## 1 Introduction

### 1.1 General Characteristics of the Tertiary to Quarternary Italian Magmatic Rocks

The Italian volcanism is a classical area to study magmatic petrology and geochemistry (e.g. Washington 1906). However the petrogenesis of the Italian rocks is not fully understood, yet. A common feature of the Italian magmatic rocks is their high enrichment of K, which classify them as potassic and ultrapotassic rocks. Potassic and ultrapotassic rocks within continental plates are distributed throughout the world but are not very abundant (e.g. Foley et al. 1992, Peccerillo 1992, Wilson 1995). According to Foley et al. (1987) the ultrapotassic rocks can be subdivided into three subgroups: lamproites, kamafugites, and Roman Province Type rocks. Lamproites have high  $K_2O$  and low  $Al_2O_3$ ,  $Na_2O$  and  $CaO$  contents. They are slightly  $SiO_2$  oversaturated to undersaturated and mineralogically characterized by the absence of plagioclase. Kamafugites are strongly  $SiO_2$  undersaturated and typically contain kalsilite and melilite as sialic phases. The Roman type ultrapotassic rocks are also  $SiO_2$  undersaturated but contain high  $Al_2O_3$  and  $CaO$  contents. Plagioclase is in these rocks a common phase. Additionally Foley et al. (1987) distinguish a fourth group, which consists of transitional rocks between lamproites and Roman Province Type rocks. Within Italy rocks of all groups can be found (e.g. Peccerillo & Panza 1999). Additionally crustal anatectic rocks are common in central Italy (e.g. Innocenti et al. 1992). Consequently the Tertiary to Quarternary magmatism of Italy shows a great variability of different rock types.

The potassic and ultrapotassic rocks from Italy are highly enriched in LILE and LREE as well as in  $^{87}Sr$  and  $^{18}O$  and depleted in  $^{143}Nd$  and  $^{206}Pb$ . As summarized by Innocenti et al. (1992) and Peccerillo & Panza (1999) a northward increase in  $^{87}Sr$  and  $^{18}O$  and a depletion of  $^{143}Nd$  and  $^{206}Pb$  can be found. The overall geochemical composition of the igneous rocks is characterized by a crustal signature even for the least evolved rocks. The place of the interaction of mantle melts with crustal material is a matter of debate (Beccaluva et al. 1991, Ferrara et al. 1986b, Foley et al. 1992, Holm & Munksgaard 1982, Peccerillo & Panza 1999, Rogers et al. 1985, Scott Smith 1996, Shaw 1996, Taylor & Turi 1976, Turi & Taylor 1976): On the one hand the mantle source itself can be contaminated and on the other hand assimilation of crustal material during the uprise of mantle melts through the crust may be the reason for the uncommon signature of these rocks. These two possibilities have to be tested for every volcano or magmatic region. Additionally the influence of a hotspot in the genesis of the Italian rocks has been assumed (e.g. Vollmer 1989). Nevertheless a subduction related genesis of the Italian rocks is now commonly accepted (e.g. Peccerillo 1985, Wilson 1995).

## 1.2 Magmatic Provinces in Italy

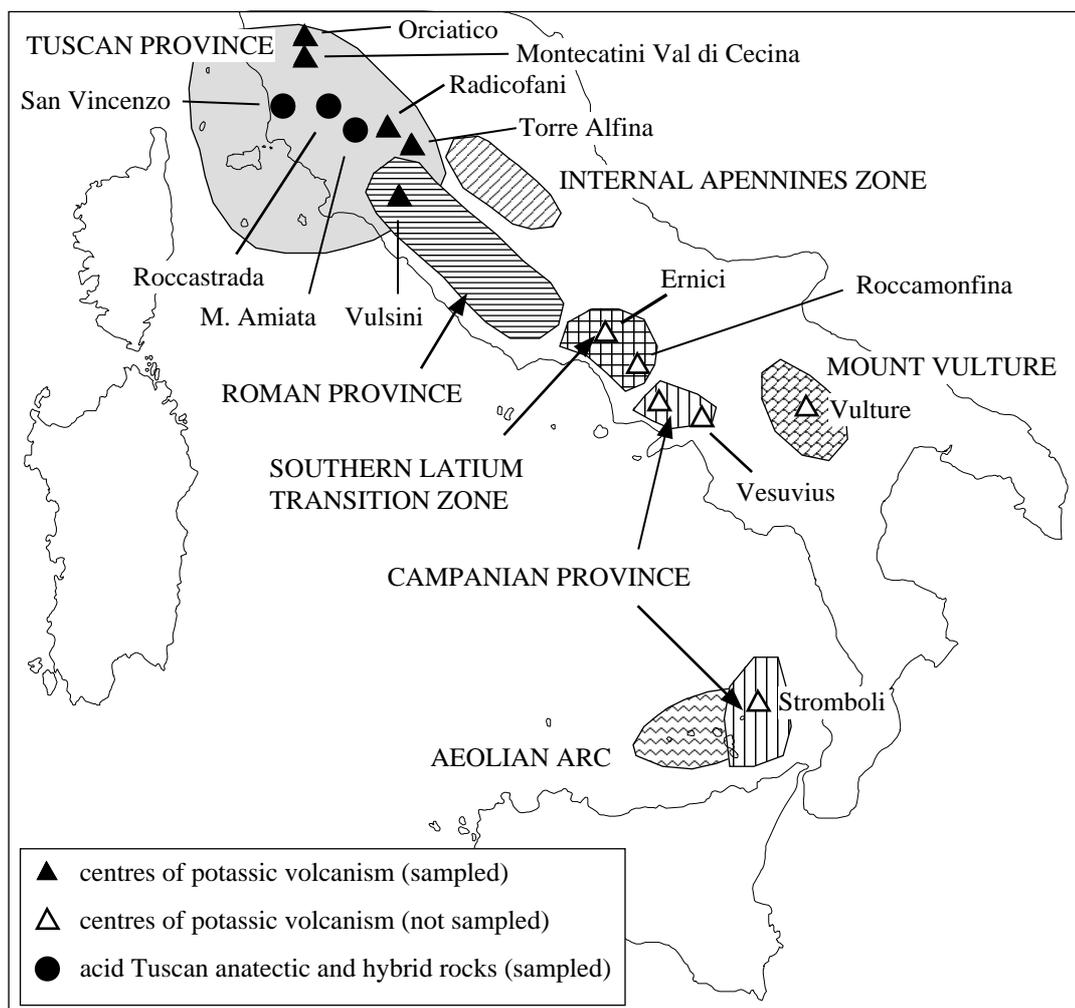

Fig. 1-1: Schematic map of the distribution of the major magmatic zones in central and southern Italy according to Peccerillo & Panza (1999). Additionally some localities, which are mentioned in this paper, are shown.

The magmatic rocks of the Italian peninsula have been subdivided into three magmatic provinces on the basis of their composition and geographical distribution. These provinces are the Tuscan, the Roman and the Campanian Magmatic Province. The Tuscan Province is characterized by frequently occurring crustal anatectic melts and by some lamproites. In contrast the Roman Province, stretching from southern Tuscany to northern Campania, and the Campanian Province are mainly built up by Roman Province type rocks. Additionally some kamafugites occur at the eastern part of the Roman Province. But this subdivision is somewhat arbitrary, because it does not consider the chemical differences within the Roman and Campanian Province. Therefore Peccerillo & Panza (1999) suggested a new subdivision into seven major zones according to the chemical and mineralogical composition of the rocks as well as on the basis of geophysical investigations. These major zones are the Tuscan Province, the Roman Province, the Campanian Province, the Southern Latium Transition

Zone, which is a transition zone between the Roman and the Campanian Province, the Internal Apennines Zone characterized by the occurrence of kamafugites, the Aeolian arc being north of the island of Sicily, and the Mount Vulture in southern Italy (fig. 1-1).

### 1.3 Overview of the Different Genetic Models

The most debated topic in the genesis of the investigated rocks is the composition of the mantle beneath the Roman and the Tuscan Magmatic Province and the degree of interaction between mantle derived melts with the crust.

Since the mid seventies it was broadly accepted, that the high enrichment of LILE, especially K, and the high  $^{87}\text{Sr} / ^{86}\text{Sr}$  ratios of the Roman Province type rocks indicate an enriched mantle source (e.g. Turi & Taylor 1976, Vollmer 1989). The process of enrichment appears to be a metasomatic mixing (Hawkesworth & Vollmer 1979) of a crustal component with mantle material. But the kind of metasomatism, the composition of the mantle source and the evolution of the mantle derived melts during the uprise through the crust is still a matter of debate.

Holm & Munksgaard (1982) postulated metasomatism of the primary mantle with a fluid enriched in LILE,  $^{87}\text{Sr}$  and  $^{18}\text{O}$ . During this metasomatism the mantle source got a heterogeneous composition. This heterogeneously composed mantle produced a large range of different primary melts with a range of  $\delta^{18}\text{O}$  values from 7.8 - 9.4 ‰ at 15.5 wt.% CaO of the bulk rock. During fractional crystallization the oxygen isotope ratios increase to 9.0 - 10.6 ‰ (at 3 wt.% CaO). Generally not more than 10 wt.% of crustal material were assimilated. This model was also supported by Rogers et al. (1985), who believed that the compositional range of the Vulsinian rocks can be produced by fractional crystallization of mantle melts and only minor crustal assimilation. They distinguished three different mantle melts, HKS (high potassic series) and KS (potassic series) rocks as well as leucite basanites. The mantle source is a metasomatized enriched MORB source with an oxygen isotopic composition of about 8 ‰.

In contrast to Holm & Munksgaard (1982), Ferrara et al. (1986b) and Turi et al. (1986) assumed, that mantle derived melts unaffected by crustal assimilation are only rarely found at the Vulsinian mountains or that these mantle melts do not occur. On the basis of a  $\delta^{18}\text{O}$  vs.  $^{87}\text{Sr} / ^{86}\text{Sr}$  diagram they showed, that the Vulsinian rocks lie on a mixing line between Alban hill rocks and Tuscan anatectic rocks or the Tuscan basement. The Alban hills, lying in the middle part of the Roman Province, represent the primary mantle melts, whereas the Vulsinian rocks are mixtures between primitive melts and crustal melts and suffered extensive crustal assimilation. Thus primitive melts from the Roman Province shall contain  $\delta^{18}\text{O}$  values

of 5.5 - 7.5 ‰ (Ferrara et al. 1986b) or 6.5 - 7.0 ‰ (Turi et al. 1986). Consequently the mantle source is not so highly enriched in  $^{18}\text{O}$  than Holm & Munksgaard (1982) presumed.

This two endmember model - Alban hill melts and Tuscan anatectic melts - of Ferrara et al. (1986b) and Turi et al. (1986) was modified by Varekamp & Kalamarides (1989). They suggested a four endmember model of the Vulsinian rocks. These endmembers are HKS leucitic melts, low K trachytic melts and assimilated crust, pelitic rocks and limestones. With these four endmembers the whole range of Sr isotope and bulk rock composition can be produced. In addition the large variability of the  $\delta^{18}\text{O}$  values is generated by the influence of hydrothermal water.

Conticelli et al. (1991) and Conticelli & Peccerillo (1992) demonstrated on the basis of mass balances including major and trace elements, that the less evolved rocks from the Vulsinian mountains represent primitive melts and are not influenced by crustal assimilation. Like Rogers et al. (1985), Conticelli et al. (1991) found three different mantle derived melts in the Vulsinian mountains. Typical HKS and KS rocks, which are generated in a fertile metasomatized mantle at different depths, and a HKS like melt, the latter one being produced from an upper slightly depleted mantle part with a rough similarity to the Tuscan mantle. These results were supported by Kamenetsky et al. (1995), who showed on melt inclusions within olivines, that the less evolved rocks from the Vulsinian mountains are indeed unaffected by crustal assimilation.

Generally the metasomatism of the mantle source is believed to be related to a subduction zone (e.g. Wilson 1995). However Vollmer (1989, 1990) favoured the influence of a hotspot beneath the Italian peninsular now lying below Pietre Nere, a small volcanic body in southern Italy. He believed that the Pietre Nere rocks are the mantle endmember and crustal material similar to the Tuscan basement is the other one. The mixing of these two endmembers can produce the variability of the mantle derived melts in central and southern Italy. This model was rejected by several authors like Kamenetsky et al. (1995), Conticelli & Peccerillo (1992), and Peccerillo (1990).

For the Tuscan mantle melts - lamproites from Orciatice and Montecatini Val di Cecina - only few papers are published. The Torre Alfina rocks can also be assigned to the lamproitic rocks. Originally the lamproites from Orciatice and Montecatini Val di Cecina were believed to belong to the Tuscan Anatectic Province and were produced from a granitic melt by filtration and gaseous transfer (Barberi & Innocenti 1967, Marinelli 1961). For the Torre Alfina rocks Ferrara et al. (1986b), Taylor & Sheppard (1986) and Turi et al. (1986) assumed on the basis of Sr and O isotopes and Sr and CaO contents of the bulk rock a genesis by mixing of Roman Province melts with crustal anatectic melts or basement rocks of the Tuscan Province. But Peccerillo (1994) and Peccerillo et al. (1988) presented strong evidence, that the lamproites

and the Torre Alfina rocks could not be produced by mixing of Roman type melts and crustal melts, because the concentrations of transitional metals are similar to a MORB source and the lamproites have high Mg values. A mixing of crustal and mantle melts should produce low Mg values and low contents of the transitional metals. Conticelli et al. (1992) and Conticelli (1998) additionally could show, that the lamproitic rocks contain Sr and Nd isotope ratios, which could not be generated by such a mixing. The Nd isotope ratios are lower than the ratios of the Roman Province rocks and the Tuscan anatectic melts or basement rocks. Therefore they explained the genesis of the lamproites by melting of a metasomatized harzburgitic mantle having different Sr and Nd isotopic composition compared to the Roman Province mantle. This was supported by the occurrence of residual phlogopite bearing peridotitic xenoliths in the Torre Alfina lavas (Conticelli & Peccerillo 1990) indicating a residual metasomatized mantle beneath Tuscany.

Transitional rocks from Tuscany like the rocks from Radicofani display an intermediate composition between Roman Province rocks and lamproites (Peccerillo et al. 1987). Originally they were believed to be a mixture between mantle melts from a metasomatically enriched mantle and a crustal melt (Poli et al. 1984). Ferrara et al. (1986b) suggested for the Radicofani rocks a Roman Province type melt as a mantle melt. The genesis of the Radicofani rocks could be modelled by mixing of Vulsinian melts and basement rocks of Tuscany on the basis of Sr isotopes and Sr contents (Ferrara et al. 1986b). But Peccerillo (1994) demonstrated, that the trace elements of the less evolved rocks could only be produced by a mixing of lamproitic and Roman Province melts.

Compared to the mantle melts of the Italian peninsular the crustal anatectic melts of the Tuscan Province have not been discussed controversially. The acidic igneous rocks are explained by partial melting of the basement (Taylor & Turi 1976). For the Roccastrada and San Vincenzo rhyolites Taylor & Turi (1976) assumed anatectic melting of pelitic metamorphic rocks. Giraud et al. (1986) support the genesis by partial melting of metapelitic rocks but they also showed, that the enrichment of LILE, like K, in the crustal melts could not be produced by partial melting. Thus a fluid overprinting of the crustal source must be involved (Giraud et al. 1986). Giraud et al. (1986) suggested a relation of this fluid with the enriched mantle part beneath Tuscany.

For the San Vincenzo rhyolites Ferrara et al. (1986a, 1989) distinguished two rock suites. The first rock suite represents pure crustal anatectic melts whereas the second suite is a mixture of mantle and crustal melts because of a large Sr isotope heterogeneity among the minerals (Ferrara et al. 1989). A melt mixing was also assumed by Innocenti et al. (1992) and Serri et al. (1993). Feldstein et al. (1994) developed a model of a layered magma chamber, where a mantle melt underlies a crustal anatectic melt producing a range from pure crustal melts to

mixtures between both melts. In addition Masuda & O'Neil (1994) found in a rhyolite from San Vincenzo a heterogeneity in the oxygen isotope composition of the phenocrystals also indicating a magma mixing.

Hybrid rocks of the Tuscan Province are mixtures between mantle and crustal melts (Peccerillo et al. 1987). For Monte Amiata it is commonly accepted, that the rocks represent a mixture between crustal anatectic and Roman Province mantle melts (e.g. Giraud et al. 1986, Poli et al. 1984, Peccerillo et al. 1987, Ferrari et al. 1996). Whether they belong to the K series (Peccerillo et al. 1987) or to the HK series (Poli et al. 1984, van Bergen 1985) is a matter of debate. Because of the Sr and Nd isotopic similarity between HKS and KS rocks the isotope ratios do not allow to distinguish between both mantle endmembers for the Monte Amiata rocks (Innocenti et al. 1992).

#### **1.4 Investigated Area and Petrogenetic Subdivision**

In southern Tuscany the Tuscan and the Roman Province overlaps. Therefore within a narrow area a large variability of different igneous rocks can be observed. An important aim of the understanding of the petrological situation of the Tertiary to Quaternary rocks is not only the genesis of the different genetic types but also the reason why the different genetic types occur in a narrow area.

Most of the different igneous rocks of the Italian peninsula are present in Tuscany and northern Latium (fig. 2-1). Ultrapotassic and potassic Roman Province type rocks with different degrees of SiO<sub>2</sub> saturation as well as lamproites and crustal anatectic melts can be observed. Furthermore the petrogenetic situation is complicated by the occurrence of mixtures between these rocks. Because of this large variability this investigation has been focussed on central Italy.

According to Peccerillo et al. (1987) five different genetic types can be distinguished in Tuscany and northern Latium:

1. Roman Province type rocks only occur in the Roman Province and are not typical rocks of the Tuscan Province. The Roman Province type rocks itself are subdivided into two groups (Civetta et al. 1981). The two groups differ in their K enrichment. The high potassic series (HKS) rocks are SiO<sub>2</sub> undersaturated and highly enriched in K. In contrast the rocks of the potassic series (KS) are SiO<sub>2</sub> saturated and contain less K at the same SiO<sub>2</sub> content compared to the HKS rocks.
2. Mantle melts are rarely found in Tuscany and only occur at Orciatico and Montecatini Val di Cecina. These rocks are lamproites.

3. Contrary to the mantle melts crustal anatectic melts frequently occur in the Tuscan Province both as plutonic and as volcanic rocks.

These three genetic types represent endmembers in the investigated region. Between these endmembers mixtures can be observed.

4. Between both mantle derived melts from the Tuscan Province and the Roman Province mixtures occur in the southern Tuscan Province. This kind of rocks are named as transitional rocks.
5. Additionally mixtures between mantle derived and crustal anatectic melts can also be found in the Tuscan and the northern Roman Province. These rocks display a high variability of composition and are classified as hybrid rocks.

The petrogenesis of these five genetic rock types is the subject of this paper, especially in the light of UV laser ablation mineral  $\delta^{18}\text{O}$  data.

## 1.5 Oxygen Isotopes

In nature three oxygen isotopes occur:  $^{16}\text{O}$ ,  $^{17}\text{O}$  and  $^{18}\text{O}$ , which can be fractionated from each other by e.g. mineral reactions, crystallization of minerals from a liquid or isotope exchange reactions between minerals and fluids. The degree of fractionation mainly depends on the oxygen isotope composition of the involved phases and on the temperature. Because of the higher fractionation between  $^{18}\text{O}$  and  $^{16}\text{O}$  and the low abundance of  $^{17}\text{O}$ , the  $^{18}\text{O} / ^{16}\text{O}$  ratio is commonly used for investigations. The high abundance of oxygen in nature facilitates the use of oxygen isotopes as a tool to investigate geological and petrological processes.

Generally  $^{18}\text{O} / ^{16}\text{O}$  ratios are measured, which are referred to a standard. For igneous systems this standard is Standard Mean Ocean Water (SMOW). Thus the notation for oxygen isotopes is:

$$\delta^{18}\text{O} = \left[ \frac{\left(\frac{^{18}\text{O}}{^{16}\text{O}}\right)_{\text{sample}} - \left(\frac{^{18}\text{O}}{^{16}\text{O}}\right)_{\text{standard}}}{\left(\frac{^{18}\text{O}}{^{16}\text{O}}\right)_{\text{standard}}} \right] \cdot 1000 \quad [\text{‰}]$$

Large areas of the upper mantle are homogeneous with respect to the oxygen isotope composition. For example mid ocean ridge basalts show a narrow range of  $\delta^{18}\text{O}$  values of about  $5.7 \pm 0.2 \text{ ‰}$  (Harmon & Hoefs 1995, Hoefs 1997). For the upper mantle a composition

of about  $5.4 \pm 0.2$  ‰ for olivines,  $5.9 \pm 0.1$  ‰ for orthopyroxenes, and  $5.7 \pm 0.2$  ‰ for clinopyroxenes is assumed (Hoefs 1997).

The primary isotopic composition of mantle melts can be modified by contamination processes either of the source itself or during the uprise of the magma through the crust. Contamination within the crust is caused by assimilation of crustal material or by alteration with fluids. Fractional crystallization changes the isotopic composition only minor resulting in a shift to higher values with a maximum shift of about  $+1.2$  ‰ for a rock suite from mafic to acidic rocks (Holm & Munksgaard 1982).

In order to deduce the primary oxygen isotope composition of mantle melts, the rocks should not be influenced by secondary processes like weathering or hydrothermal reactions. These secondary processes cause a H<sub>2</sub>O enrichment of the rocks combined with a change of the  $\delta^{18}\text{O}$  values. Taylor et al. (1984) and Ferrara et al. (1985, 1986b) proposed, that the  $\delta^{18}\text{O}$  values of the altered rocks can be calculated back to primary values using the present H<sub>2</sub>O content of the rock and the primary H<sub>2</sub>O content of the magma. The primary H<sub>2</sub>O content is believed to be lower than 0.5 wt.% for mantle derived melts (Ferrara et al. 1985, 1986, Taylor et al. 1984). However, if the mantle source itself is modified fluids or melts, the magmas can contain higher H<sub>2</sub>O contents. Therefore a change of the  $\delta^{18}\text{O}$  values by processes within the continental crust can not be computed back to original values. Furthermore the groundmass or late crystallizing phases like plagioclase or sanidine are often secondarily influenced and are therefore in disequilibrium to the first crystallizing clinopyroxenes or olivines (see also chapter 4). But this change of the  $\delta^{18}\text{O}$  values of the feldspars is not significantly correlated to the H<sub>2</sub>O content of the bulk rock. Thus bulk rock analysis must not reflect the original oxygen isotopic composition of the bulk rock, even if the H<sub>2</sub>O content of the bulk rock is taken into account.

