidende Konsequenzen für den Kreislauf und Verluste des Bodenstickstoffs hat, wenn der vorhergesagte Anstieg anthropogener N Einträge stattfindet.

## 7. Summary

The significance of climate changes and of increasing N deposition to the interaction of both carbon and nitrogen cycles in tropical soils is still unknown and deserves more attention. For that, it is important to identify individual processes and their consequences to changes in the climate. In this study I evaluate soil CO<sub>2</sub> dynamics and N cycling in an old-growth forest of Caxiuanã, Eastern Amazonia. The study was divided in three parts: 1) measurement of soil CO<sub>2</sub> efflux and its environmental controls from two Oxisol sites with contrasting soil texture and at different landscape positions, 2) observation of how a throughfall exclusion (TFE) experiment affected soil CO<sub>2</sub> production in a deeply weathered sandy Oxisol of Caxiuanã, and 3) evaluation of the soil N status of two heavily weathered soils which contrast in texture (sand versus clay). Over the course of two years, soil CO<sub>2</sub> efflux and soil CO<sub>2</sub> concentrations, soil temperature and moisture in pits down to 3 m depth was measured. Using <sup>15</sup>N pool dilution, for both soils rates of N cycling (gross rates of N mineralization and nitrification) and N retention (microbial N immobilization, dissimilatory NO<sub>3</sub><sup>-</sup> reduction to NH<sub>4</sub><sup>+</sup>, and abiotic N immobilization) were quantified. To further support the N status assessment, the δ<sup>15</sup>N signals from the litter layer down the soil profile was measured, to get an overall measure of the degree of <sup>15</sup>N enrichment for each soil type.

The most important results are:

1) Average CO<sub>2</sub> efflux was 21 % higher for sand ( $3.93 \pm 0.06 \mu\text{mol CO}_2 \text{ m}^{-2}\text{s}^{-1}$ ) than for the clay ( $3.08 \pm 0.07 \mu\text{mol CO}_2 \text{ m}^{-2}\text{s}^{-1}$ ). No difference was detected for soil temperature between sites, while soil water content in sandy soil ( $23.2 \pm 0.33 \%$ ) was much lower than the clay soil ( $34.5 \pm 0.98 \%$ ), for the two-year period. Soil CO<sub>2</sub> efflux did not differ between dry and wet season, but I detected a significant interaction between season and topographic position. The variation caused by topography was in the same order of magnitude as temporal variation. Mean contribution of the litter layer to the CO<sub>2</sub> efflux rates was 20 % and varied from 25 %

during the wet season to close to 0 % during the dry season. The relation between soil water content and soil CO<sub>2</sub> efflux showed an optimum for both soil textures but the shape and optimum of the curves were different. The results of our study illustrate that soil moisture is an important driver of temporal variations in soil CO<sub>2</sub> efflux in this old-growth forest. When extrapolating soil CO<sub>2</sub> efflux to larger areas, a significant influences of soil texture, litter, and the interaction of topographical position and time illustrate that it is necessary to include some of the complexity of landscapes.

2) TFE reduced soil CO<sub>2</sub> efflux from  $4.3 \pm 0.1 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$  (control) to  $3.2 \pm 0.1 \mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$  (TFE). The contribution of the subsoil (below 0.5 m depth) to the total soil CO<sub>2</sub> production was higher in the TFE plot (28 %) compared to the control plot (17 %), and it did not differ between years. I distinguished three phases of drying after the TFE was started. The first phase was characterized by a translocation of water uptake (and accompanying root activity) to deeper layers and not enough water stress to affect microbial activity and/or total root respiration. During the second phase a reduction in total soil CO<sub>2</sub> efflux in the TFE plot was related to a reduction of soil- and litter decomposers activity. The third phase of drying, characterized by a continuing decrease in soil CO<sub>2</sub> production was dominated by a water stress-induced decrease in total root respiration. These results strongly contrast to results of a drought experiment on clay Oxisols which I explain with differences in water holding capacity and depth of rooting zone. I conclude that Amazonian forest ecosystems located on soils with coarse texture are more sensitive to drought than forests located on heavier textures because they cannot compensate the relatively low water holding capacity in the top soil with water stored in deeper soil layers.