A method to circumvent this problem is to measure the oxygen isotope composition of phenocrystals in the rock. The first crystallizing minerals may give the best estimate of the original  $\delta^{18}\text{O}$  composition of the melt. Furthermore possible isotopic heterogeneities can be shown. Therefore the study of phenocrystals may give better results with respect to the primary composition and the evolution history of the melt. For example some rocks contain phenocrystals being in isotopic disequilibrium with each other. This may indicate a mixing of different melts.

A laser ablation system for oxygen isotope analysis has the advantage that single minerals can be measured. Additionally using a high energy UV laser facilitates the in situ measurement, so that possible heterogeneities within a mineral or rock section can be shown. The new UV laser ablation method developed in Göttingen (Fiebig et al. 1999, Wiechert & Hoefs 1995) has thus been applied to the volcanic rocks of the various magmatic provinces in central Italy.

## 2 Sample Description

### 2.1 Sampling

In order to analyze oxygen isotopes of phenocrystals only porphyric rocks were sampled. From every genetic type rocks have been investigated (Tab. 2-1).

Roman Province rocks are represented by rocks from the Vulsinian mountains. Both HKS and KS rocks were sampled. Mantle derived rocks from the Tuscan Province occurring as lamproites have been taken from Orciatico and Montecatini Val di Cecina. As representatives of the crustal anatectic rocks rhyolites from Roccastrada and San Vincenzo have been analyzed. Transitional rocks between the Tuscan and the Roman Province mantle melts have been sampled at Torre Alfina and Radicofani. Samples from the Monte Amiata represent mixtures between mantle and crustal melts.

*Tab. 2-1: Localities, sampled rocks and assignment to the genetic types according to Peccerillo et al. (1987). (1): Rhyolites from San Vincenzo have a prevailing crustal anatectic origin. (2): For the classification of the Torre Alfina rocks also see chapter 2.3. (3): The sample Montefiascone has kindly been put at disposal by Prof. Peccerillo (University of Perugia). Montefiascone is a volcano of the Vulsinian mountains.*

Locality (Abbreviation)	Rocks	Type of Genesis
Monti Vulsini (VUL, Montefiascone (3))	potassic trachybasalts to phonolites shoshonites	Roman Province Type high potassic series (HKS)  potassic series
Orciatico (ORC)	lamproites	Tuscan Province mantle melts
Montecatini Val di Cecina (MVC)	lamproites	Tuscan Province mantle melts
Roccastrada (ROC)	rhyolites	Tuscan Province anatectic melts
San Vincenzo (SVC)	rhyolites	Tuscan Province anatectic melts (1)
Torre Alfina (TA)	transitional rocks (2)	transitional rocks between Tuscan and Roman melts
Radicofani (RAD)	basaltic andesites	Transitional rocks between Tuscan and Roman melts
Monte Amiata (AMT)	shoshonites to trachytes	Hybrid rocks between mantle and crustal melts

## 2.2 Geological and Petrographical Description of the Samples

The geographic position and the petrological classification of the rocks are listed in tabular form in the appendix. The spatial distribution of the different genetic rock types is shown in fig. 2-1.

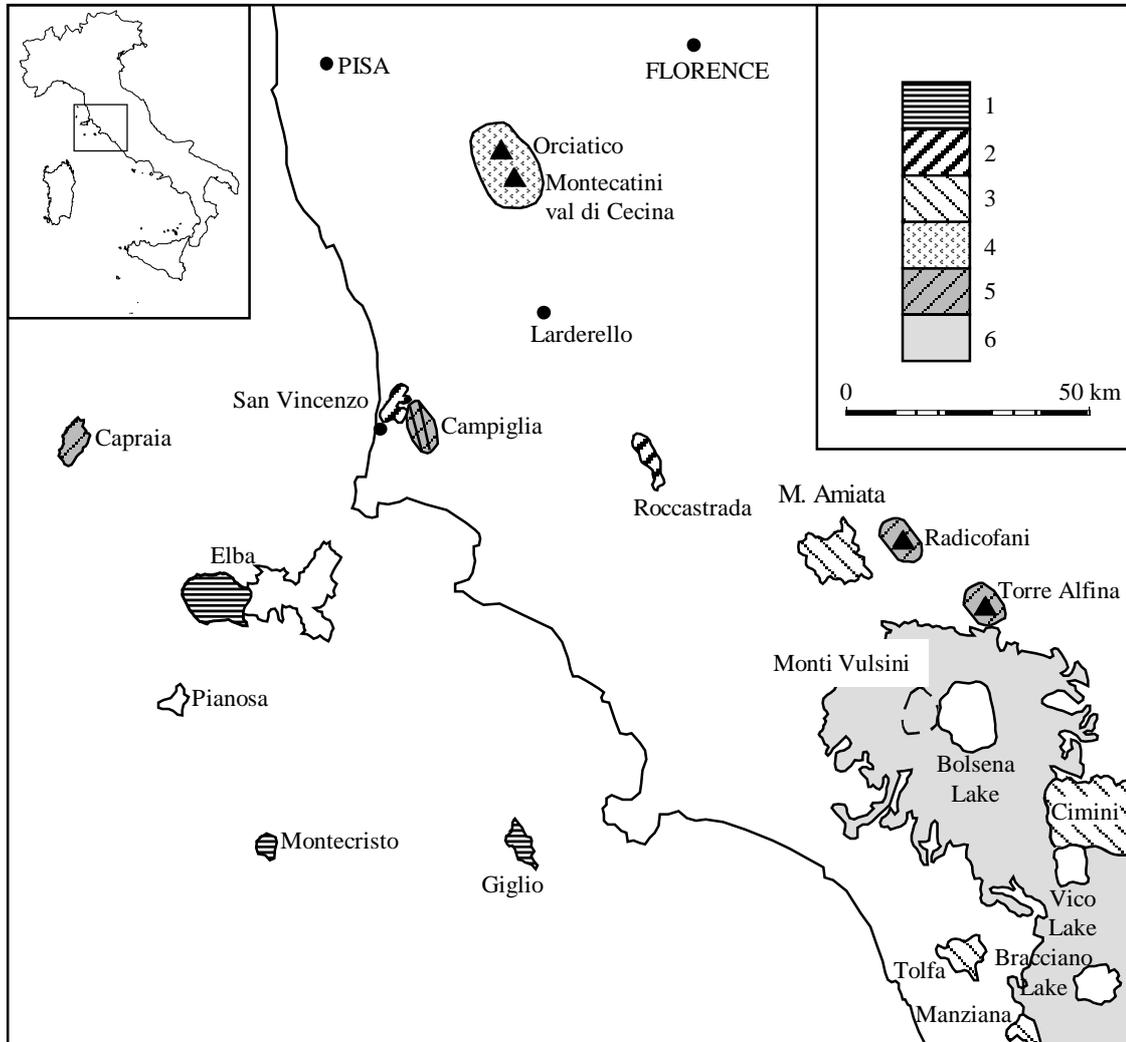

Fig. 2-1: Schematic map of the Tertiary to Quarternary volcanism in southern Tuscany and northern Latium (modified after Peccerillo et al. 1987). Genetic types: 1) Acidic plutonic rocks of prevailing anatectic origin; 2) acidic volcanic rocks of prevailing crustal anatectic origin; 3) Hybrid rocks between crustal and mantle melts; 4) Lamproites; 5) Transitional rocks between lamproites and Roman Province type rocks; 6) Roman Province type rocks.

### 2.2.1 Monti Vulsini - Roman Province Type Rocks

The Vulsinian Volcanic District is the northern part of the Roman Magmatic Province. It lies on the western slope of the central Apennines around the lake Bolsena and spreads over an area of about 2280 km<sup>2</sup>, so that it is the largest volcanic system of the Roman Magmatic

Province. The district is built up by over 100 volcanoes and can be subdivided into four domains: the Latera Volcanic Complex in the western part, the Bolsena-Orvieto Volcanic Complex in the eastern part, the Montefiascone Volcanic Complex in the southeastern part and the Southern Vulsini Zone (Vezzoli et al. 1987). The region is characterized by calderas, cinder cones, pyroclastic layers, ignimbrites, and lava flows. The geology and petrology of the Vulsinian mountains is extensively described by Innocenti & Trigila (1987) and Varekamp (1979).

Both high potassic rocks as well as potassic rocks occur at the Vulsinian mountains. Major phases of the HKS rocks are olivine, clinopyroxene, and plagioclase and, additionally leucite in the more evolved rocks. The KS rocks consist of olivines, clinopyroxenes, and plagioclases. From the HK series less evolved rocks, potassic trachybasalts, to highly evolved phonolites have been sampled as well as tephriphonolites and phonotephrites. Also less evolved rocks, shoshonites, from the K series could be sampled from one lava flow.

### **2.2.2 Orciatico and Montecatini Val di Cecina - Lamproites**

Mantle melts of the Tuscan Magmatic Province crop out near Orciatico and Montecatini Val di Cecina both lying in the northern part of Tuscany. The magmas from both localities intruded as subvolcanic bodies in shallow level Pliocene argillaceous sediments (Peccerillo et al. 1988) and are located on the western edge of the Val d'Era graben (Conticelli et al. 1992). The outcrops are small with an area of less than 0.6 km<sup>2</sup> for each locality. Their emplacement was influenced by NNW-SSE trending faults, which are related to a post-tectonic extensional regime (Conticelli et al. 1992).

Rocks from both localities are petrographically classified as diopside sanidine phlogopite lamproites according to the classification scheme of Woolley et al. (1996) and Foley et al. (1987); following the older scheme of Sahama (1974) these rocks are orendites. Major phases are phenocrysts of olivines, diopsides, and phlogopites in a groundmass consisting of additional sanidines. Generally the phenocrysts are small.

The magmatic body of Orciatico displays a rough chemical homogeneity. A late-stage hydrothermal metamorphism has been recognized, which affected the Sr-isotopes of the country rock but without an influence of the Sr-isotopes of the magmatic body (Ferrara et al. 1988). In contrast to the rocks from Orciatico three different petrographic facies can be distinguished in the Montecatini magmatic body; a marginal facies in contact to the thermally metamorphosed country rock, a massive crystalline facies and a massive crystalline facies in contact to unmetamorphosed country rock (Conticelli et al. 1992). The groundmass of the Montecatini lamproites are fine grained and disintegrate easily.

The localities are described in detail by Barberi & Innocenti (1967), Conticelli et al. (1992) and Rodolcio (1934).

### **2.2.3 Roccastrada - Rhyolites**

The Roccastrada volcanic centre represents crustal melts of the Tuscan Province and is composed of lava flows, ignimbrites, and one lava dome. It is placed in the Grosseto province, where acidic volcanic rocks form isolated outcrops stretching over 30 km<sup>2</sup> (Giraud et al. 1986, Taylor & Turi 1976). The magmas were erupted from fractures trending in an Apennine direction (Peccerillo et al. 1987).

The rocks from Roccastrada are rhyolites with plagioclase, sanidine, quartz, and biotite as major phenocrystalline phases and have a vitreous or microcrystalline groundmass.

### **2.2.4 San Vincenzo - Rhyolites**

San Vincenzo is the second locality, where crustal anatectic rocks have been sampled. The volcanic centre covers an area of about 10 km<sup>2</sup> and is built up by lava flows and a highly altered volcanic unit (Feldstein et al. 1994). Petrologically these rocks are rhyolites with relatively low SiO<sub>2</sub> contents, so that they were sometimes classified as rhyodacites (Peccerillo et al. 1987).

After Ferrara et al. (1989) the San Vincenzo rhyolites can be subdivided into two groups according to their MgO content. Group A contains less than 0.61 wt.% MgO and group B more than 0.75 wt.%. Both groups also have different Sr concentrations with less than 140 ppm for group A and more than 200 ppm for group B. Group A rhyolites are characterized by plagioclase, sanidine, quartz, biotite, and cordierite assemblages. In contrast group B rhyolites additionally contain sometimes clinopyroxenes, orthopyroxenes, and mafic magmatic inclusions (Ferrara et al. 1989).

### **2.2.5 Torre Alfina - Transitional Rocks Between Tuscan and Roman Mantle Melts**

The Torre Alfina volcano consists of a few lava flows erupted from a small volcanic centre and a small neck cropping out north of the village of Torre Alfina (Conticelli 1998) with a close spatial relation to the Vulsinian mountains. The eruptions were coeval with the nearby Radicofani volcano (Conticelli 1998). The volcano is placed on the sedimentary basement consisting of carbonaceous and argillaceous rocks (Conticelli 1998).

Petrographically the Torre Alfina rocks can be subdivided into two groups (Conticelli & Peccerillo 1990). Type A lavas are aphyric to slightly prophyric with olivine as the only phenocrystalline phase and a groundmass consisting of microphenocrystals of olivine, phlogopite, clinopyroxene, and sanidine (Conticelli 1998, Conticelli & Peccerillo 1990).

Often ultramafic xenoliths can be found in the type A lavas (Conticelli & Peccerillo 1990). In contrast type B lavas are porphyric with olivine as single phenocrystalline phase and xenocrystals of plagioclase, biotite, cordierite, orthopyroxene, and quartz and large amounts of crustal xenoliths (Conticelli 1998, Conticelli & Peccerillo 1990). The groundmass is comparable to the type A lavas but the micas are strongly oxidized (Conticelli 1998, Conticelli & Peccerillo 1990).

The geology and petrology of the Torre Alfina volcano is described in detail by Conticelli (1998) and Conticelli & Peccerillo (1990).

### **2.2.6 Radicofani - Transitional Rocks Between Tuscan and Roman Mantle Melts**

The Radicofani volcano consists of a few remnants of thin lava flows and a small (~ 100 m elevation) heavily weathered neck surrounded by Pliocene clay rich sediments (Innocenti 1967, Poli et al. 1984). It lies at the eastern edge of the Siena-Radicofani graben opposite to the Monte Amiata (Ferrari et al. 1996). Petrographically the rocks range from trachybasalts to latites and trachytes (Innocenti 1967). The rocks can be assigned to the shoshonitic association (Poli et al. 1984). Major phenocrystals are olivines, clinopyroxenes and plagioclases (Innocenti 1967, Poli et al. 1984). The petrography is described in detail by Innocenti (1967).

From this volcano less evolved rocks, basaltic andesites, have been sampled.

### **2.2.7 Monte Amiata - Hybrid Rocks Between Mantle and Crustal Melts**

The Monte Amiata volcano is one of the largest volcanoes in southern Tuscany (van Bergen 1984). It covers an area of about 85 km<sup>2</sup> with up to 1000 m thick volcanic products and is built up by lava flows and domes (van Bergen 1984). The volcano is located at the western edge of the Siena-Radicofani graben (Ferrari et al. 1996). According to the geochemical composition and age these rocks can be subdivided into three groups: 1) an early basal trachydacitic complex, 2) trachydacitic to trachytic and latitic domes and lava flows and 3) final ultrapotassic latite lava flows (Ferrari et al. 1996). In the volcanic rocks mafic inclusions as well as crustal xenoliths are embedded (e.g.: van Bergen 1984, van Bergen & Barton 1984, Ferrari et al. 1996). The petrography of the rocks - trachytic and mafic rocks as well as xenoliths - indicate two source components. On the one side mafic subcrustal melts and on the other side crustal anatectic melts (e.g. van Bergen et al. 1983, Poli et al. 1984). Therefore the rocks are classified as hybrid rocks between crustal and mantle melts.

From this volcano acidic and mafic rocks were sampled: two trachytes from the basis and the top of the volcano and two latites from a final stage lava flow. Additionally two xenoliths from a trachyte could be analyzed, a latitic and a shoshonitic xenolith.

## 2.3 Classification of the Investigated Rocks

The investigated rocks have been classified using their chemical and normative composition. According to the subdivision of Le Bas et al. (1986) all rocks are potassic ones with a ratio of  $K_2O / Na_2O$  greater than 1. From the potassic rocks ultrapotassic rocks can be separated but the definition of ultrapotassic rocks is still a matter of debate (Carmichael et al. 1974, Foley et al. 1987, Peccerillo 1992). In this paper the term ultrapotassic is used for rocks with the chemical criteria given by Foley et al. (1987):  $K_2O / Na_2O > 2$ ,  $K_2O > 3$  wt.% as well as  $MgO > 3$  wt.% in order to restrict to mafic rocks.

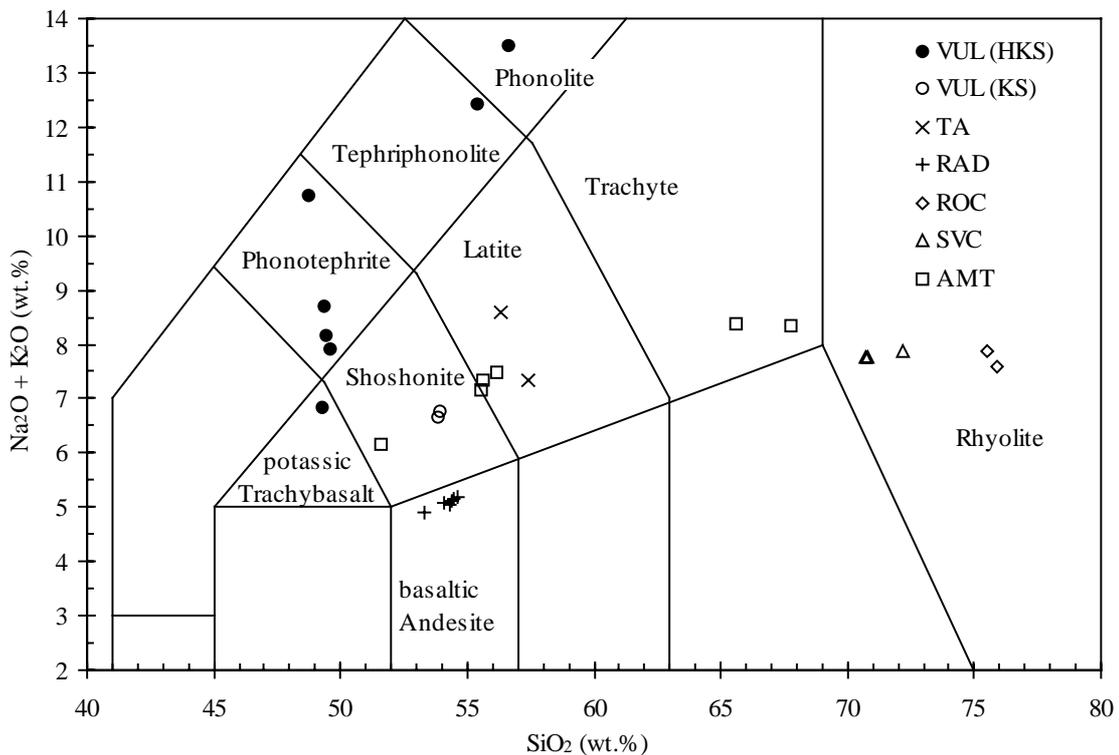

Fig. 2-2: Total alkali-silica diagram for the classification of the rocks according to Le Bas et al. (1986), VUL (HKS): Monti Vulsini, high potassic series, VUL (KS): Monti Vulsini, potassic series, TA: Torre Alfina, RAD: Radicofani, ROC: Roccastrada, SVC: San Vincenzo, AMT: Monte Amiata.

Ultrapotassic rocks occur at Monti Vulsini, Orciatico, Montecatini Val di Cecina, Monte Amiata, and Torre Alfina. These rocks belong to two different types of ultrapotassic rocks. According to Foley et al. (1987) the rocks from Monti Vulsini and Monte Amiata are members of the Roman Province Type. Woolley et al. (1996) suggest the classification of these rocks by either the QAPF diagram (Streckeisen 1979) or the total alkali-silica diagram (Le Bas et al. 1986). The rocks from Orciatico and Montecatini Val di Cecina are lamproites according to the classification schemes of Foley et al. (1987). Their mineralogical composition - major phases are sanidines, olivines, clinopyroxenes, and phlogopites combined

with the lack of plagioclases - is a typical mineral assemblage for lamproites (Mitchell & Bergman 1991, Woolley et al. 1996).

Figure 2-2 shows the classification scheme of Le Bas et al. (1986) for the rocks from Monti Vulsini, San Vincenzo, Roccastrada, Monte Amiata, Radicofani, and Torre Alfina. The rocks of HK series from the Vulsinian mountains are potassic trachybasalts, phonotephrites, tephriphonolites, and phonolites. The K series rocks have lower alkali contents at the same  $\text{SiO}_2$  content and are shoshonites. From San Vincenzo and Roccastrada, rhyolites have been sampled. The rocks of Monte Amiata include a wide range of compositions from shoshonites to latites, and trachytes. The sampled rocks from Radicofani are very similar in their chemical composition and petrographically are basaltic andesites.

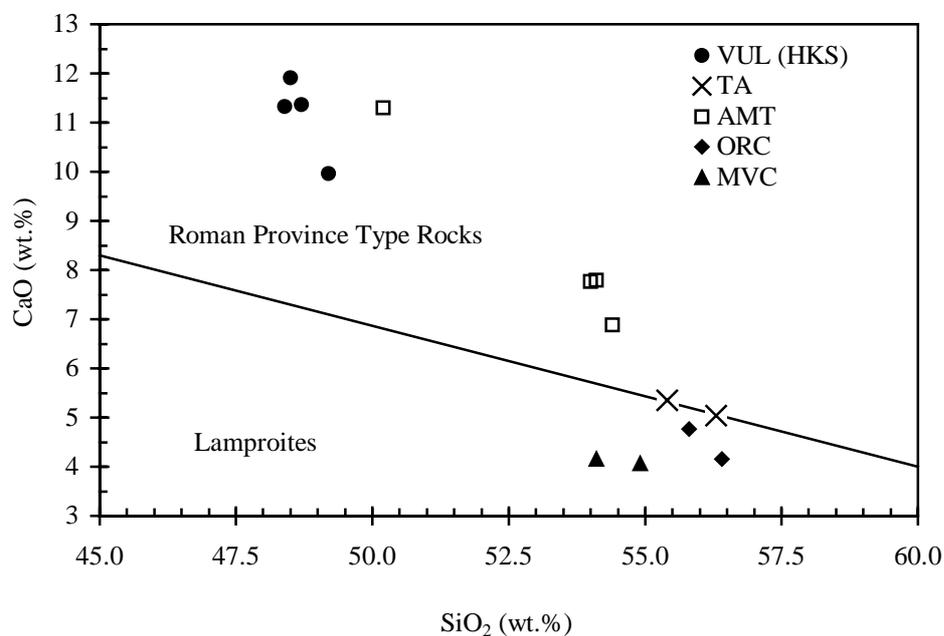

Fig. 2-3: Subdivision of ultrapotassic rocks in a CaO vs.  $\text{SiO}_2$  diagram according to Foley et al. (1987). VUL (HKS): Monti Vulsini, high potassic series, TA: Torre Alfina, AMT: Monte Amiata, ORC: Orciatico, MVC: Montecatini Val di Cecina.

In fig. 2-3 one possible subdivision of the ultrapotassic rocks is shown on the basis of their CaO vs.  $\text{SiO}_2$  contents (Foley et al. 1987). The rocks from Orciatico and Montecatini Val di Cecina are composed of diopside, sanidine, and phlogopite. Therefore they are classified as diopside sanidine phlogopite lamproites according to Mitchell & Bergman (1991); following the older scheme of Sahama (1974) these rocks are orendites. The rocks from Torre Alfina are a special case. They can be classified as latites according to Le Bas et al. (1986) and Woolley et al. (1996), but their chemical composition is intermediate between lamproites and Roman Province Type rocks (fig. 4-2). Thus Foley et al. (1987) suggest, that these rocks should be

classified as "transitional rocks" between both ultrapotassic types. The Torre Alfina rocks thus will be named transitional rocks in the following discussion.

## **3 Analytical Methods**

### **3.1 Sample Preparation**

One part of each sample was powdered for chemical bulk rock analysis. From the other part thin sections for microscopy and thick sections (about 0.6 - 1 mm) for chemical mineral investigations (electron microprobe and LA-ICP-MS) were prepared. Furthermore thick sections for oxygen isotope ratio analysis have been prepared. Additionally some samples were crushed and the phenocrystals were separated optically or separated by their densities for single grain analysis of oxygen isotope ratios.

### **3.2 Bulk Rocks Analysis**

For bulk rock analysis international reference material (JA-2, JB-3, JR-2; Ando et al. 1989) were analyzed to control the quality of the analytical results.

#### **3.2.1 X-ray Fluorescence Analysis (XFA)**

Major elements (Si, Ti, Al, Fe, Mn, Mg, Ca, Na, K and P) and selected trace elements (Ba, Co, Cr, Ga, Nb, Ni, Pb, Rb, Sc, Sr, V, Y, Zn, Zr) were measured with a XFA (Philips PW 1480 automated sequential spectrometer). For analysis the sample powder was melted with Li-borate to glass disks. The detection limit for most trace elements is 5 ppm except for Ba, Ni, Pb, and Zr with 10 ppm. The relative error of the measurement is < 2 % for SiO<sub>2</sub>, TiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>, Fe<sub>2</sub>O<sub>3</sub>, MnO, MgO, CaO, and K<sub>2</sub>O, < 7 % for Na<sub>2</sub>O and P<sub>2</sub>O<sub>5</sub>, and < 10 % for the trace elements. The method with the analytical setup of the XFA is described by Hartmann (1994).

#### **3.2.2 C and S Analysis by Infrared Absorption Spectroscopy**

C and S were analyzed by infrared detection (ELTRA Metalyt CS 100 / 1000 RF). The rock powder is mixed with Fe and W and then inductively heated up to 1600 °C in an oxygen stream. The released oxidized C and S is finally measured by infrared absorption. Analytical precision (1s) is better than 14 % for S and better than 10 % for C.

#### **3.2.3 H<sub>2</sub>O Analysis by the Method of Karl Fischer**

H<sub>2</sub>O of the samples were measured with the method after Karl Fischer (Scholz 1984) with a Karl Fischer device from Metrohm Herisau Inc.. The relatively error (1s) is better than 10 %.

### 3.2.4 FeO Analysis

The FeO content of the bulk rock were titrimetrically measured by the method of Pratt (1894) with an analytical precision better than 4 %.

### 3.2.5 Inductively Coupled Plasma - Mass Spectrometry (ICP-MS)

Additional trace elements ( $^7\text{Li}$ ,  $^{45}\text{Sc}$ ,  $^{59}\text{Co}$ ,  $^{60}\text{Ni}$ ,  $^{63}\text{Cu}$ ,  $^{120}\text{Sn}$ ,  $^{121}\text{Sb}$ ,  $^{133}\text{Cs}$ ,  $^{139}\text{La}$ ,  $^{140}\text{Ce}$ ,  $^{141}\text{Pr}$ ,  $^{146}\text{Nd}$ ,  $^{147}\text{Sm}$ ,  $^{151}\text{Eu}$ ,  $^{157}\text{Gd}$ ,  $^{159}\text{Tb}$ ,  $^{163}\text{Dy}$ ,  $^{165}\text{Ho}$ ,  $^{166}\text{Er}$ ,  $^{169}\text{Tm}$ ,  $^{172}\text{Yb}$ ,  $^{175}\text{Lu}$ ,  $^{176}\text{Hf}$ ,  $^{181}\text{Ta}$ ,  $^{205}\text{Tl}$ ,  $^{208}\text{Pb}$ ,  $^{209}\text{Bi}$ ,  $^{232}\text{Th}$ ,  $^{238}\text{U}$ ) were measured with an ICP-MS (Fisons VG PlasmaQuad PQ 2+). For this analysis the rock powder (ca. 100 mg) was dissolved in 3 ml  $\text{HClO}_4$  and 6 ml HF at 180 °C (10 h) under pressure. The method of acid dissolution is described by Heinrichs & Hermann (1990). The relative errors (1s) of the analyses are  $\leq 30\%$  for Sn,  $\leq 20\%$  for Co, Ni, and Sb,  $\leq 15\%$  for Hf and Pb and  $\leq 10\%$  for the other trace elements. Internal reference elements were In and Re.

## 3.3 Analysis of the Mineral Chemistry

From every genetic rock type representative samples were prepared for the analysis of the chemical composition of the minerals.

### 3.3.1 Electron Microprobe Analysis (EMPA)

For EMPA analysis thick sections (0.5 - 1 mm) were used. On these thick sections the trace element chemistry were also analyzed by LA-ICP-MS.

The analyses were carried out on a JEOL JXA 8900 R electron microprobe using the correction methods of Armstrong (1991).

For major element composition of the minerals Si, Ti, Al, Fe, Mn, Mg, Ca, Ba, Na, and K were analyzed at 15 kV acceleration voltage, 12 nA probe current and a defocussed beam with a diameter of 5  $\mu\text{m}$ . In addition some rock samples have been analyzed for major REE containing phases especially feldspars and phosphates. For this Si, Al, Fe, Ti, Mg, Ca, Na, K, P, La, Ce, Pr, and Nd were measured at 20 kV acceleration voltage, 12 nA probe current and a focussed electron beam. Fe is always expressed as total FeO.

The detection limit can be estimated by three times standard deviation of the background plus the background in counts per second (Reed 1996, Scott et al. 1995). It depends on the composition of the minerals but can generally estimated with 3000 ppm for  $\text{SiO}_2$ , 1200 ppm for  $\text{TiO}_2$ , 1800 ppm for  $\text{Al}_2\text{O}_3$ , 1600 ppm for FeO, 1400 ppm for MgO, 500 ppm for CaO, 300 ppm for MnO, 270 ppm for BaO, 1600 ppm for  $\text{Cr}_2\text{O}_3$ , 600 ppm for  $\text{Na}_2\text{O}$  and 450 ppm for  $\text{K}_2\text{O}$  for the major element analyses. For the REE investigation of the apatites the

detection limits are about: SiO<sub>2</sub> 7600 ppm, TiO<sub>2</sub> 1470 ppm, Al<sub>2</sub>O<sub>3</sub> 950 ppm, FeO 620 ppm, MgO 530 ppm, CaO 290 ppm, Na<sub>2</sub>O 1450 ppm, K<sub>2</sub>O 230 ppm, P<sub>2</sub>O<sub>5</sub> 2.44 wt.%, La<sub>2</sub>O<sub>3</sub> 580 ppm, Ce<sub>2</sub>O<sub>3</sub> 700 ppm, Pr<sub>2</sub>O<sub>3</sub> 1200 ppm, Nd<sub>2</sub>O<sub>3</sub> 780 ppm. Generally the reproducibility of the measurements is better than 4 %. But element concentrations near the detection limit can have higher errors.

### **3.3.2 Laser Ablation - Inductively Coupled Plasma - Mass Spectrometry (LA-ICP-MS)**

The trace element composition of the phenocrystals were analyzed by a LA-ICP-MS (Fisons VG Plasmaquad PQ 2) with a 266 nm Nd:YAG laser (VG-UV-Microprobe). The trace elements <sup>52</sup>Cr, <sup>60</sup>Ni, <sup>85</sup>Rb, <sup>88</sup>Sr, <sup>137</sup>Ba, <sup>139</sup>La, <sup>140</sup>Ce, <sup>141</sup>Pr, <sup>143</sup>Nd, <sup>147</sup>Sm, <sup>151</sup>Eu, <sup>157</sup>Gd, <sup>163</sup>Dy, and <sup>172</sup>Yb were measured. <sup>29</sup>Si was used as internal reference element. The system was calibrated with NIST SRM 610 and NIST SRM 612 glass disks (Pearce et al. 1997); the glass references were regularly measured for a drift correction - every third to eighth analysis was an analysis of the glass reference material. The detection of the isotopes by the mass spectrometer was carried out in a time resolved modus, so that heterogeneities within a mineral like inclusions could be recognized. The acquisition time was 100 s with a laser repetition rate of 10 Hz and a pit size of 100 µm. Analytical precision (1s) is ≤ 30 % for Cr, Ni, Sm, Gd, Dy, and Yb and ≤ 25 % for Rb, Sr, La, Ce, Pr, Nd, and Eu. The method is described by Simon et al. (1997).

## **3.4 Oxygen Isotope Analyses by UV Laser Ablation System**

### **3.4.1 Introduction**

In the conventional method established by Baertschi & Silverman (1951) and later by Clayton & Mayeda (1963) oxygen is extracted by reaction of a heated sample with fluorine gas or halogene-fluoride gas. In 1990, Sharp (1990) first successfully used an infrared (IR) laser for heating the sample. In both methods a thermally induced chemical reaction between the sample and the F containing gas is used to liberate the oxygen. The advantage of the laser fluorination technique is, that small samples can be analyzed including refractory minerals like olivine, zircon, garnet or kyanite (Elsenhimer & Valley 1992, Matthey & Macpherson 1993, Valley et al. 1994). But because of the heating of the sample by the laser, partial melting occurs around the laser pits generating isotope fractionation (Conrad & Chamberlain 1992, Elsenhimer & Valley 1992, Kirschner et al. 1993, Sharp 1990, Sharp 1992, Young & Rumble 1993). In order to avoid these fractionation effects the sample must completely be vaporized. Therefore in situ analysis are not practicable.

Recently the problem of isotope fractionation was solved by evaporation of the sample with a high energy ultraviolet excimer laser facilitating the in situ analysis of silicate and oxide minerals (Fiebig et al. 1999, Rumble et al. 1997, Wiechert & Hoefs 1995). In contrast to the ablation behaviour of IR lasers, like CO<sub>2</sub> laser, UV lasers liberate oxygen by electronic excitation of the chemical bonds and thus breaking of these bonds (Fiebig et al. 1999). Nevertheless fluorine is necessary for the measurement in order to prohibit the recombination of the vaporized metal atoms with the oxygen. The metal atoms generate fluorides, which are precipitated or frozen out in cold traps like SiF<sub>4</sub>.

### 3.4.2 Sample Pretreatment

In situ measurements have several advantages compared to the analysis of single grains because in situ measurements can show spatial distributions of possible oxygen isotope inhomogeneities within a mineral or rock section. Another reason to use in situ measurements is the grain size. Many samples contain only small grains, which cannot be separated for analysis. Because the minerals can not be fixed within the sample holder the minimum size of single grains is generally about 1 mm • 1 mm • 1 mm. Otherwise the grains are generally shot out of the holder by the laser pulses.

The main problem of in situ measurements of volcanic rocks is the groundmass. It reacts with the fluorine gas without using the laser resulting in the release of oxygen and other impurities like HF and CF<sub>4</sub>, which can influence the measurement. Secondary minerals like hydroxides, zeolites and carbonates are very reactive. Additionally vitreous groundmass and fine grained feldspar (Elsenheimer & Valley 1992) reacts easily with the fluorine. Therefore a pretreatment of the sample is necessary. The aim of any sample pretreatment is the removal of secondary minerals and a reduction of the reaction of vitreous and feldspar containing groundmass with the fluorine gas.

In principle three different methods can be used to reduce the blank. I) The sample can be coated to prohibit a contact between fluorine and sample. The coating material must be transparent to observe the phenocrystal during laser ablation, so that an evaporation of the surrounding groundmass or a sampling of underlying material can be prohibited. Furthermore the coating material must be resistant against fluorine, should not cause any oxygen fractionation and must not consist of carbon, oxygen or sulphur because these elements influence the analysis. A material which fulfils these requirements has not been found. II) The sample can be passivated by the fluorine itself. The secondary minerals are removed through reaction with the fluorine and the groundmass is protected by the reaction products with the fluorine. Tests have shown, that this method works, but the duration of the sample pretreatment is a disadvantage. III) The third method is a pretreatment with acids. The

disadvantage of this method is, that the success of the etching can only be tested in the sample chamber of the laser ablation device.

A combination of acid pretreatment and passivation was used to prepare the samples for analysis. The etching was carried out in four steps:

1. The rock section is pretreated in acetone or ethanole to remove organic impurities.
2. The sample is etched with HF (10%) for 1 to 6 min in order to dissolve secondary minerals and to produce a coating on the sample surface. The coating is generated by the reaction of the silicates of the groundmass with the HF. Reaction products are fluorine salts and fluorosilicates (Meyer 1926, Meyer & Pietsch 1959, Wiberg 1995). The longer the duration of treatment with HF the better the blank is minimized but the stronger the structure of the rock section is weakened.
3. The third step is an etching with HCl (10 %) for 5 to 15 min. The remaining secondary minerals are solved and the fluorine salts are removed. This is necessary because the fluorine salts are partly hygroscopic and water produces a high blank in the laser ablation system.
4. The sample is cleaned with demineralized water for about 10 to 15 min.

Every cleaning step is done in an ultrasonic bath and between steps 1 to 3 the sample is additionally cleaned with demin. water. The duration of etching depends on the composition of the sample. Generally the higher the content of vitreous or feldspar containing groundmass the longer the sample is treated with acids. After etching the sample is dried within a drying box for at least 1 h and then heated up to 300 °C in a vacuum oven for at least 10 h to remove any adsorbed water.

Single grains were treated in the same way except the HF etching.

After pretreatment of the rock sections or single grains the sample is introduced in the sample chamber. Rock sections are placed on the bottom of the sample chamber without fixing. For individual mineral analyses single grains are put into a holder, a Ni disk with drilled holes. After loading of the sample chamber it is heated (approximately 80 °C) under vacuum for at least 8 h. In addition the sample is passivated to minimize the blank.

Figure 3-1 shows the development of  $\delta^{18}\text{O}$  values depending on the kind of pretreatment and the duration of passivation. The sample chamber was filled with a rock section and olivine reference minerals ( $\delta^{18}\text{O} = 5.1 \text{ ‰}$ ). The raised  $\delta^{18}\text{O}$  values for the reference olivines are generated by the mixing of oxygen from the olivines and blank oxygen from the sample. The rock section, which was only cleaned by water, had to be treated with fluorine for 5 days in order to get a negligible blank. The pretreatment with HCl reduced the passivation for 2 days.

An additional cleaning step with HF minimized the duration of passivation depending on the time of treatment of the sample with HF.

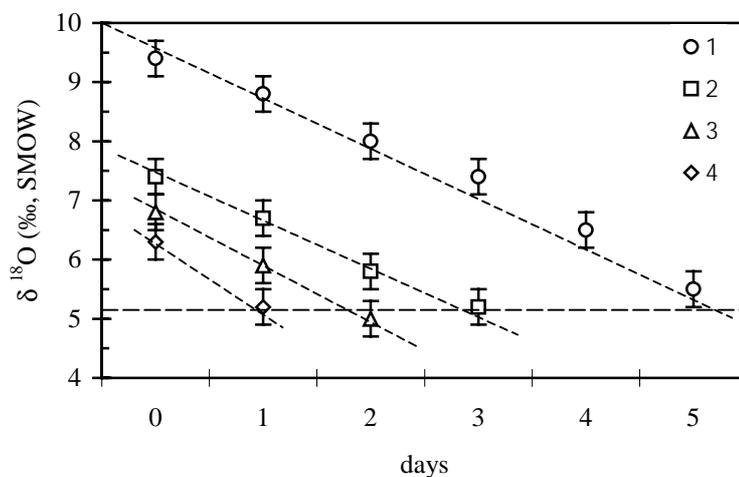

Fig. 3-1:  $\delta^{18}\text{O}$  values of olivine reference minerals as a function of the time of passivation of a rock section from Torre Alfina. 1) untreated rock section; 2) rock section treated with HCl (10 %) for 4 min.; 3) rock section treated with HCl (10 %) for 4 min. and HF (10 %) for 1.5 min.; 4) rock section treated with HCl (10 %) for 4 min. and HF (10 %) for 3 min. Dashed horizontal line is the true value of the olivine reference minerals (5.1 ‰).

### 3.4.3 Instrumentation

Because the laser ablation method is still in a stage of development two different devices have been used for the analyses.

The device is built up by a laser, an optical bench to observe the sample and to focus the laser beam, a vacuum extraction line with a fluorine generator and a mass spectrometer. The sample chamber, made of stainless steel, has a volume of 20 cm<sup>3</sup> and an inner diameter of 2 cm.

Pure fluorine gas is necessary for the ablation process in order to prohibit the recombination of evaporated metal atoms with the released oxygen gas. The fluorine gas is produced by heating a K<sub>3</sub>NiF<sub>7</sub> salt within a nickel vessel to 400 °C. At 200 °C K<sub>3</sub>NiF<sub>7</sub> reacts to K<sub>2</sub>NiF<sub>6</sub> • KF and impurities are pumped away. At 400 °C K<sub>3</sub>NiF<sub>6</sub> and F<sub>2</sub> is generated (Asprey 1976). The fluorine is then condensed in a cold finger at liquid nitrogen temperature. At the end of one measurement day the surplus fluorine is reacted back in the nickel vessel to K<sub>3</sub>NiF<sub>7</sub>.

Two different UV excimer lasers were used. A KrF laser (Lextra 200 excimer laser, Lambda Physik Inc.) radiating at 248 nm and an ArF laser (Compex 205 excimer laser, Lambda Physik Inc.) radiating at 193 nm. The used parameters of the lasers are 10 - 25 Hz and 220 - 400 mJ per puls for the ArF laser and 10 - 25 Hz and 300 - 580 mJ per puls for the KrF laser.

### 3.4.4 Conversion of Oxygen to CO<sub>2</sub>

This technique has been described in detail by Wiechert & Hoefs (1995) with the modifications of Fiebig et al. (1999). An ArF laser was employed.

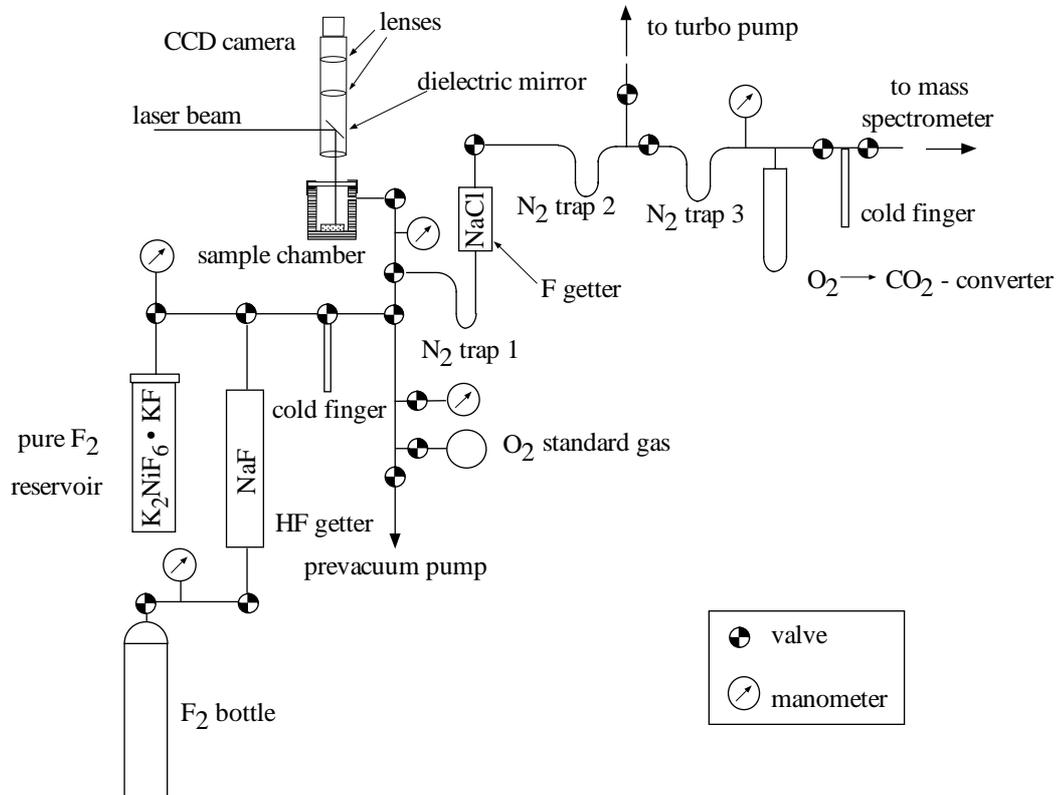

Fig. 3-2: Schematic outline of the gas extraction and fluorine delivery system modified after Wiechert & Hoefs (1995).