3) The clay Oxisol had high gross rates of N mineralization, nitrification and <sup>15</sup>N enrichment factor and hence high potential for N losses. The sand Oxisol had low gross rates of N cycling and <sup>15</sup>N enrichment factor, and reacted more like a soil that is N-limited. Faster turnover rates

of  $\text{NH}_4^+$  compared to  $\text{NO}_3^-$  signified that  $\text{NH}_4^+$  cycles faster through microorganisms than  $\text{NO}_3^-$ , possibly contributing to better retention of  $\text{NH}_4^+$  than  $\text{NO}_3^-$ . However this was opposite to abiotic retention processes, which showed higher conversion of  $\text{NO}_3^-$  to the organic N pool than  $\text{NH}_4^+$ . The combined results suggest that some Amazonian forest soils have higher N availability than others which will have important consequences for soil N cycling and losses when projected increases in anthropogenic N deposition will occur.

## **Acknowledgements**

I want to thank God for the strength and perseverance He has put in my heart to achieve this goal in my life. I also want to thank my family, specially my husband, for their support and love in all times.

I am grateful to Dr. Michel Keller who trusted my work and presented me as a candidate to the PhD position offered by the University of Göttingen in the LBA project.

I would like to thank Prof. Dr. Edzo Veldkamp from the Institute of Soil Science and Forest Nutrition for supervising the thesis, for his support during the study and for his critical input during the development of the field work, data analysis and writing of the thesis.

I would also like to thank Dr. Luitgard Schwendenmann for her unconditional support and supervision in the field work, as well as during the analysis and discussion of the data.

In the same way I want to thank Dr. Marife Corre for her continuous support and supervision during the field and lab work, as well as during the analysis and writing of the thesis.

Many thanks to the Caxiuanã LBA-EU team, especially Prof. Antonio Carlos Lola da Costa for his constant support in field work, Dr. Patrick Meir for his encouragement, and Rafael Ferreira da Costa, Alan Pantoja and Joao Athayde for their companionship and helpful ideas and work force in difficult times.

I gratefully acknowledge the help of Dr Maria de Lourdes Ruivo, and the valuable work of Brenda Rocha Guimaraes, Rosiene Keila Paixao and Alessandro Rosario.

And finally I want to thank CNPq/DAAD for the financial support through the scholarship.

## Curriculum vitae

Eleneide Doff Sotta

Forest Engineer

born on the 28 May 1972 in Curitiba, Paraná, Brazil

- 1991 - 1995 Graduation in Forest Engineering - Federal University of Parana - UFPR, Curitiba, Paraná, Brazil.
- 1996 - 1998 Masters in Tropical Forest Science, National Research Institute of Amazon - INPA, Manaus, Amazonas, Brazil. CO<sub>2</sub> flux between soil and atmosphere in tropical rain forest of central Amazonia.
- 1999 - 2000 Researcher in Instituto do Homem e Meio Ambiente da Amazonia – IMAZON, in Belém, Pará, Brazil. Indicators for Sustainable Development in Eastern Amazon. Project coordination and execution.
- 2001 - 2002 Research Assistant in Institute of Soil Science and Forest Nutrition – IBW, University of Göttingen, Germany. Soil CO<sub>2</sub> dynamics in Eastern Amazon, Para, Brazil. Project execution.
- 2003 - 2006 PhD student in University of Göttingen, Germany. Soil CO<sub>2</sub> dynamics and N cycling in an Eastern Amazon Rainforest, Caxiuanã, Brazil.

Sotta ED, Corre M, Veldkamp E. (in preparation). Mechanisms of soil N retention in an Eastern Amazonian Rainforest, Caxiuanã, Brazil. Ecosystems

Sotta ED, Veldkamp E, Schwendenmann L, Guimarães BR, Paixão RK, Meir P, Ruivo MLP, da Costa ACL. (in preparation) Effects of an induced drought on the soil CO<sub>2</sub> production and soil CO<sub>2</sub> efflux in an Eastern Amazonian Rainforest, Brazil.

Sotta ED, Veldkamp E, Guimarães BR, Ruivo MLP, Almeida S. (in review) Landscape and climatic controls on spatial and temporal variation in soil CO<sub>2</sub> efflux in an Eastern Amazonian Rainforest, Caxiuanã, Brazil. Forest Ecology and Management.