For the ablation process the sample chamber is filled with 30 to 50 mbar fluorine. The amount of vaporized oxygen is limited by the vacuum line and the mass spectrometer. In order to prohibit large fractionation effects within the gas lines 3 to 5.5  $\mu\text{mol}$  O<sub>2</sub> were produced. After the ablation of the sample under a fluorine atmosphere, gaseous impurities like SiF<sub>4</sub> and HF are frozen out in a cold trap at liquid nitrogen temperature. Then the surplus fluorine is reacted to chlorine and solid NaF over heated NaCl. Afterwards the chlorine is frozen out in a nitrogen cold trap. The generated oxygen is converted to CO<sub>2</sub> with heated diamonds and then fixed in a cold trap. The O<sub>2</sub> have to be converted to CO<sub>2</sub> because the mass spectrometer (Finnigan MAT 251) cannot detect O<sub>2</sub> but CO<sub>2</sub>. After fixing the CO<sub>2</sub> the sample gas is heated to room temperature and analyzed by the mass spectrometer.

During daily analysis the laser line showed sometimes a shift to smaller  $\delta^{18}\text{O}$  values. This shift can be explained by fractionation effects within the vacuum line probably occurring by the conversion of O<sub>2</sub> to CO<sub>2</sub>. The values were therefore corrected by a regular measurement of reference minerals.

### 3.4.5 Direct Measurement of Oxygen Without Conversion

The laser fluorination device without O<sub>2</sub> conversion is the next stage of development compared to the device described above. Because another mass spectrometer (Delta Plus, Finnigan) has been used O<sub>2</sub> can directly be measured without conversion to CO<sub>2</sub>. This method has been applied with an ArF and a KrF laser.

This device is similar to the device described above. But behind the F getter an U-tube of a known volume is set. After laser ablation the released oxygen is expanded in this U-tube. An aliquot of the gas is then purged with He over a molesieve 5Å, GC and open split into the mass spectrometer (Fiebig et al. 2000). Compared to the system with CO<sub>2</sub> conversion this method needs less fluorine (5 - 15 mbar) and less amounts of the sample must be evaporated (down to 300 nmol O<sub>2</sub>).

### 3.4.6 Accuracy of the Oxygen Isotope Measurements

Reference minerals have been used to guard against unexpected errors such as leaks and for data correction. As reference minerals olivines (FIN 9506-1, 5.1 ‰ - Wiechert, personal information), garnets (UWG-2, 5.8 ‰ - Valley et al. 1995), and quartz (Dörentrup, 12.1 ‰ - see Fiebig et al. 1999) have been analyzed.

The error (1s) of the isotope ratio measurements using the method with O<sub>2</sub> conversion is  $\pm 0.2 - 0.3$  ‰ and the standard deviation for the method without O<sub>2</sub> conversion is  $\pm 0.3$  ‰.

## 3.5 Oxygen Isotope Analyses by CO<sub>2</sub> Laser Ablation System

Selected mineral grains were also analyzed by a CO<sub>2</sub> laser ablation system. The analyses were carried out by B. Hagen at the University of Bonn. The CO<sub>2</sub> laser ablation system in Bonn also works with fluorine gas and oxygen is directly measured by a mass spectrometer (ANCA-SL 20-20 Stable Isotope Analyser, Europa Scientific Inc.). The device is described by Hagen (2000).

### 3.6 Comparison of the Different Methods for Oxygen Isotope Ratio Measurement

Selected rock samples were analyzed by the three different methods of oxygen isotope ratio measurement - UV laser ablation system with O<sub>2</sub> conversion to CO<sub>2</sub>, the direct measurement of oxygen and the CO<sub>2</sub> laser ablation system - in order to control the correctness of the individual methods.

In tab. 3-1 the analytical results of the different methods are compared. They correspond well to each other.

*Tab. 3-1: Comparison of the results of the different methods of oxygen isotope ratio measurement (n = number of analyses, n.a. = not analyzed).*

## 4 Results

The volcanic rocks of central Italy are characterized by a large diversity within a narrow area. As mentioned in chapter 1 the sampled rocks can be assigned to five different genetic types:

1. mantle derived melts of the Roman Magmatic Province occurring at the Vulsinian mountains,
2. lamproitic mantle melts of the Tuscan Magmatic Province,
3. crustal anatectic rocks of the Tuscan Province,
4. transitional rocks between Roman and Tuscan mantle melts, and
5. hybrid rocks representing mixtures between mantle and crustal melts.

For a better comparison of the results, rocks from the different localities have been embraced into three groups, I) mantle derived rocks, II) crustal derived rocks and III) hybrid rocks between crustal and mantle melts.

Major and trace element composition of the bulk rocks has been analyzed for all samples. Because the oxygen isotope analyses are the major aspect of this work nearly all samples have been investigated. Only some samples could not be analyzed because of the small grain size of the phenocrystals.

Additionally the mineral chemistry of some samples has been analyzed. Representative rock samples from each genetic type have been selected as well as less and highly evolved rocks from the Vulsinian mountains. An overview of the applied analytical methods is shown in table 4-1.

*Tab. 4-1: The different analytical methods used are summarized (+ applied on the sample). (LA-SIRMS: laser ablation – stable isotope ratio mass spectrometry, EMPA: electron beam microprobe analysis, LA-ICP-MS: laser ablation – inductively coupled plasma – mass spectrometry).*

The analytical results are summarized in tabular form in the appendix.

## 4.1 Mantle Derived Rocks

### 4.1.1 Introduction

For a discussion of the mantle composition beneath central Italy the most primitive rocks are important. In general primitive rocks are characterized by high Mg values, high Ni-, and Cr-contents and a narrow SiO<sub>2</sub> concentration in tectonic regimes, for example oceanic plates, where low pressure evolution and interaction with the crust is negligible (Sun & McDonough 1989). But in the case of potassic continental volcanics, where a metasomatized mantle is considered as a potential source, the identification of primitive magmas using the traditional geochemical parameters is at least problematically (Peccerillo 1994, Wilson 1995). In order to deduce the composition of the mantle the investigation should be focused on the less modified rocks. Rogers et al. (1985) suggested rocks with MgO > 6 wt.% and CaO > 8 wt.% as the least evolved rocks for the Roman Province.

Mantle derived melts are common in the Roman Province and thus are also common in the Vulsinian mountains. But they are often modified by processes like crystal fractionation and assimilation of crustal material. According to Civetta et al. (1981) two different rock suites can be distinguished in the Roman Province, a high potassic series (HKS) with SiO<sub>2</sub> undersaturated rocks and a potassic series (KS) with SiO<sub>2</sub> saturated rocks. Major phases of the rocks are olivine, clinopyroxene, and plagioclase and additionally leucite in the evolved rocks of the HK series.

Mantle melts in the Tuscan Province occur as lamproites at Orciatice and Montecatini Val di Cecina. They can be classified as sanidine clinopyroxene phlogopite lamproites according to the classification proposals of Woolley et al. (1996) and Foley et al. (1987).

These two kinds of mantle melts - the Roman Province Type rocks and the Tuscan Province lamproites - represent two endmembers. Between these endmembers mixtures occur, which are classified as transitional rocks on a petrogenetic basis. Rocks from Torre Alfina and Radicofani are assumed to belong to those transitional rocks (Peccerillo et al. 1987).

Rocks from Torre Alfina display a clear affinity to the lamproites because of their chemical and mineralogical composition: the assemblage of olivine, clinopyroxene, sanidine, and phlogopite (Conticelli 1998). However their chemical composition is not identical with the lamproitic composition. Thus there is no common agreement on the petrographical classification of these rocks (e.g. Conticelli 1998, Peccerillo et al. 1987). According to Foley et al. (1987) the rocks are classified as transitional rocks between Roman Province Type rocks and lamproites on the basis of their chemical composition (short: transitional rocks).

The rocks from Radicofani show an intermediate composition between the Roman Province rocks and the Tuscan Province lamproites. They can be assigned to the shoshonitic association (Poli et al. 1984). Major phenocrystals are olivines, clinopyroxenes and plagioclases (Innocenti 1967, Poli et al. 1984).

#### 4.1.2 Whole Rock Chemistry

Both rock series, HKS and KS, occur at the Vulsinian mountains. The subdivision of the series used differs slightly from the suggestions of Civetta et al. (1981). Rocks of the HKS are SiO<sub>2</sub> undersaturated with K<sub>2</sub>O > 4.5 wt.% and K<sub>2</sub>O / Na<sub>2</sub>O > 2. Petrologically they range from potassic trachybasalts to phonotephrites, tephriphonolites and finally phonolites with olivines, clinopyroxenes, plagioclases, and leucites as major minerals depending on the degree of evolving stage. In contrast rocks of the KS are SiO<sub>2</sub> saturated and contain less K<sub>2</sub>O (< 4.5 wt.%) with a lower K<sub>2</sub>O / Na<sub>2</sub>O ratio (< 2). From this series shoshonites were sampled. Major minerals are olivine, clinopyroxene and plagioclase.

The less evolved rocks from the Vulsinian mountains contain relatively high Al<sub>2</sub>O<sub>3</sub> (13.7-15.5 wt.%) and CaO (10 - 11.3 wt.%) contents. The general trend of increasing SiO<sub>2</sub> with an increase in K<sub>2</sub>O, Na<sub>2</sub>O, and Al<sub>2</sub>O<sub>3</sub> and a decrease of MgO, CaO, and Fe<sub>2</sub>O<sub>3(tot)</sub> can be explained by fractional crystallization and crustal assimilation processes.

Compared to lamproites from elsewhere the central Italian lamproites are SiO<sub>2</sub> rich - between 54.1 and 56.4 wt.% and quartz normative - and have a low K<sub>2</sub>O / Na<sub>2</sub>O ratio of 3.5 - 4.4; generally lamproite ratios lie above 5 (Mitchell & Bergman 1991). They are neither peralkaline (molar (K<sub>2</sub>O + Na<sub>2</sub>O) / Al<sub>2</sub>O<sub>3</sub> = 0.8 - 1.0) nor perpotassic (molar K<sub>2</sub>O / Al<sub>2</sub>O<sub>3</sub> = 0.87 - 0.8). But the chemical composition is similar to the composition of the Spanish lamproites (Venturelli et al. 1984a). Further geochemical features are the low Al<sub>2</sub>O<sub>3</sub>, CaO, and Na<sub>2</sub>O contents compared to the less evolved rocks from the Roman Province.

Tab. 4-2: Chemical composition of some major and trace elements for selected, less evolved, mantle derived rock samples from the three different genetic types: Roman Province rocks from the Vulsinian mountains, Tuscan Province lamproites from Orciatice, transitional rocks from Torre Alfina and Radicofani. (\*) For comparison the chemical composition of a MORB is shown (Schilling et al. 1983).

Two samples have been collected from the Torre Alfina volcano, one sample from the type A lavas (TA 9701) and one from the type B lavas (TA 9702). The major element chemistry is similar to the lamproites but with higher Al<sub>2</sub>O<sub>3</sub> and CaO contents.

From Radicofani less evolved rocks have been sampled, which can be classified as basaltic andesites. The rocks are SiO<sub>2</sub> oversaturated (quartz normative) and have relatively low K<sub>2</sub>O contents (2.99 - 3.29 wt.%). The K<sub>2</sub>O / Na<sub>2</sub>O ratios (1.5 - 1.9) are lower than those in the

lamproites or in less evolved rocks from the Vulsinian mountains. Major element concentrations of the Radicofani rocks lie between the values of the lamproites from Orciatico and Montecatini on the one hand and the less evolved rocks from the Vulsinian mountains on the other hand.

A common feature of all rocks is a high enrichment of LREE, high LREE / HREE ratios, a negative Eu anomaly and a flat curve of enrichment for the HREE (fig. 4-1 and 4-2). Vulsinian rocks however show a relatively steep gradient in the LREE (La, Ce, Pr) whereas the lamproites and the transitional rocks from Torre Alfina and Radicofani display a flat curve of enrichment.

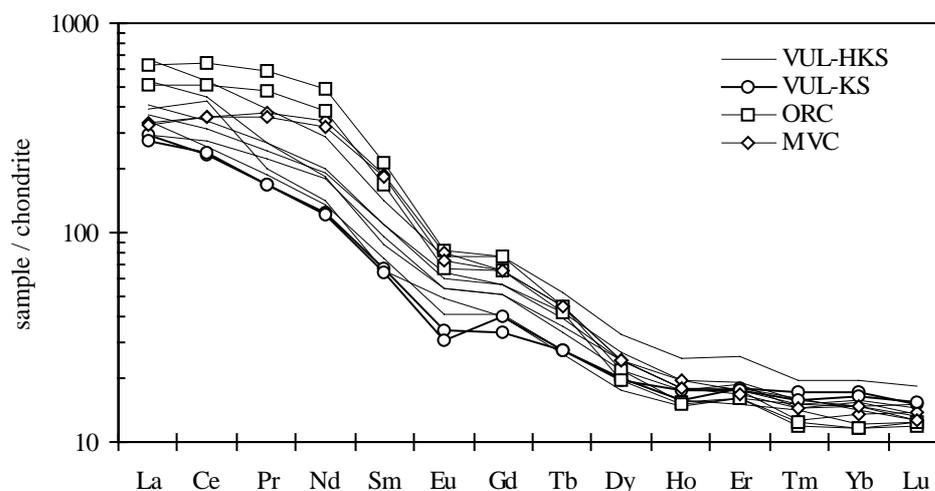

Fig. 4-1: Chondrite normalized REE patterns of the Vulsinian rocks (VUL) from the Roman Province and the lamproites from the Tuscan Province (ORC: Orciatico, MVC: Montecatini Val di Cecina). Normalizing values are taken from Anders & Grevesse (1989).

The lamproites are more enriched in HREE and middle REE than the less evolved rocks from the Vulsinian mountains. In addition HKS rocks from the Vulsinian mountains are more enriched in LREE and middle REE than the KS rocks. For the Torre Alfina rocks the degree of enrichment is the same as for the lamproites but the Radicofani rocks show an enrichment of REE similar to the KS rocks from the Vulsinian mountains.

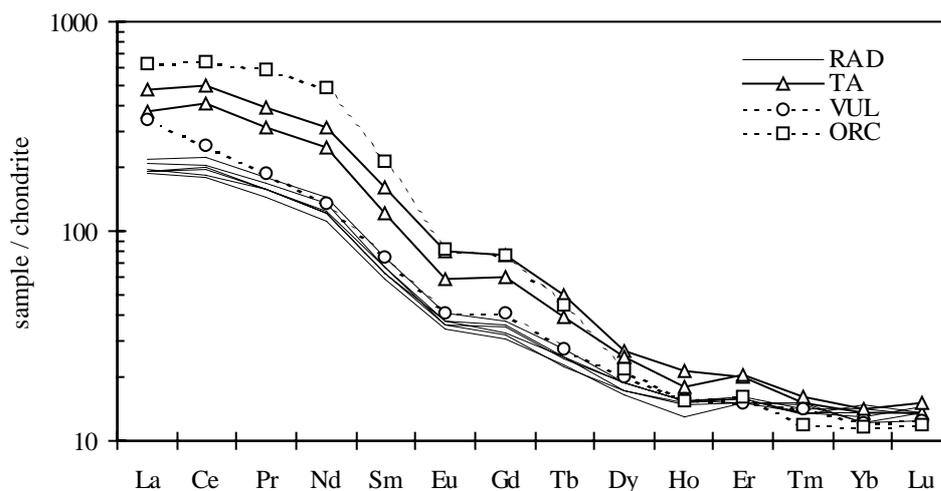

Fig. 4-2: Chondrite normalized REE patterns of the transitional rocks between Roman Province type rocks and Tuscan Province lamproites. RAD: basaltic andesites from Radicofani, TA: rocks from Torre Alfina; for comparison are also shown: VUL: less evolved rock sample from the Vulsinian mountains, ORC: lamproite sample from Orciatice (normalizing values are taken from Anders & Grevesse 1989)

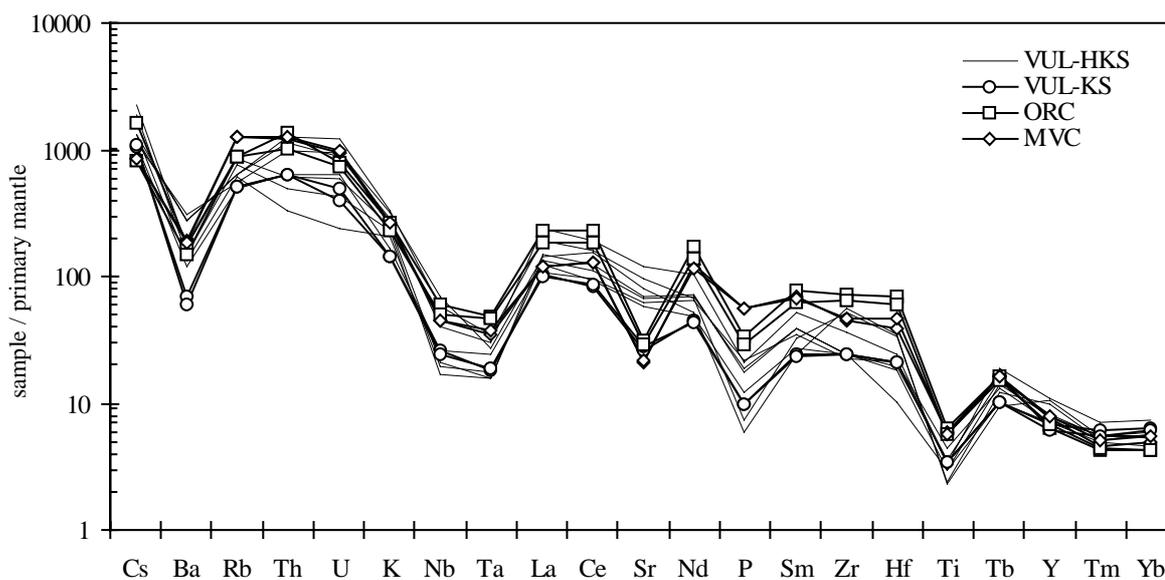

Fig. 4-3: Multi element diagram of the Vulsinian rocks and the lamproites, element concentrations are normalized to primary mantle (values of McDonough & Sun 1995). VUL: Vulsini, ORC: Orciatice, MVC: Montecatini Val di Cecina.

Other common features of the mantle derived rocks from central Italy are high enrichments of LILE and high LILE / HFSE ratios. Multi element diagrams (fig. 4-3 and 4-4) are typical for crustal or crustally influenced rocks (e.g. Wilson 1995). Rocks from different localities display a similar multi element pattern. Generally a decrease of enrichment is observed in the

order of lamproites > Torre Alfina rocks > less evolved rocks from the Vulsinian mountains > Radicofani rocks.

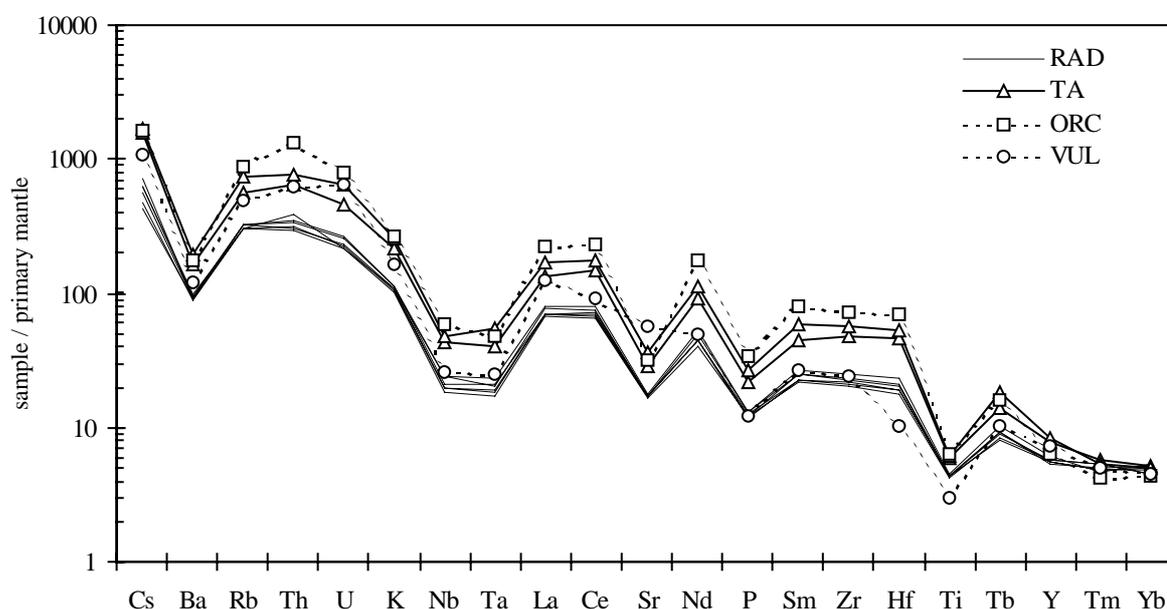

Fig. 4-4: Multi element diagram of transitional rocks, element concentrations are normalized to primary mantle (values of McDonough & Sun 1995). RAD: Radicofani, TA: Torre Alfina, for comparison are also shown a less evolved rock sample from the Vulsinian mountains (VUL) and a lamproitic sample from Orciatico (ORC).

#### 4.1.3 Mineral Chemistry

Mineral chemistry has been investigated on selected samples from each genetic type. The selected samples are shown in table 4-1.

From the Vulsinian Mountains rock samples from the HK series and the K series have been analyzed. From the HK series less, intermediately and highly evolved rocks have been investigated. Major phenocrystalline phases in the less evolved rocks are olivine, clinopyroxene, and plagioclase and additionally leucite in the highly evolved rocks. As a representative of the lamproites the sample ORC 9701 has been analyzed. From Torre Alfina a rock sample from the type A lavas has been investigated. This sample contains an embedded ultramafic xenolith, so that both - the bulk rock and the xenolith - have been analyzed. From Radicofani two samples have been selected.

#### 4.1.3.1 Olivines

In all mantle derived rocks olivines occur. Their chemical composition is shown in tab. 4-3 for representative samples.

Olivines only occur in the less evolved rocks of the HKS from the Vulsinian mountains. The cores are forsteritic (fo91-fo92) with increasing fayalite component to the mineral rim (fig. 4-5). FeO / MgO ratios of the olivines approximately are in equilibrium with the bulk rock using the experimentally determined partitioning coefficients of Roeder & Emslie (1970). CaO contents vary between 0.46 and 0.59 wt.% and MnO between 0.12 and 0.29 wt.%. CaO / MgO ratios do not fit with any of the trends for olivines of potassic igneous suites reported by Ferguson (1978). They have, however, similar compositions to olivines from other localities of the Roman Province (Federico et al. 1994).

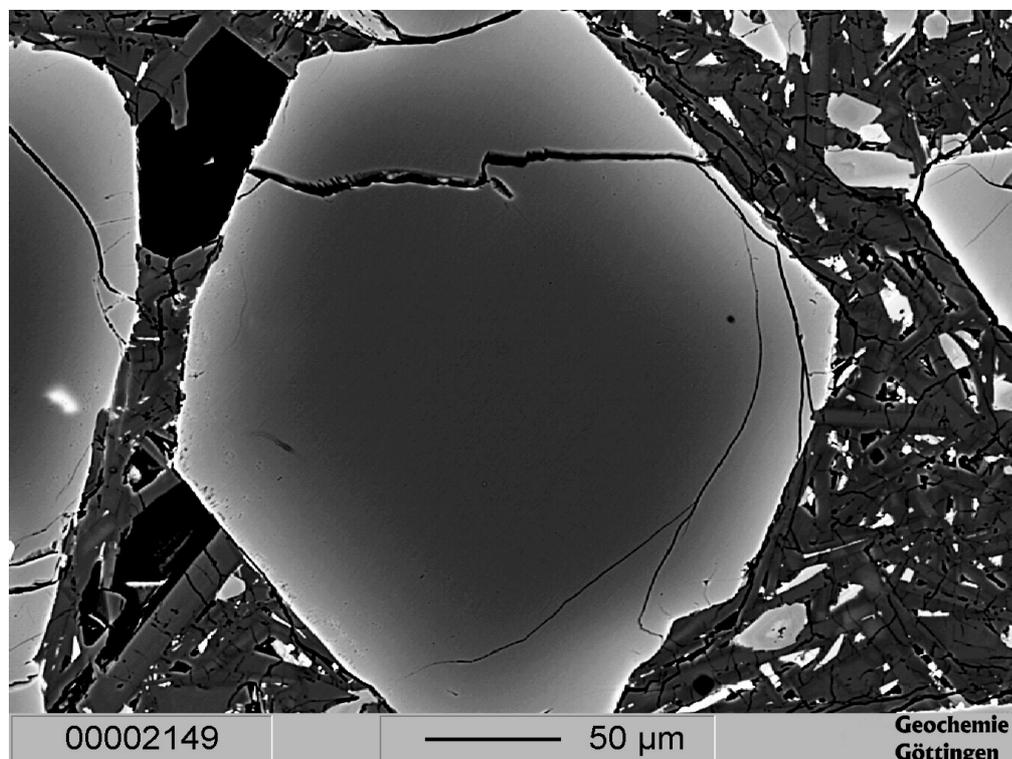

Fig. 4-5: EMPA picture (composition mode) of an olivine from the Vulsinian mountains, K series (VUL 9703 B)

Olivines from the KS are homogeneous with lower MgO contents (fo86 - fo90), CaO between 0.30 - 0.37 wt.% and a greater variability of MnO contents ( $\leq 0.50$  wt.%). Like olivines of the high potassic series they show an increasing fayalitic component to the rim. The forsteritic component decreases to fo76 with increasing MnO and no significant change of the CaO content. The REE content is below the detection limit of the LA-ICP-MS.

Tab.4-3: Comparison of representative olivine analyses from different rock types. HKS: Vulsinian mountains, HK series; KS: Vulsinian mountains, K series; ORC: lamproite from Orciatico, RAD: Radicofani; TA-px: Torre Alfina, peridotitic xenolith (b.d.l.: below detection limit of the EMPA).

wt.%	HKS	KS	ORC	RAD	TA-px
SiO <sub>2</sub>	40.4	40.7	39.5	37.8	40.9
FeO	10.53	10.13	16.90	25.20	9.42
MgO	48.3	49.4	44.4	37.7	49.1
CaO	0.377	0.349	0.116	0.242	b.d.l.
MnO	b.d.l.	b.d.l.	0.296	0.407	b.d.l.
fo component	89	90	82	72	90

Olivines from the lamproites show a larger compositional range (fo79 - fo90) than the Vulsinian olivines with a continuously increasing fayalitic component to the mineral rim. CaO and MnO increase sympathetically with decreasing MgO. Trace elements in olivines are homogeneously composed with high LREE / HREE ratios due to the high LREE / HREE ratio of the bulk rock. The HREE are often below the detection limit.

In the case of the Torre Alfina rocks the chemical similarity of the phenocrystals of the whole rock to the olivines of the ultramafic xenolith supports a xenocrystic origin of the phenocrystals by disintegration of ultramafic xenoliths. Olivines of the ultramafic xenolith contain a narrow range of forsterite composition of fo89 - fo90 with low CaO (< 0.121 wt.%) and MnO (below detection limit of the electron microprobe) contents. They display no chemical zonation but the olivines at the boundary to the host lava show a reaction rim with slightly higher CaO (~ 0.12 wt.%) and lower forsteritic contents (fo84 - fo86). The low CaO and MnO concentrations are typically for high pressure olivines (Simkin & Smith 1970). Olivines of the bulk rock have a similar composition with an additional reaction rim. The rim is also higher concentrated in FeO and CaO. The REE content of the olivines of the ultramafic xenolith is mostly below the detection limit of the LA-ICP-MS. For olivines of the host rock the LREE could be sometimes measured with 0.01 fold bulk rock concentration.

In the Radicofani rocks olivines are homogeneously composed with a forsteritic component of 66 - 74 mol%, which is lower than in mantle melts from other localities. Olivines of the sample RAD 9702 A show secondary alteration processes - iddingsite was produced at the outer parts of some small olivines in the groundmass (Innocenti 1967). Generally the REE contents were below the detection limit. Only in some olivines the REE concentrations could

be measured showing a higher depletion of the LREE than the HREE compared to the bulk rock concentration.

#### 4.1.3.2 Clinopyroxenes

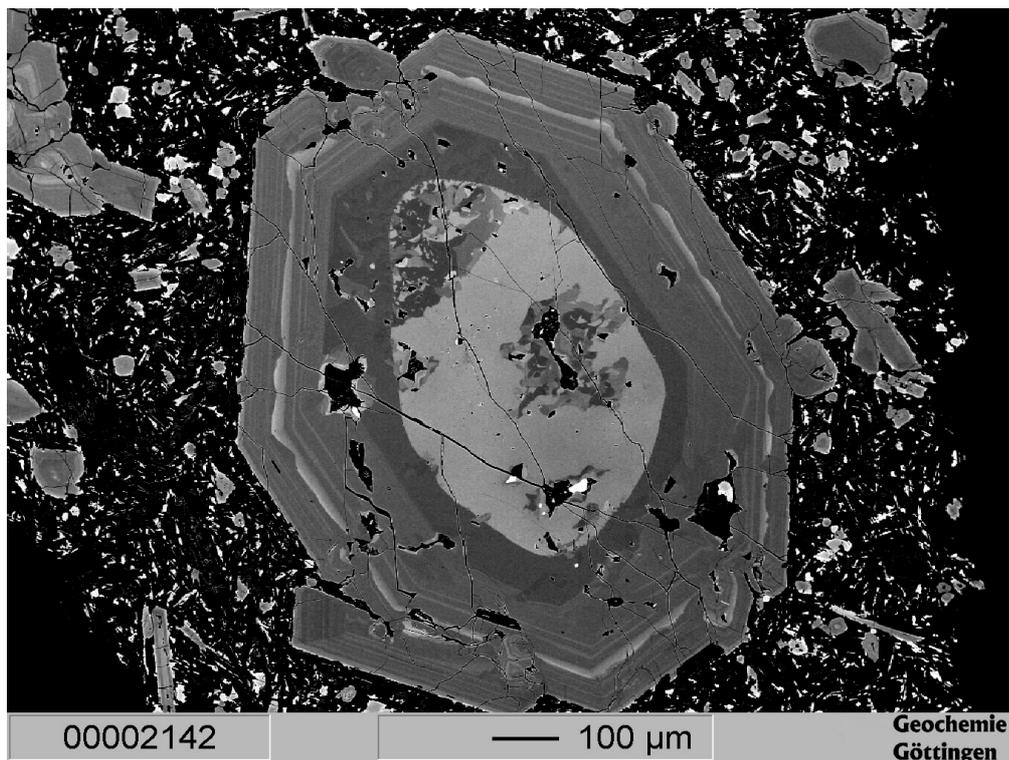

Pyroxenes are classified according to the scheme of Morimoto (1989). Some representative analyses are shown in tab. 4-4.

*Tab. 4-4: Comparison of representative clinopyroxene analyses from different rock types. HKS: Vulsinian mountains, HK series; KS: Vulsinian mountains, K series; ORC: lamproite from Orciatice, RAD: Radicofani; TA-px: Torre Alfina, peridotitic xenolith (b.d.l.: below detection limit of the EMPA).*

wt.%	HKS	KS	ORC	RAD	TA-px
SiO <sub>2</sub>	52.0	52.4	54.0	51.1	53.3
TiO <sub>2</sub>	0.419	0.496	0.585	0.759	0.657
Al <sub>2</sub> O <sub>3</sub>	3.14	3.37	0.56	3.77	1.22
FeO	3.96	4.08	3.58	4.66	4.19
MgO	16.0	16.4	18.0	16.7	16.9
CaO	23.7	23.6	22.4	21.5	22.5
MnO	b.d.l.	b.d.l.	b.d.l.	0.162	b.d.l.
Cr <sub>2</sub> O <sub>3</sub>	0.419	b.d.l.	0.776	1.042	0.473
Na <sub>2</sub> O	0.199	0.207	0.162	0.161	0.106

From the Vulsinian mountains HKS clinopyroxenes are diopsides whereas KS clinopyroxenes range from a diopsidic to an augitic composition. Oscillatory zoning is a common feature of these minerals (fig. 4-7, fig. 4-8). Sometimes inherited, Fe-rich, and patchy zoned cores are observed within the clinopyroxenes (fig. 4-6, fig. 4-9). Resorption edges are also visible in some minerals. As typically found in clinopyroxenes from the Roman Magmatic Province, the tetrahedral site is filled only with Si and Al, with significant Al in the M1 site and a Ca deficiency in the M2 site (Bindi et al. 1999, Caggianelli et al. 1990, Cellai et al. 1994, Dal Negro et al. 1985, De Fino et al. 1986). The Ca content of the HKS clinopyroxenes increase with increasing Fe content up to 52 mol% wollastonite component. Na and Ti contents of the clinopyroxenes are variably with a negative correlation between Mg and Ti for the HKS clinopyroxenes. Clinopyroxenes with similar Mg / (Mg + Fe) ratios of both series have similar Ti and Al<sup>IV</sup> contents indicating a similar pressure regime of crystallization (Thompson 1974, Tracy & Robinson 1979, Vieten 1980, Wass 1979).

*Fig. 4-8: EMPA image (composition mode) of a clinopyroxene from the Vulsinian mountains, HK series (VUL 9701).*

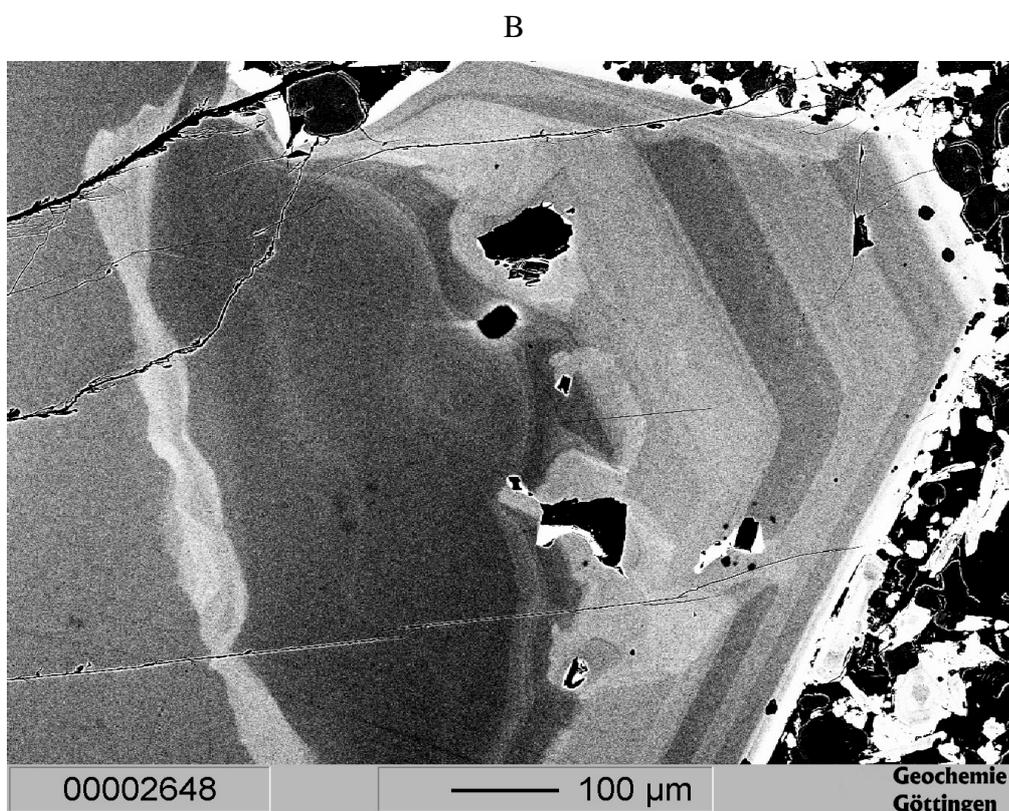

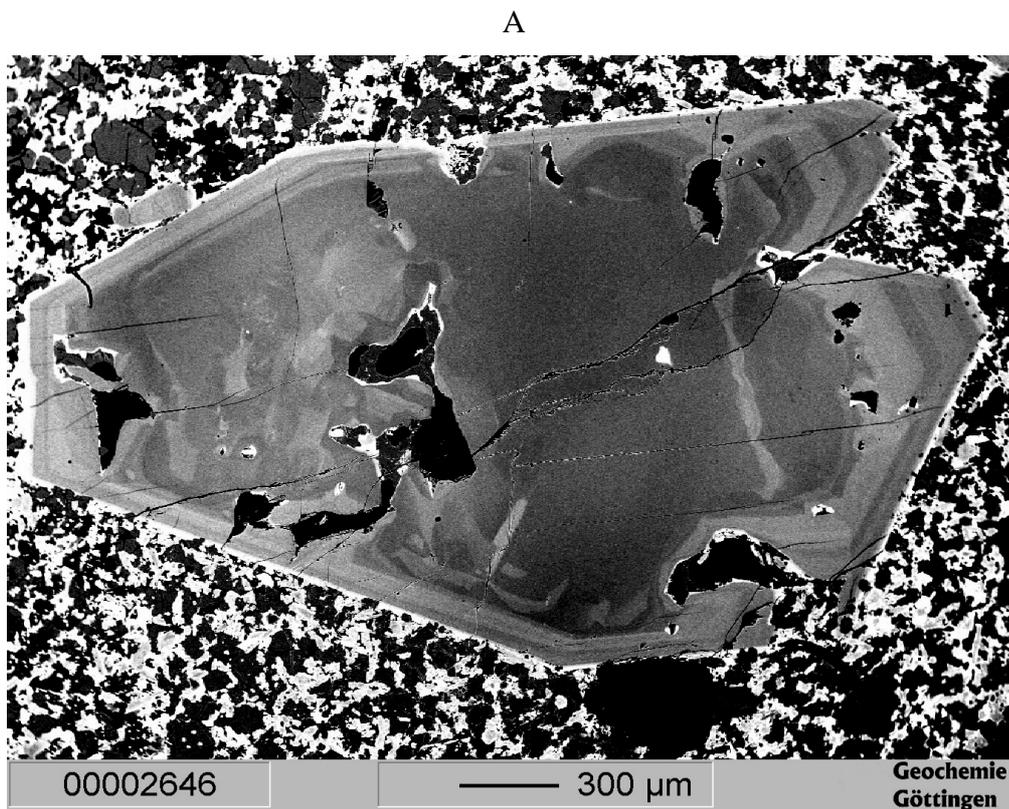

Fig. 4-9: EMPA images (composition mode) of clinopyroxenes from the Vulsinian mountains, HK series (VUL 9705); A: overview, B: detail.

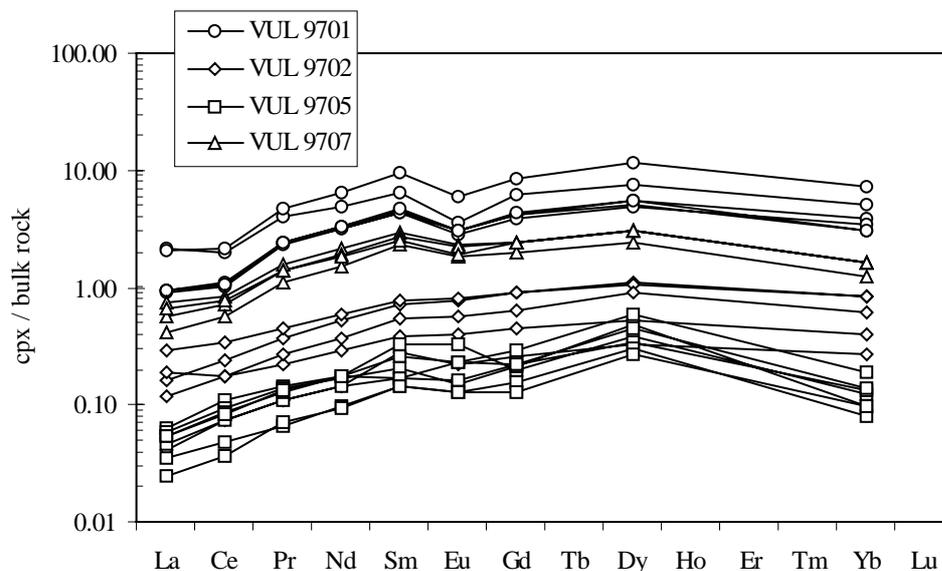

Fig. 4-10: REE patterns of clinopyroxenes from HKS rocks from Monti Vulsini normalized to bulk rock data. Mg values of the bulk rock: VUL 9701: 27, VUL 9702: 51, VUL 9705: 65, VUL 9707: 28.

Cr, Ni, Rb and Ba contents are low or beneath the detection limit of the electron microprobe or LA-ICP-MS whereas Sr concentrations between 50 and 860 ppm were found for HKS clinopyroxenes. Contrary KS pyroxenes have higher Cr contents. For all Vulsinian rocks clinopyroxenes are partly enriched or depleted in the REE normalized to bulk rock (fig. 4-10, fig.4-11). The  $REE_{cpx} / REE_{bulk\ rock}$  ratios generally increase with increasing atomic number. The highest enrichment of REE is found in the more evolved rocks with lower Mg values. Additionally some clinopyroxenes show a minor negative Eu anomaly.

Clinopyroxenes from the lamproites are diopsides and are characterized by high Mg values of 84 - 92. They display a weak oscillatory zoning. Compared to Vulsinian clinopyroxenes they contain less Al contents ( $Al_2O_3 < 0.83$  wt.%). Si and Al are not sufficient to fill the T site completely, which is a characteristic feature of clinopyroxenes from lamproitic magmas (Jaques et al. 1984, Mitchell & Bergman 1991, Mitchell et al. 1987). The tetrahedral site deficiency can be compensated by  $Ti^{4+}$  or  $Fe^{3+}$  (Cellai et al. 1994). Also the Ca deficiency in the M2 site is higher compared to Roman Province clinopyroxenes. In contrast to Roman Province clinopyroxenes they show a rough negative correlation between Ca and Fe.

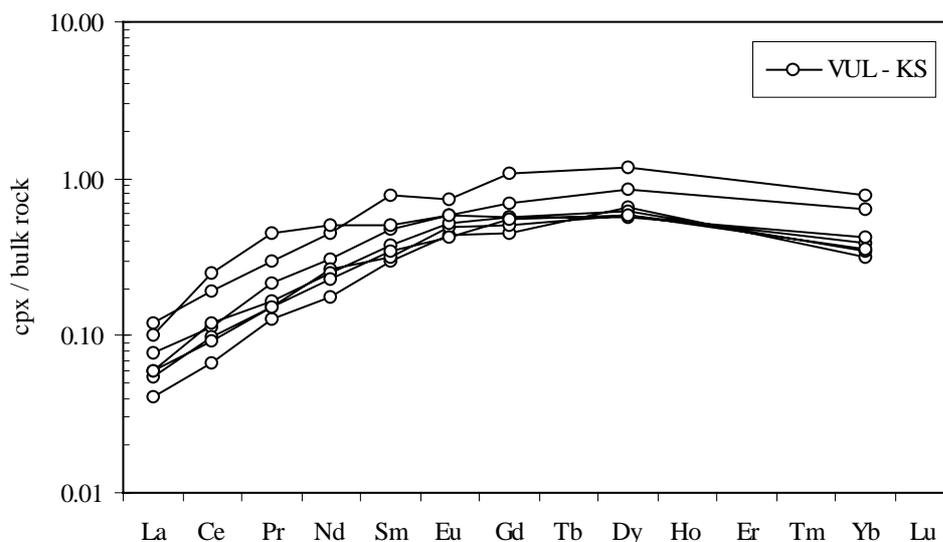

Fig. 4-11: REE patterns of clinopyroxenes from KS rocks from Monti Vulsini normalized to bulk rock data.

$\text{Cr}_2\text{O}_3$  contents are below 0.92 wt.% and Ni concentrations range between 60 - 150 ppm. The chondrite normalized REE patterns display a higher enrichment of LREE than HREE with a peak at Nd. These patterns are generated by the REE pattern of the bulk rock what can also explain the negative Eu anomaly. Remarkable is that the clinopyroxenes can be subdivided into two groups with different degrees of depletion of the REE compared to bulk rock data (fig. 4-12). But there is no other difference between these two groups, neither in the major element concentration nor in the shape of the trace element pattern. The major element chemistry clearly points to a melt origin of the clinopyroxenes (Conticelli et al. 1992), so that a xenocrystic origin can be excluded.

Clinopyroxenes of the ultramafic xenolith from Torre Alfina display an augitic to diopside composition (wo43 - wo46, en48 - en51). Their chemical composition - low  $\text{Na}_2\text{O}$ ,  $\text{TiO}_2$ , and  $\text{Al}_2\text{O}_3$  contents - is typically for ultramafic xenoliths from Torre Alfina (Conticelli & Peccerillo 1990). The LREE are more enriched than the HREE with about 100 times chondritic values for La and 20 times chondritic values for Yb. Additionally they display a negative Eu anomaly.

Clinopyroxenes of the bulk rock from Torre Alfina show a slightly oscillatory zoning. Their chemical composition is similar to the clinopyroxenes of the ultramafic xenolith. For the whole rock suite from Torre Alfina Conticelli (1998) found a range of clinopyroxene compositions from lamproitic to Roman Province type clinopyroxenes with the more lamproitic clinopyroxenes in the type A lavas. The analyzed rocks in this work display clinopyroxenes with an intermediate composition. Al and Si are sufficient to fill the

tetrahedral site completely, what is a characteristic feature of the Roman type clinopyroxenes. Contrary the Ca deficiency of the M2 site is higher than for Roman type clinopyroxenes and is in the range of lamproitic clinopyroxenes.

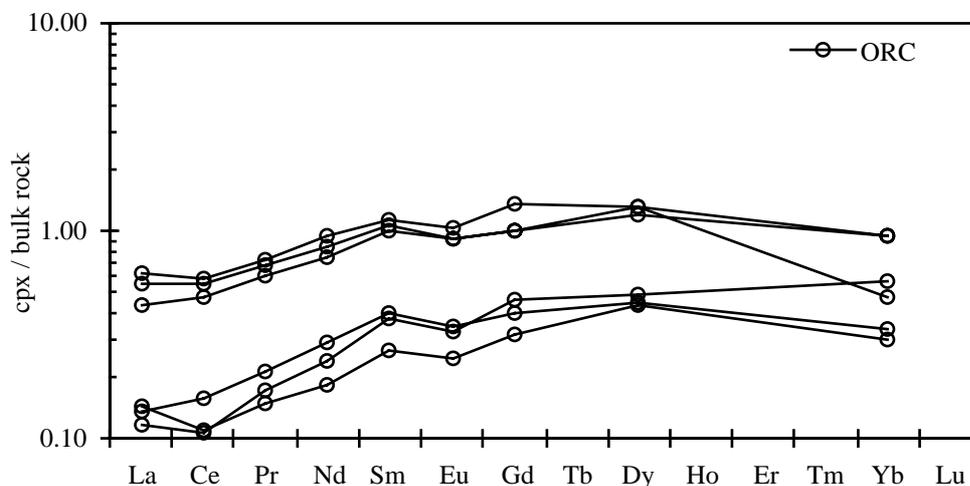

Fig. 4-12: REE patterns of clinopyroxenes from the Orciatico lamproite normalized to bulk rock data.

The Radicofani clinopyroxenes are homogeneously composed showing only weak oscillatory and sometimes patchy zoning. They are augites with an enstatite component of 43 - 53 mol% and wollastonite of 39 - 45 mol%. Si and Al are sufficient to fill the tetrahedral site completely with minor amount of Al in the M1 site as it is typically for Roman Province type rocks (Bindi et al. 1999, Caggianelli et al. 1990, Cellai et al. 1994, Dal Negro et al. 1985, De Fino et al. 1986). But the Ca deficiency in the M2 site for the Radicofani clinopyroxenes is higher and comparable to the Orciatico lamproites. A correlation for Mg and Ti as well as for Ca and Fe, as being typical for Roman Province clinopyroxenes, could not be found. The  $\text{Cr}_2\text{O}_3$  content is high up to 1.4 wt.%. The homogeneous composition is also reflected by the REE concentrations. Normalized to the bulk rock composition the HREE are only slightly and the LREE are more depleted. The negative Eu anomaly of the augites can be caused by different oxidation stages of Eu.

#### 4.1.3.3 Orthopyroxenes

Orthopyroxenes only occur in the ultramafic xenolith from the Torre Alfina lava. They are homogeneously composed and do not show any zonation. The orthopyroxenes are enstatites (en88 - en89, wo ~ 2) with  $\text{Cr}_2\text{O}_3$  of 0.449 - 0.579 wt.% and  $\text{Al}_2\text{O}_3$  of 3.56 - 3.77 wt.%.

#### 4.1.3.4 Alkali Feldspars

K feldspar in the Vulsinian rocks only occur as phenocrystals in the phonolite. They are homogeneously composed with a slight increase of Si and Na and a decrease of Al, Ca, Ba, and, K from the core to the rim. Alkali feldspars of the phonolite range from sanidine to hyalophane with 49.2 - 59.6 mol% orthoclase and 4.9 - 9.3 mol% celsian component.

Sanidine is a groundmass phase of the lamproites and is homogeneously composed with or77 - or80 and FeO concentrations between 0.48 and 0.95 wt.%. Compared with the sanidines of the Roman Province the lamproitic feldspars contain less Na<sub>2</sub>O and BaO and higher K<sub>2</sub>O. The sanidine composition is typically for lamproites (Mitchell & Bergman 1991). The REE patterns of the sanidines show a great variability of enrichment, which is caused by enclosed apatites. The apatites are highly enriched in REE so that small amounts of apatite can overprint the REE patterns of the sanidines. Using distribution coefficients of Francalanci et al. (1987) and Wörner et al. (1983) a maximum content of apatite of about 1.5 wt.% in the sanidines can be calculated.

Sanidines are also common phases of the groundmass of the Torre Alfina lavas. They are comparable to the lamproitic sanidines with high orthoclase contents (or80 - or83), low Na<sub>2</sub>O (~ 1.4 wt.%) and CaO (0.8 - 1.4 wt.%) concentrations as well as low BaO concentrations (below the detection limit of the electron microprobe). The REE content of the sanidines is heterogeneous what may be caused by inclusions of apatites as it is observed for the Oricatico lamproites.

In the Radicofani rocks sanidines are absent.

#### 4.1.3.5 Plagioclases

In the Vulsinian rocks plagioclase is a common phase of the groundmass and occurs sometimes as larger crystals (mm-scale). The anorthite content of the plagioclases from the different Vulsinian rocks range between 76 - 95 mol% for the HKS and 45 - 84 mol% for the KS, respectively. Besides the lower anorthite content KS plagioclases differ from HKS plagioclases by lower Fe contents. Minerals of both series are characterized by high Sr (0.18 - 1.1 wt.%) and relatively high Ba contents (170 - 4000 ppm). The plagioclases show the feature that LREE are more enriched than HREE resulting in a continuously decreasing curve. The HREE are sometimes below the detection limit. All plagioclases show a positive Eu anomaly. Sometimes the plagioclases display an uncommon REE pattern, which is caused by embedded apatites with high REE concentrations. The amount of apatite, which is necessary to produce the uncommon REE patterns of the plagioclases, can be calculated. For this calculation the REE concentrations of the plagioclases is computed using the bulk rock

concentrations of REE and the distribution coefficients of Wörner et al. (1983). A maximum amount of 2 wt.% apatite enclosed in the plagioclases may be responsible for the REE patterns.

Plagioclases from the Radicofani rocks occur as small laths and display a weak oscillatory zoning. The anorthite component ranges between 69 - 87 mol%. Ba concentrations are between 70 - 190 ppm and Sr between 450 - 1000 ppm. Therefore they are depleted in Ba and Sr compared to Roman Province plagioclases. Normalized to the bulk rock the REE with the exception of Eu are depleted in the plagioclases. The HREE are often below the detection limit. Sometimes analysis of plagioclases were distorted by enclosed apatites containing high REE concentrations.

Lamproites as well as the Torre Alfina rocks do not contain plagioclases.

#### **4.1.3.6 Leucites**

Leucites only occur as phenocrystals in the evolved rocks of the HK series from the Vulsinian mountains. In the less evolved rocks they are only present as a groundmass constituent. The minerals are rather homogeneous in composition. Low FeO and high Na<sub>2</sub>O contents are a characteristic feature of Roman Province leucites (Conticelli et al. 1997). The leucites contain low REE concentrations with an enrichment of LREE and a depletion of HREE relative to chondritic values. The HREE are often below the detection limit. But the analyses are often influenced by enclosed apatites. Another feature is the varying Rb, Sr, and, Ba content of the leucites from different localities of the Vulsinian mountains.

#### **4.1.3.7 Micas**

According to Deer et al. (1996) the distinction between biotites and phlogopites has been carried out on the basis of Mg / Fe ratios. Phlogopites contain Mg / Fe > 2 and biotites < 2.

Phlogopites are common minerals of lamproites but are rarely found in the Roman Province type rocks. Only sample VUL 9702, a phonotephrite, contains phlogopite in the groundmass. Phlogopites display dissolution processes at their crystal rim pointing to a xenocrystic origin. Compared to lamproitic micas Vulsinian phlogopites contain lower TiO<sub>2</sub>, BaO, and SiO<sub>2</sub> and higher Al<sub>2</sub>O<sub>3</sub> contents. Low Ti contents and low K / Al ratios indicate a high pressure (Foley 1990), although differentiation may also affect the mica composition. Si and Al are sufficient to fill the tetrahedra site and K + Na are also sufficient to fill the interlayer site, completely. In summary the phlogopites have preserved their characteristic features of a higher pressure origin compared to lamproitic micas but probably are of xenocrystic origin.

Phlogopites from the Orciatice lamproite are fairly homogeneous in their composition with minor core - rim variations and a BaO decrease to the mineral rim (fig. 4-13). They have high

concentrations of  $\text{TiO}_2$ ,  $\text{BaO}$ , and  $\text{MgO}$  and low contents of  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ , and  $\text{Cr}_2\text{O}_3$ . The content of  $\text{K} + \text{Na}$  is not sufficient to fill the interlayer sites completely. Low  $\text{K}$  and  $\text{Na}$  contents are typical for lamproitic phlogopites but the  $\text{Si}$  and  $\text{Al}$  contents are high enough to fill the tetrahedral site completely - what is uncommon for lamproitic phlogopites (Conticelli et al. 1992, Wagner & Velde 1986). Mitchell et al. (1987) believed, that a negative correlation of  $\text{Al}$  and  $\text{Ti}$  is a specific characteristic feature of the evolution of micas in lamproites. In contrast the Orciatico phlogopites show a weak positive correlation between both elements, what is also observed in Spanish lamproites (Venturelli et al. 1988). Venturelli et al. (1988) and Conticelli et al. (1992) suggested the bulk rock composition to be the important factor controlling the behaviour of  $\text{Al}$ ,  $\text{Fe}$ ,  $\text{Mg}$  and  $\text{Ti}$  in the micas. With regard to the physico-chemical conditions of crystallization  $\text{Ti}$  solubility in phlogopite is considered to depend on pressure (Trönnnes et al. 1985, Foley 1990), whereas  $\text{K} / \text{Al}$  ratios reflect variations in oxygen fugacity (Foley 1989). Therefore the phlogopites from Orciatico crystallized in a narrow  $p$ - $T$  range at relatively low pressure and high temperature (Conticelli et al. 1992).

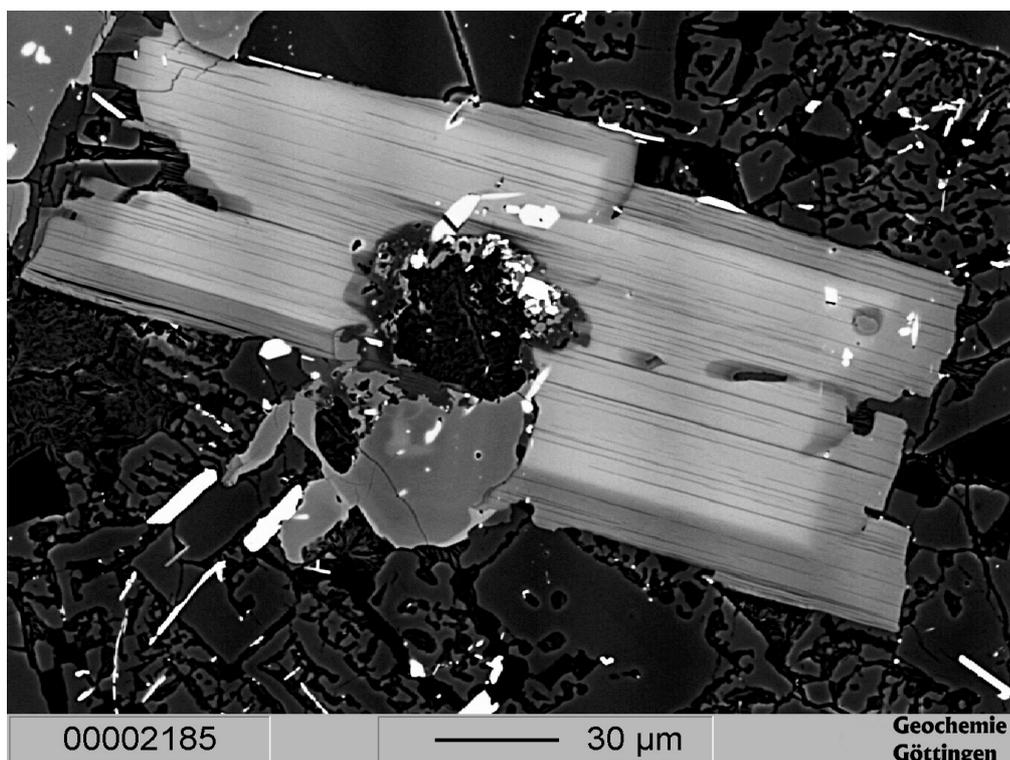

Fig. 4-13: EMPA image (composition mode) of a phlogopite from Orciatico lamproite (ORC 9701).

Micas of the ultramafic xenolith from Torre Alfina are phlogopites with only a minor chemical variation. Compared to phlogopites in lamproites from Orciatico the micas from the ultramafic xenolith contain similar contents of  $\text{SiO}_2$ , lower concentrations of  $\text{TiO}_2$  and  $\text{FeO}$  and higher concentrations of  $\text{Al}_2\text{O}_3$  and  $\text{Cr}_2\text{O}_3$ . But their chemical composition still falls in the range of mantle phlogopites (Conticelli & Peccerillo 1990). Normalized to chondritic

values REE are enriched with a higher enrichment of the LREE than the HREE. But compared to the REE contents of the host rock the phlogopites of the ultramafic xenolith contain the same abundance of REE. In contrast to micas from the ultramafic xenolith micas from the bulk rock can be subdivided into two groups. The first group are phlogopites with same or similar composition of the ultramafic xenolith phlogopites. The phlogopites show resorption edges and reaction rims with the surrounding melt. These features indicate a xenocrystic origin of the micas resulting from the disintegration of ultramafic xenoliths. The second group of micas are more variable in composition and have a biotitic composition. For these micas a crystallization within the magma can be assumed. The  $\text{TiO}_2$  content is similar to the lamproitic phlogopites whereas the  $\text{SiO}_2$  and  $\text{Al}_2\text{O}_3$  contents and K / Al ratios correspond to phlogopites from Roman Province type rocks. Biotites are higher enriched in REE than phlogopites of the ultramafic xenolith. Additionally LREE / HREE ratios of the biotites are higher.

#### 4.1.3.8 Oxides

Oxides of the HKS are Ti-magnetite with variable ulvöspinel and magnesioferrite content. Some samples display spinels with a narrow range in composition whereas other rocks have oxides with a wider range. Oxides of the KS are spinels with a lower magnetite content or magnesioferrite and spinel sensu stricto.

In the Orciatico lamproites oxides are represented by ilmenite and spinel. Ilmenites contain relatively high MgO contents whereas spinels are characterized by high FeO and high  $\text{Cr}_2\text{O}_3$  concentrations and are believed to represent a liquidus phase (Conticelli et al. 1992).

Spinel is a common oxide in the ultramafic xenolith from Torre Alfina. It is  $\text{Cr}_2\text{O}_3$  (54.7 - 58.3 wt.%) and FeO (17.6 - 22.0 wt.%) rich. Spinel of the bulk rock is  $\text{Cr}_2\text{O}_3$  (63.8 - 65.7 wt.%) and FeO (10.1 - 14.2 wt.%) rich, too. Additionally ilmenites occur in the lavas.

In the Radicofani rocks ilmenite and spinel occur in the groundmass.

#### 4.1.3.9 Apatites

Apatite is a common component in the Tuscan and Roman rocks. REE analysis of feldspars from the Vulsinian mountains and the Orciatico lamproites were distorted by enclosed apatites. In order to calculate the influence of apatites on the REE analysis of the feldspars the concentration of La, Ce, Pr, and Nd of the apatites were measured. Apatites from both rock types - lamproites and Roman Province type rocks - contain high REE concentrations, e.g. up to 1.24 wt.%  $\text{Ce}_2\text{O}_3$  for the Vulsinian rocks and up to 1.76 wt.%  $\text{Ce}_2\text{O}_3$  for the lamproites.

#### 4.1.4 Oxygen Isotopes

From the Vulsinian mountains clinopyroxenes were analyzed in all samples and, when possible, plagioclase and olivine, too. Olivines only occur in the KS samples and in the less evolved sample from the HKS (sample Montefiascone). HKS clinopyroxenes display a positive trend of increasing  $\delta^{18}\text{O}$  values with increasing  $\text{SiO}_2$  content of the bulk rock from 7.6 ‰ up to 8.9 ‰. The observed range of  $\delta^{18}\text{O}$  values nearly coincides with the range of 7.8 - 9.4 ‰ for primary  $\delta^{18}\text{O}$  values of the Vulsinian rocks suggested by Holm & Munksgaard (1982). With 7.4 - 7.6 ‰ KS clinopyroxenes display the same values as the less evolved sample of the HKS indicating the same  $\delta^{18}\text{O}$  values of the source. But KS clinopyroxenes show a large variation in oxygen isotope ratios ranging from 6.9 to 8.3 ‰. This inhomogeneity may be a result of some enclosed old inherited clinopyroxene cores, which may differ in their  $\delta^{18}\text{O}$  composition from the other clinopyroxenes. But these cores were too small to be analyzed.

$\delta^{18}\text{O}$  values of olivines of the less evolved HKS rock are 6.7 ‰ and for the KS rocks 7.0 ‰ and 7.1 ‰, respectively. These and the clinopyroxene values are too high for a melt derived from a primary unmodified mantle (Harmon & Hoefs 1995, Hoefs 1997, Matthey et al. 1994). Normal mantle values for olivines are about 5.2 ‰ (Hoefs 1997, Matthey et al. 1994). Oxygen isotope fractionations between olivines and clinopyroxenes agree with the high temperatures of the melts (Chiba et al. 1989, Zheng 1993).

Plagioclases from Vulsinian rocks display  $\delta^{18}\text{O}$  values from 9.5 to 12.1 ‰. Only the plagioclases of the sample VUL 9701 with 9.6 ‰ are in isotopic equilibrium with the clinopyroxenes (8.9 ‰). The fractionation of  $\delta^{18}\text{O}$  values between clinopyroxenes and plagioclases of the two samples VUL 9705 and Montefiascone are too large for magmatic processes indicating a disequilibrium (Chiba et al. 1989, Matthews et al. 1983, Zheng 1993). Therefore the isotopic composition of the plagioclases may have changed during secondary low temperature processes.

The case of plagioclase clearly shows that it is necessary to analyze phenocrystals for estimating the oxygen isotopic composition of the less evolved rocks and the source. Bulk rock data may be affected by such secondary processes and result in too high values. For example Turi & Taylor (1976) measured a range of 8.1 - 11.7 ‰ for the Vulsinian rocks using bulk rock data, which are higher than the values of Holm & Munksgaard (1982) or of this work. However Turi & Taylor (1976) also found an augite with 7.08 ‰.

The lamproites are relatively fine grained, so that only few oxygen isotope analyses could be carried out for the sample ORC 9701. Olivines display  $\delta^{18}\text{O}$  values of 7.2 ‰ and sanidines in the groundmass of 11.1 ‰. The olivine values are too high for a melt generated in an

unmodified mantle. Additionally the oxygen isotope fractionation of 3.9 ‰ between sanidines and olivines is too high for magmatic processes (Zheng 1993). Therefore it seems plausible, that the oxygen isotope ratios of the groundmass sanidines are modified by low temperature alteration processes such as an oxygen isotope exchange with a fluid. Olivines itself display no characteristic feature of a low temperature reaction with a fluid. Compared to the less evolved Vulsinian rocks olivines of the lamproites approximately show the same  $\delta^{18}\text{O}$  values indicating a similar  $\delta^{18}\text{O}$  composition of the source.

For the Torre Alfina rocks oxygen isotope investigations have been done on an ultramafic xenolith, a crustal xenolith and on olivines from the samples TA 9701 and TA 9702.

The ultramafic xenolith displays heterogeneous  $\delta^{18}\text{O}$  compositions of the olivines with increasing values from the core of the xenolith to its rim (fig. 4-14). The total range lies between 5.9 ‰ and 10.9 ‰. In the centre, olivines are also variable with  $\delta^{18}\text{O}$  values of 5.9 - 7.4 ‰. Additionally an orthopyroxene could be analyzed with 8.8 ‰. Unmodified mantle minerals have lower  $\delta^{18}\text{O}$  values with 5.2 - 5.4 ‰ for olivines and about 5.9 ‰ for orthopyroxenes (Hoefs 1997, Matthey et al. 1994).

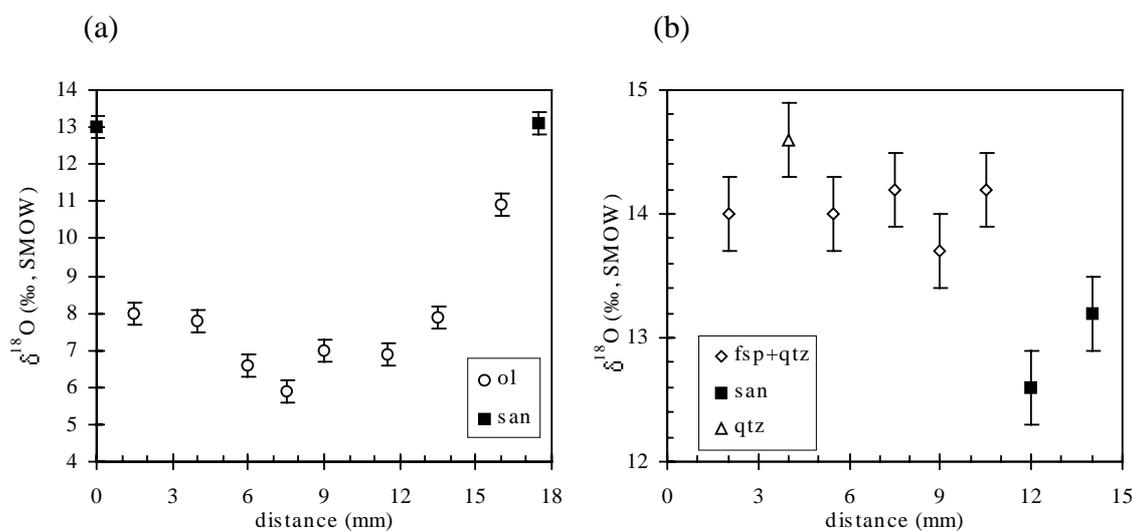

Fig. 4-14: Traverse of oxygen isotope ratios in a peridotitic xenolith (a) and a crustal xenolith (b) from the Torre Alfina group A lavas (Barnekow et al. 1998). Sanidines are from the groundmass of the host rock. Fsp+qtz means a fine grained feldspar quartz intergrowth of the crustal xenolith. For diagram 4-8 a the analytical error is in the range of the symbol size.

A crustal xenolith consisting of a larger quartz crystal embedded in a fine grained intergrowth of feldspar and quartz does not show any inhomogeneity (fig. 4-14). The quartz has an  $\delta^{18}\text{O}$  value of 14.6 ‰ and the fine grained groundmass of 13.7 - 14.2 ‰.

From the sample TA 9701 larger olivines could be analyzed. They also show a wide range of composition from 5.3 ‰ to 9.1 ‰. Therefore minerals are not in equilibrium with the bulk

rock. The chemical composition indicate a xenocrystalline origin from the disintegration of ultramafic xenoliths, which is supported by the  $\delta^{18}\text{O}$  values. The sanidine groundmass has a  $\delta^{18}\text{O}$  value of 13.1 ‰. This value agree well with two bulk rock data by Ferrara et al. (1986b), who calculated the oxygen isotope ratios with 13.26 and 13.80 ‰, respectively.

The sample TA 9702 is fine grained, so that only two separated olivines could be analyzed with the  $\text{CO}_2$  laser at the University of Bonn. These two olivines show typical mantle values of 5.3 ‰ and 5.5 ‰, respectively.

From Radicofani only few minerals could be analyzed from each sample, because of the small size of the phenocrystals. Mostly olivines have been analyzed and in the case of the sample RAD 9702 A also clinopyroxenes have been investigated. In the other samples the clinopyroxenes were always too small.

All samples from Radicofani display a very homogeneous composition of the oxygen isotope ratios. The range of  $\delta^{18}\text{O}$  values of olivines lie between 7.1 - 7.4 ‰. This difference is within the reproducibility of the LA-SIRMS. In the sample RAD 9702 A clinopyroxenes contain slightly higher  $\delta^{18}\text{O}$  values of 7.4 ‰ compared to the olivines with 7.1 ‰. Even this difference is within the error of the measurement. Despite the inaccuracy of the  $\Delta$  value between clinopyroxenes and olivines the temperature of the melt can roughly estimated as being around or above 1000 °C but a large error must be taken into account (fractionating equations of Chiba et al. 1989, Zheng 1993). Generally for a mantle derived melt these  $\delta^{18}\text{O}$  values are also too high and indicate an  $^{18}\text{O}$  enriched mantle source.

Comparing the different genetic mantle types  $\delta^{18}\text{O}$  values of olivines are similar within the reproducibility ( $\pm 0.3\text{‰}$ ) of the LA-SIRMS: Orciatico lamproite 7.2 ‰, Roman Province HK series 6.7 ‰, Roman Province K series 7.0 - 7.1 ‰ and Radicofani 7.1 - 7.4 ‰. Compared to olivines from an unaffected mantle these values are considerably higher.

## 4.2 Crustal Derived Rocks

### 4.2.1 Introduction

Crustal anatectic melts are widely distributed in the Tuscan Province and occur as volcanic and plutonic rocks (e.g. Innocenti et al. 1992, Peccerillo et al. 1987). Two rhyolite localities have been sampled. The first locality is Roccastrada, where two samples from a lava flow have been sampled (ROC 9701 and ROC 9702) and San Vincenzo is the second. San Vincenzo rhyolites have relatively low SiO<sub>2</sub> contents, so that they were sometimes classified as rhyodacites (Peccerillo et al. 1987). After Ferrara et al. (1989) San Vincenzo rhyolites can be subdivided into two groups according to their MgO content. Group A contains less than 0.61 wt.% MgO and group B more than 0.75 wt.%. Both groups also have different Sr concentrations with less than 140 ppm for group A and more than 200 ppm for group B. Group A rhyolites are characterized by plagioclase, sanidine, quartz, biotite, and cordierite assemblages. In contrast group B rhyolites additionally contain sometimes clinopyroxenes, orthopyroxenes, and magmatic inclusions (Ferrara et al. 1989).

### 4.2.2 Whole Rock Chemistry

Roccastrada rhyolites are the most SiO<sub>2</sub> enriched volcanic rocks of the Tuscan Province (Taylor & Turi 1976) with up to 74.5 wt.% SiO<sub>2</sub>. They are peraluminous with corundum as a norm-mineral. Compared to the Roccastrada rocks rhyolites from San Vincenzo contain less SiO<sub>2</sub> (68.5 - 69.6 wt.%). Rhyolites of both groups have been sampled, sample SVC 9703 (MgO = 0.52 wt.%, Sr = 105 ppm) belongs to group A and samples SVC 9701 (MgO = 0.78 wt.%, Sr = 190 ppm) as well as SVC 9702 (MgO = 0.72 wt.%, Sr = 260 ppm) can be assigned to group B.

Compared to mantle derived rocks trace element concentrations are low. REE are enriched less than 100 fold chondritic with a higher enrichment of the LREE than the HREE (fig. 4-15). Also a negative Eu anomaly is visible indicating the influence of plagioclase in the source or crystal fractionation of plagioclase. REE patterns of San Vincenzo rhyolites (fig. 4-15) are similar to REE patterns of Roccastrada rhyolites but group A rhyolite (SVC 9703) is less enriched in HREE. Rhyolites of group B (SVC 9701, SVC 9702) are higher enriched compared to group A rhyolite and are also higher enriched in LREE compared to Roccastrada samples. The multi element diagram of the rhyolites is typical for crustal derived rocks with a similar pattern for both Roccastrada and San Vincenzo rocks (fig. 4-16).

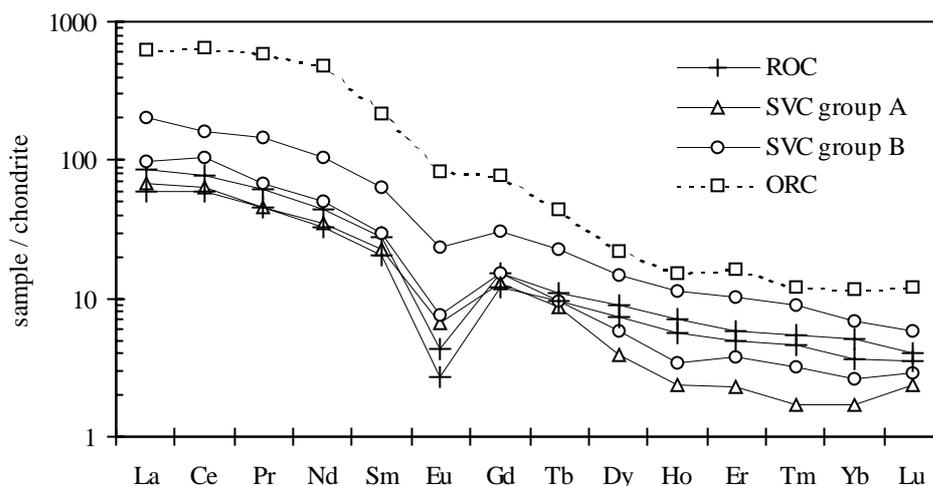

Fig. 4-15: Chondrite normalized (values from Anders & Grevesse 1989) REE patterns of the rhyolites (ROC: Roccastrada, SVC: San Vincenzo). For comparison a lamproite from Orciatico is shown (ORC).

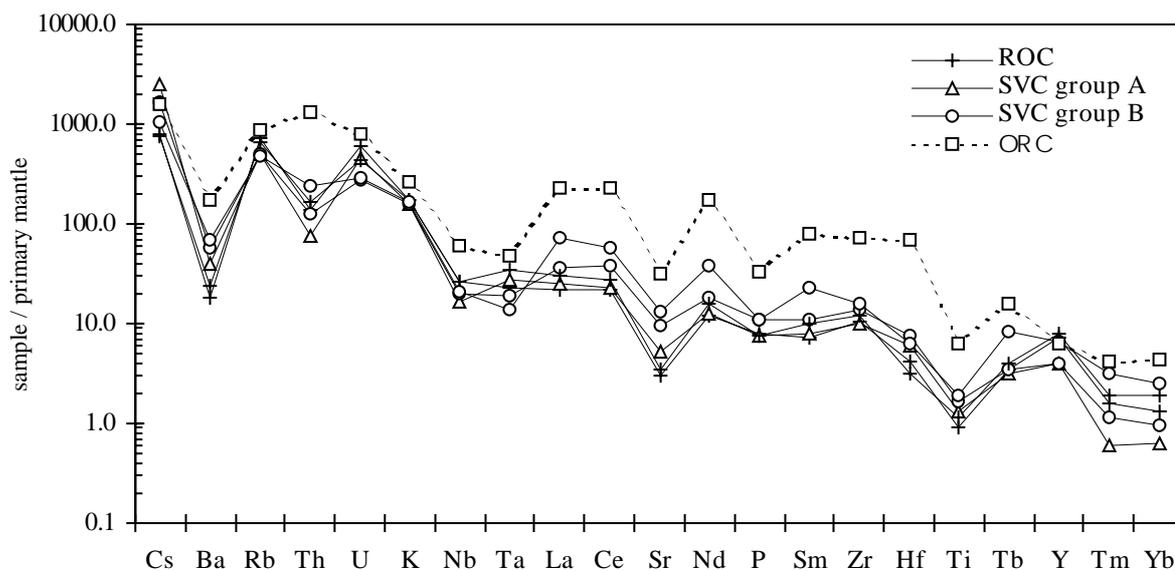

Fig. 4-16: Multi element diagram of the rhyolites (ROC: Roccastrada, SVC: San Vincenzo). Elements are normalized to primary mantle (values of McDonough & Sun 1995). For comparison the normalized concentrations of one Orciatico lamproite are shown.

### 4.2.3 Mineral Chemistry

The investigation has focussed on one sample (ROC 9701) from Roccastrada and on one sample of each group from San Vincenzo (SVC 9702, SVC 9703).

Groundmasses of the rhyolites are vitreous or microcrystalline. Phenocrystals in the Roccastrada rhyolites are plagioclase, sanidine, quartz, and biotite. Accessory phases and important trace element carriers of the bulk rock are zircon, apatite, and monazite. San Vincenzo rhyolites also contain plagioclase, sanidine, quartz, and biotite as phenocrystals and sample SVC 9703 additionally contain cordierite.

#### 4.2.3.1 Plagioclases

Plagioclases from Roccastrada show a slightly oscillatory zoning. The anorthite content varies between an<sub>57</sub> and an<sub>72</sub>. Sr contents are between 280 and 550 ppm and Ba between 10 and 120 ppm. Contrary REE concentrations are relatively constant with a decreasing enrichment of 190 fold chondritic for La and 1 fold for Yb (fig. 4-17). A positive Eu anomaly is well shaped.

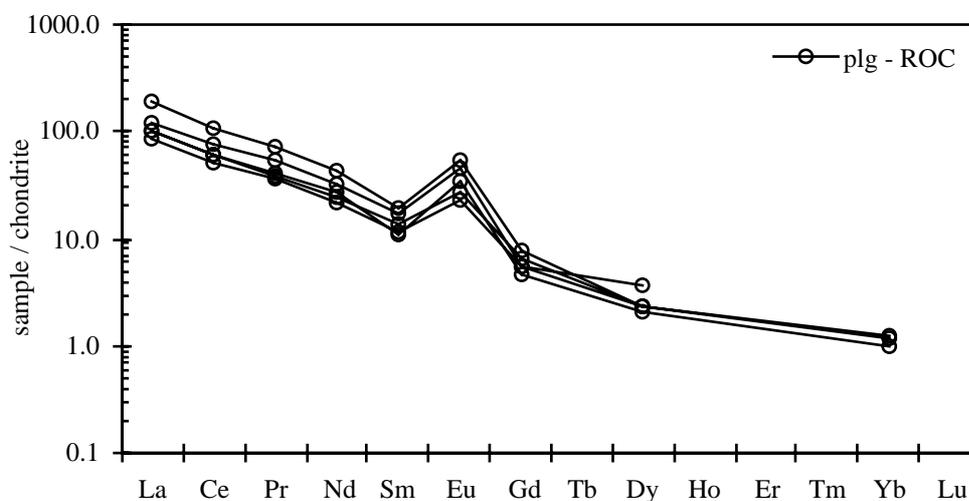

Fig. 4-17: Chondrite normalized REE patterns of plagioclases from Roccastrada (normalizing values from Anders & Grevesse 1989).

San Vincenzo plagioclases also display an oscillatory zoning with a Ca rich core and a decreasing anorthite component to the mineral rim. Plagioclases from group A are less calcic with a narrow range of composition from an<sub>48</sub> in the core to an<sub>37</sub> at the mineral rim. Group B plagioclases show a wider range of composition between an<sub>59</sub> in the core and an<sub>32</sub> at the rim. Feldstein et al. (1994) observed a larger range of plagioclase compositions. When normalizing REE concentrations of the plagioclases to the bulk rock concentration the patterns are chaotic

with different degrees of enrichment or depletion and positive or negative Eu anomalies. Sample SVC 9702 shows LREE / HREE ratios of more and less than 1, whereas sample SVC 9703 only contains ratios lower than 1. These uncommon REE patterns are caused by enclosed apatites with high REE contents - LREE / HREE ratios of below 1 indicate this, too. Using the partitioning coefficients of Arth (1976) and Nash & Crecraft (1985) REE concentrations of the plagioclases can roughly be calculated and therefore the amount of apatite, which is necessary to produce the observed REE patterns. The Ce contents has been used for this calculation. For SVC 9702 a maximum value of 5 wt.% and for SVC 9703 of 1 wt.% of enclosed apatites within the plagioclases is necessary to produce the resulting REE patterns.

#### 4.2.3.2 Sanidines

Sanidines from Roccastrada are homogeneous with a composition of about or70 - ab29 - an01. Ba concentrations up to 2100 ppm are higher than in plagioclases and Sr is in the range of 130 - 320 ppm. The REE are less enriched showing a positive Eu anomaly. HREE concentrations are often below the detection limit.

Sanidines from San Vincenzo also show minor chemical variations. The orthoclase component of sample SVC 9702 is similar to the Roccastrada sample with or72 - or 77, whereas sanidines from sample SVC 9703 display a lower orthoclase component (or55 - or61). Feldstein et al. (1994) found inclusions of biotite and plagioclase oriented parallel to the crystal faces. These textures point to a magmatic origin of sanidines in the San Vincenzo rhyolites (Wall et al. 1987). But in the rhyolites investigated for this study these textures could not be observed. Normalizing REE concentrations to bulk rock composition the REE patterns are flat with a small decrease to the HREE and a positive Eu anomaly. Sample SVC 9702 is less enriched in REE with 0.3 - 1.1 times the value of the bulk rock for La. The composition seems to be heterogeneous but concentrations are near the detection limit of the LA-ICP-MS, so that a larger standard deviation has to be taken into account. The REE patterns of sample SVC 9703 are similar with a higher enrichment, e.g. La 2.3 - 3.4 fold the bulk rock. These values are uncommonly high, because the partition coefficient of the  $REE_{\text{sanidine}} / REE_{\text{bulk rock}}$  is normally below 1 with the exception of Eu (Arth 1976, Nash & Crecraft 1985, Mahood & Hildreth 1983). Although apatites with high REE contents are sometimes enclosed in sanidines, the relatively high REE concentrations of sanidines can not solely be influenced by apatites, because the REE patterns of the sanidines show a positive Eu anomaly and apatites do not display positive Eu anomalies (Arth 1976, Fujimaki 1986).

#### 4.2.3.3 Biotites

Biotites are common phenocrystals in the rhyolites from both localities. But their chemical composition differs, Roccastrada biotites are MnO rich and MgO poor whereas biotites from San Vincenzo are MnO poor and MgO rich. REE concentrations are highly variable and may result from inclusions (Giraud et al. 1986).

#### 4.2.3.4 Cordierites

Cordierites were found in sample SVC 9702 from San Vincenzo. They display zonation with Mg values from 43 - 73, which is a wider range than observed by Feldstein et al. (1994). In a detailed study of cordierites Feldstein et al. (1994) showed, that some cordierites have textures of a restitic or xenocrystalline origin whereas other cordierites have textures pointing to a magmatic origin (Clemens & Wall 1984, Wall et al. 1987). Clemens & Wall (1981, 1984) showed that cordierite can crystallize as a solidus phase in peraluminous magmas.

#### 4.2.3.5 Ilmenites

Ilmenite is a common oxide mineral in the rhyolites.

#### 4.2.3.6 Apatites

Apatites are important REE containing minerals with high REE concentrations, e.g.  $\text{Ce}_2\text{O}_3$  between 0.157 - 0.244 wt.% for San Vincenzo rhyolites. Because some apatites are embedded in feldspars they can influence the REE signatures of the feldspars.

#### 4.2.4 Oxygen Isotopes

Phenocrystals of quartz, sanidine, and plagioclase from all rhyolitic samples has been analyzed. Additionally orthopyroxenes from sample SVC 9701 could be analyzed. The values are shown in fig. 4-18 and fig. 4-19.

The two samples from Roccastrada rhyolites have similar  $\delta^{18}\text{O}$  values within the reproducibility of the LA-SIRMS ( $\pm 0.3$  ‰). Differences of  $\delta^{18}\text{O}$  values between quartz, sanidine, and plagioclase are in a typical range for volcanic rocks. Therefore the minerals are in isotopic equilibrium with respect to oxygen. Also minerals of the San Vincenzo group A rhyolite (SVC 9703) are homogeneously composed and are in equilibrium. In contrast two samples from group B rhyolites from San Vincenzo display a large range of  $\delta^{18}\text{O}$  values indicating a disequilibrium. For example  $\delta$  values of the sample SVC 9701 vary between 13.3 - 15.7 ‰ for quartz and 10.8 - 14.6 ‰ for plagioclase so that some plagioclases have higher  $\delta^{18}\text{O}$  values than quartz. This heterogeneity of oxygen isotope ratios cannot be produced by fractional crystallization of a melt.

However the high  $\delta^{18}\text{O}$  values of  $> 10 \text{ ‰}$  for feldspars and  $> 11 \text{ ‰}$  for quartzes from all rhyolites are typical for melts of crustal anatectic origin. Differentiation products of mantle melts cannot reach such high values (Hoefs 1997, Sheppard & Harris 1985).

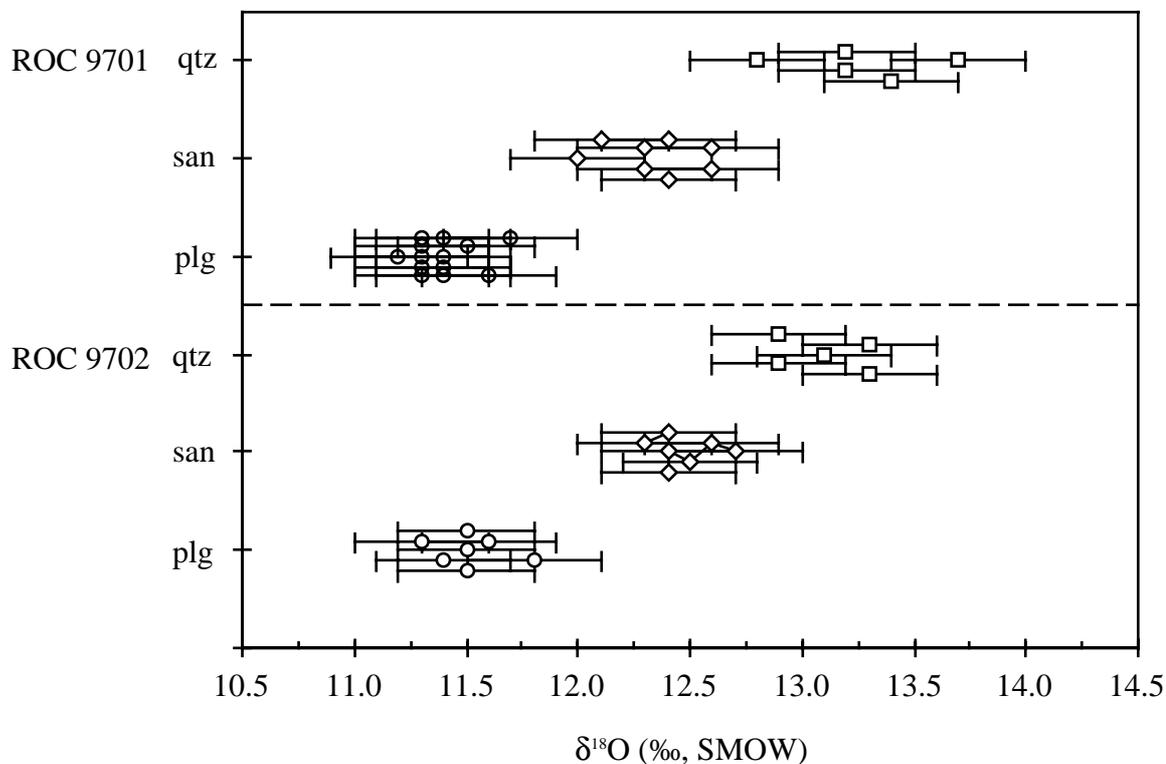

Fig. 4-18: Oxygen isotope ratios of phenocrystals of the rhyolites from Roccastrada.

Analyzed  $\delta^{18}\text{O}$  values correspond well with data from the literature. Taylor & Turi (1976) analyzed one quartz with  $13.09 \pm 0.08 \text{ ‰}$  and one K-feldspar with  $12.03 \pm 0.05 \text{ ‰}$  from Roccastrada rhyolites. In this study values of 13.3 / 13.1 ‰ for quartz and 12.3 / 12.5 ‰ for sanidines were measured for samples ROC 9701 / ROC 9702. By comparison Taylor & Turi (1976) investigated one quartz (13.90 ‰) and one K-feldspar (13.05 ‰) from a San Vincenzo rhyolite but their sample could not be assigned to one of the two groups. Masuda & O'Neil (1994) carried out a  $\text{CO}_2$  laser microprobe investigation on one rhyolite, presumably belonging to group B. They found  $\delta^{18}\text{O}$  values of 13.9 - 14.3 ‰ for quartz, 12.1 - 14.6 ‰ for alkali feldspar and 11.9 - 13.8 ‰ for plagioclase within a small rock section. This range of  $\delta$  values for alkali feldspars and plagioclases indicates an oxygen isotopic disequilibrium.

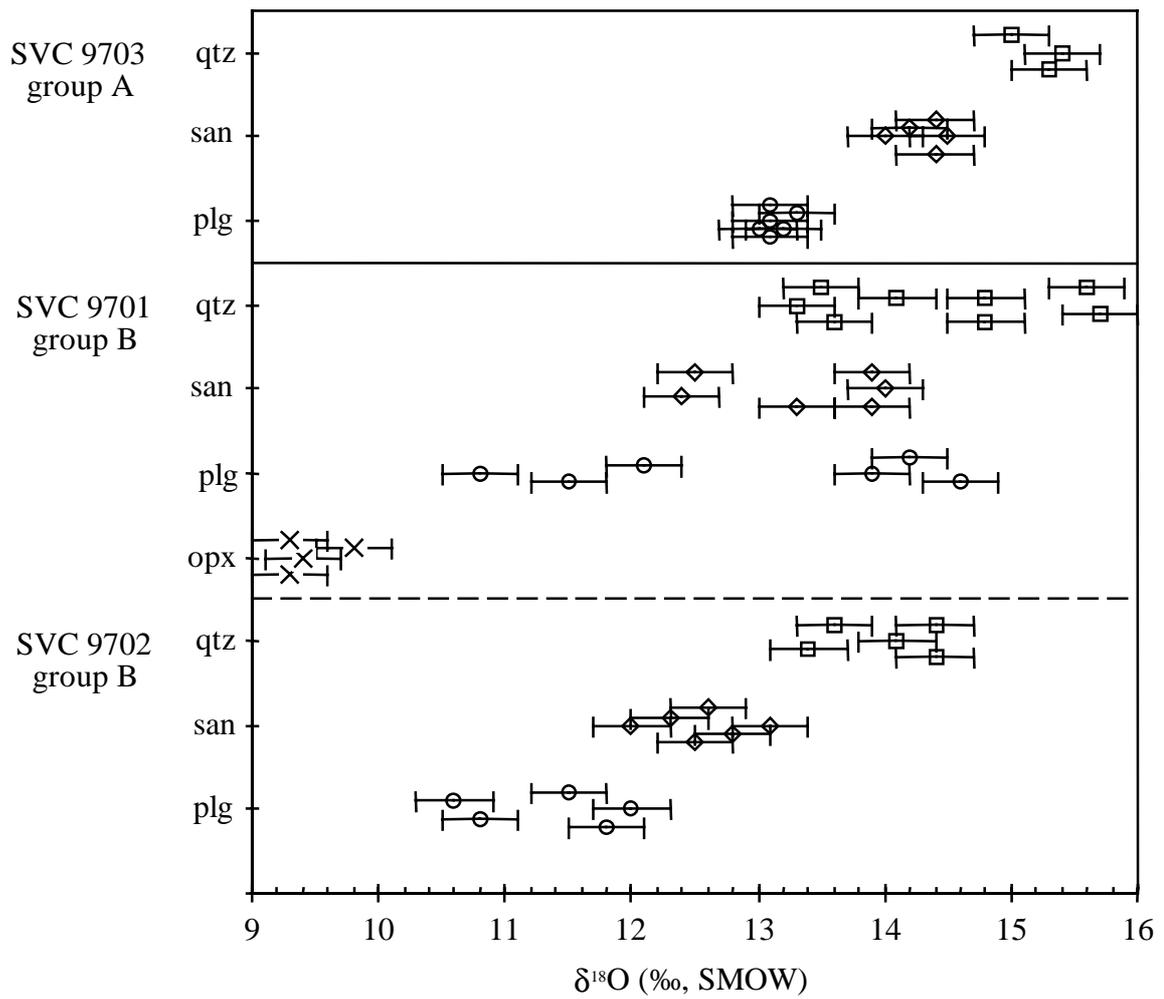

Fig. 4-19: Oxygen isotope ratios of phenocrystals of group A and B rhyolites from San Vincenzo.

### 4.3 Hybrid Rocks Between Mantle and Crustal Melts

#### 4.3.1 Introduction

In the Tuscan Province rocks derived from mixtures between mantle and crustal melts can be observed. These mixtures are classified as hybrid rocks (Peccerillo et al. 1987). At Monte Amiata trachytic and mafic rocks as well as mafic xenoliths occur indicating magma mixing between a crustal and a mantle melt (e.g. van Bergen et al. 1983, Poli et al. 1984). Therefore Monte Amiata rocks have been sampled as representatives of hybrid rocks.

#### 4.3.2 Whole Rock Chemistry

To cover the whole chemical range of Monte Amiata rocks two trachytes and two latites (AMT 9704 A, B) from the late stage Ermeata lava flow (on top of Monte Amiata) have been sampled. Also two xenoliths from trachyte AMT 9702 have been investigated. These xenoliths have a shoshonitic (AMT 9703 I) and latitic (AMT 9703 II) composition.

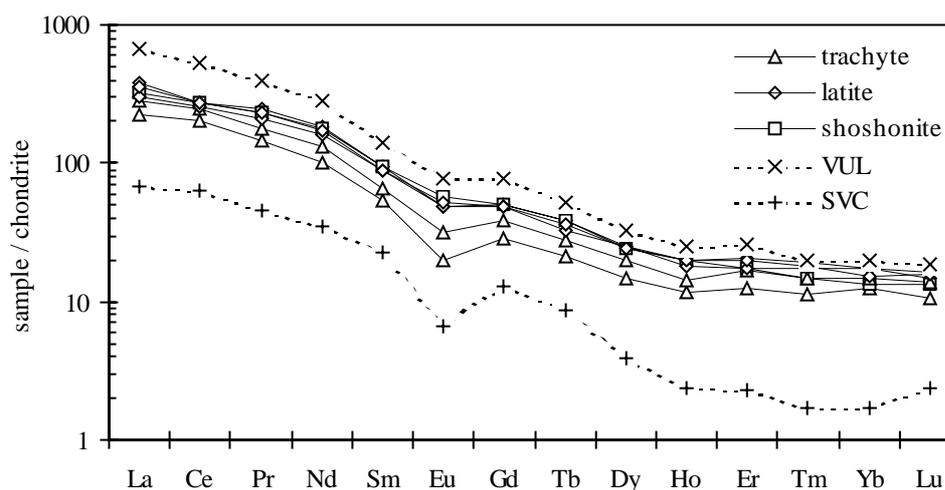

Fig. 4-20: Chondrite normalized REE patterns of Monte Amiata rocks (normalizing values from Anders & Grevesse 1989). For comparison a less evolved rock from the Vulsinian mountains (VUL) and a rhyolite from San Vincenzo (SVC) is shown.

Rocks from Monte Amiata thus range from shoshonites to trachytes (fig. 2-2). Trachytes and latites are  $\text{SiO}_2$  oversaturated with quartz in the norm whereas the shoshonitic xenolith lies at the boundary between  $\text{SiO}_2$  saturated to undersaturated rocks. The major element chemistry of trachytes is similar to San Vincenzo rhyolites with slightly higher  $\text{MgO}$ ,  $\text{CaO}$ ,  $\text{K}_2\text{O}$  and  $\text{TiO}_2$  and lower  $\text{Na}_2\text{O}$  contents. Contrary the shoshonite is similar to less evolved rocks from the Vulsinian mountains but with slightly lower  $\text{Al}_2\text{O}_3$  contents. Latites have an intermediate composition between shoshonite and trachytes. Both the shoshonite and the latites are ultrapotassic rocks.

REE concentrations and patterns (fig. 4-20) are similar to the Vulsinian rocks. For SiO<sub>2</sub> rich rocks like trachytes REE patterns can be produced by a mixture of Vulsinian and rhyolitic melts like the San Vincenzo rhyolites. Trace element patterns (fig. 4-21) reflect this mixing. Latites and the shoshonite contain trace element concentrations similar to the Vulsinian rocks.

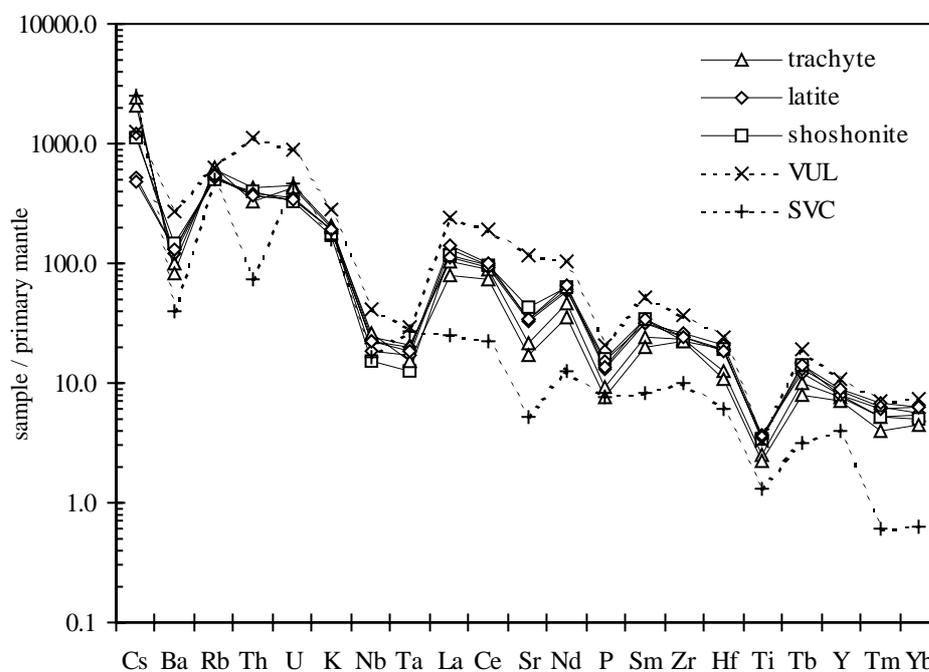

Fig. 4-21: Primary mantle normalized multi element diagram for Monte Amiata rocks (normalizing values are taken from McDonough & Sun 1995). For comparison a less evolved rock from the Vulsinian mountains (VUL) and a rhyolite from San Vincenzo (SVC) is plotted.

### 4.3.3 Mineral Chemistry

Mineral compositions have been analyzed in three samples: trachyte - AMT 9702, latite AMT 9704 A, shoshonite - AMT 9703 II. The trachyte consists of sanidine and quartz as major phenocrystals and minor amounts of plagioclases, biotites, orthopyroxenes, and oxides. The latite and shoshonite samples display a fine grained groundmass. Major phenocrystals are clinopyroxenes and sanidines in the shoshonite and clinopyroxenes and plagioclases in the latites. Less abundant minerals are micas and oxides in both rocks as well as sanidines in the latite.

### 4.3.3.1 Clinopyroxenes

Clinopyroxenes occur as phenocrystals in the latite and the shoshonitic xenolith. They display an oscillatory zoning. According to the classification of Morimoto (1989) clinopyroxenes in the latite are diopsides, except the outer part of the mineral rim, which have an augitic composition with a wollastonite component slightly lower than 45 mol% (fig. 4-22). Cores are Mg rich with Mg values of 92 (AMT 9704 A) and 88 (AMT 9703 II), respectively. Towards the mineral rim the Mg content decreases to Mg values of 56 (AMT 9704 A) and 52 (AMT 9703 II). Si and Al are sufficient to fill the tetrahedral site with Al in the M1 site as it is typically for Roman Province type rocks. Also the Ca deficiency is similar to the Vulsinian rocks. In contrast Ca and Fe do not correlate positively but Mg and Ti correlate negatively. Compared with Vulsinian clinopyroxenes Monte Amiata clinopyroxenes contain similar Ti and Al<sup>IV</sup> for rocks with the same Mg / (Mg + Fe) ratios. Major and minor element characteristics of the Monte Amiata clinopyroxenes are thus similar to the Vulsinian clinopyroxenes (fig. 4-23).

*Tab.4-5: Comparison of representative clinopyroxene analyses from Monte Amiata shoshonite (less evolved rock) with clinopyroxenes from Vulsinian mountains and Tuscan lamproites. HKS: Vulsinian mountains, KS series; KS: Vulsinian mountains, K series; ORC: lamproite from Orciatico, RAD: Radicofani; TA-px: Torre Alfina, peridotitic xenolith (b.d.l.: below detection limit of the EMPA).*

wt. %	HKS	KS	ORC	AMT
SiO <sub>2</sub>	52.0	52.4	54.0	51.7
TiO <sub>2</sub>	0.419	0.496	0.585	0.518
Al <sub>2</sub> O <sub>3</sub>	3.14	3.37	0.56	3.09
FeO	3.96	4.08	3.58	4.40
MgO	16.0	16.4	18.0	16.5
CaO	23.7	23.6	22.4	2.9
MnO	b.d.l.	b.d.l.	b.d.l.	0.149
Cr <sub>2</sub> O <sub>3</sub>	0.419	b.d.l.	0.776	b.d.l.
Na <sub>2</sub> O	0.199	0.207	0.162	0.119

Normalized to the bulk rock the REE of the clinopyroxenes are depleted with LREE / HREE ratios lower than 1 (fig. 4-16). Generally REE patterns are similar to Vulsinian

clinopyroxenes. Concentrations of Cr and Ni are also similar to the contents in KS clinopyroxenes.

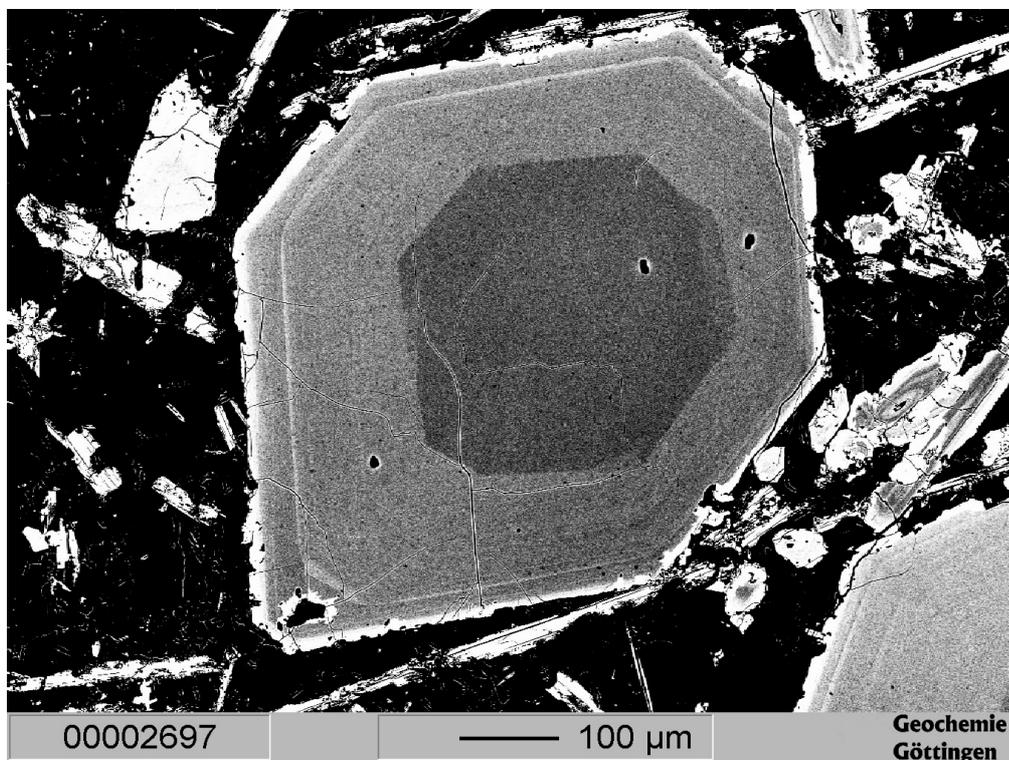

Fig. 4-22: EMPA image (composition mode) of a clinopyroxene of a latite from the Monte Amiata (AMT 9704 A).

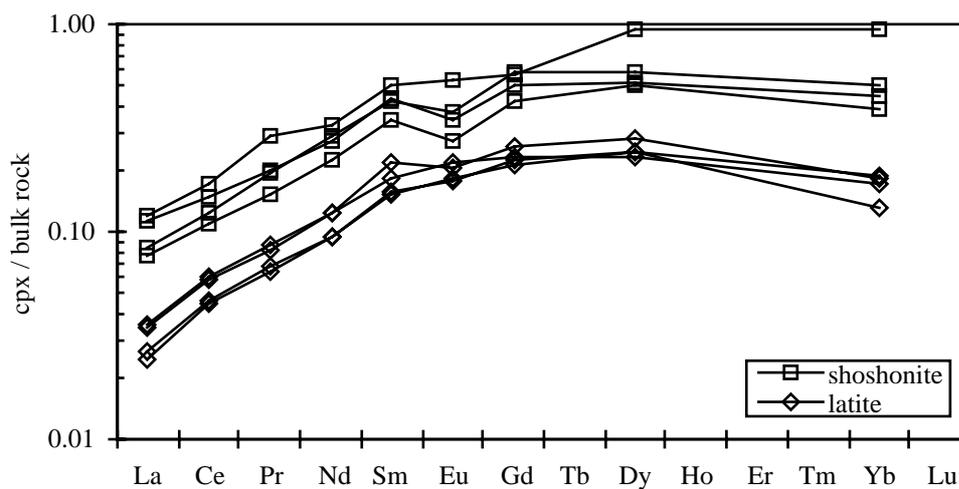

Fig. 4-23: REE patterns of clinopyroxenes from a shoshonite and a latite, values are normalized to chondritic values (Anders & Grevesse 1989).

#### 4.3.3.2 Orthopyroxenes

Orthopyroxenes are present in the trachyte sample only. They have a homogeneous composition and display no zonation. Orthopyroxenes are ferrosilites with 51 - 55 mol% ferrosilite component and 2 - 3 mol% wollastonite component (classification according to Morimoto 1989). The chemical composition is typical for orthopyroxenes from Monte Amiata (van Bergen 1984).

#### 4.3.3.3 Plagioclases

Plagioclases occur as small crystals in the groundmass of the trachyte and are a major constituent of the latite. In the trachyte plagioclase shows a minor oscillatory zoning with anorthite components between 51 - 69 mol% whereas plagioclases in the latite are oscillatory zoned and contain a wide range of composition with an anorthite component of 47 - 82 mol%. This variability is in the range of KS plagioclases from the Vulsinian mountains.

Plagioclases of both samples have high Sr concentrations (400 - 1200 ppm) whereas Ba concentrations of plagioclases in the latite (130 - 480 ppm) are higher than in the trachyte (30 - 50 ppm). Normalized to the bulk rock the REE content is depleted with a higher depletion in the trachyte than in the latite. The HREE of trachyte plagioclases are below the detection limit of the LA-ICP-MS. Plagioclases of both rocks, trachytes and latites, display a positive Eu anomaly. REE patterns of the plagioclases from the latite are sometimes overprinted by enclosed apatites. Using REE concentrations of the plagioclases without embedded apatites the maximum amount of apatites in the plagioclases with the disturbed REE pattern can be calculated with less than 2 wt.%.

#### 4.3.3.4 Sanidines

Sanidines as phenocrystals display a weak or no chemical zoning whereas sanidines from the groundmass show a variability with lower orthoclase contents compared to the phenocrystals. The phenocrystals generally contain higher orthoclase components with 79 - 81 mol% for the trachyte, 70 - 81 mol% for the latite and 79 - 84 mol% for the shoshonite than sanidines of the rhyolites from San Vincenzo and Roccastrada.

Trace element investigations by LA-ICP-MS have been carried out for trachyte AMT 9702 and shoshonite AMT 9703 II. Sanidines from the trachyte are depleted in REE compared to the bulk rock chemistry. They show a positive Eu anomaly; the HREE are sometimes below the detection limit. Contrary the REE patterns of the shoshonitic plagioclases are heterogeneously composed with different degrees of enrichment or depletion compared to the bulk rock and with positive or negative Eu anomalies. This can be caused by enclosed

apatites. REE and P containing phases have been found in the sanidines but they were too small to be quantitatively analyzed.

#### 4.3.3.5 Micas

According to Deer et al. (1996) the Mg / Fe atomic ratio can be used as a dividing criterion between biotite and phlogopite. When the ratio is higher than 2 the mineral is named phlogopite otherwise it is classified as biotite.

Micas occur as phenocrystals in the trachytes, whereas in the latite micas are a constituent of the groundmass. In the shoshonitic xenolith micas are rarely found. When they occur they show resorption edges. In trachyte the micas are biotites with a similar composition to biotites from San Vincenzo rhyolites with Mg values between 53 - 56, K<sub>2</sub>O 9.12 - 9.50 wt.% and TiO<sub>2</sub> 5.74 - 6.48 wt.%. They display no large chemical variation. In contrast micas of the shoshonite have a biotitic to phlogopitic composition and show a larger variability with Mg values ranging between 47 - 82. The chemical characteristics are similar to phlogopites of the Vulsinian mountains, e.g. the K / Al ratio and the concentration of Na and K. Groundmass micas of the latite are biotites with a composition between the micas of the trachyte and the shoshonite.

Only biotites of the trachyte were large enough for LA-ICP-MS analysis but their REE patterns are extremely heterogeneous as it is observed for biotites from San Vincenzo or Roccastrada. This may also be a result of inclusions of oxides and apatites within the biotites.

#### 4.3.3.6 Oxides

The shoshonite contains magnetites with high contents of Ti and Al. Contrary the trachyte and the latite have as major oxides Mg and Mn containing ilmenites.

#### 4.3.3.7 Apatites

Apatites are common minerals in Monte Amiata rocks. They are important REE bearing minerals. In sample AMT 9704 A (latite) apatites were large enough to be analyzed with the electron microprobe. High REE concentrations could be found, e.g. Ce<sub>2</sub>O<sub>3</sub> 0.398 - 0.464 wt.%.

#### 4.3.4 Oxygen Isotopes

Oxygen isotope compositions of the phenocrystals have been measured for all samples (fig. 4-24) except the latitic xenolith (AMT 9703 I) where minerals were too small.

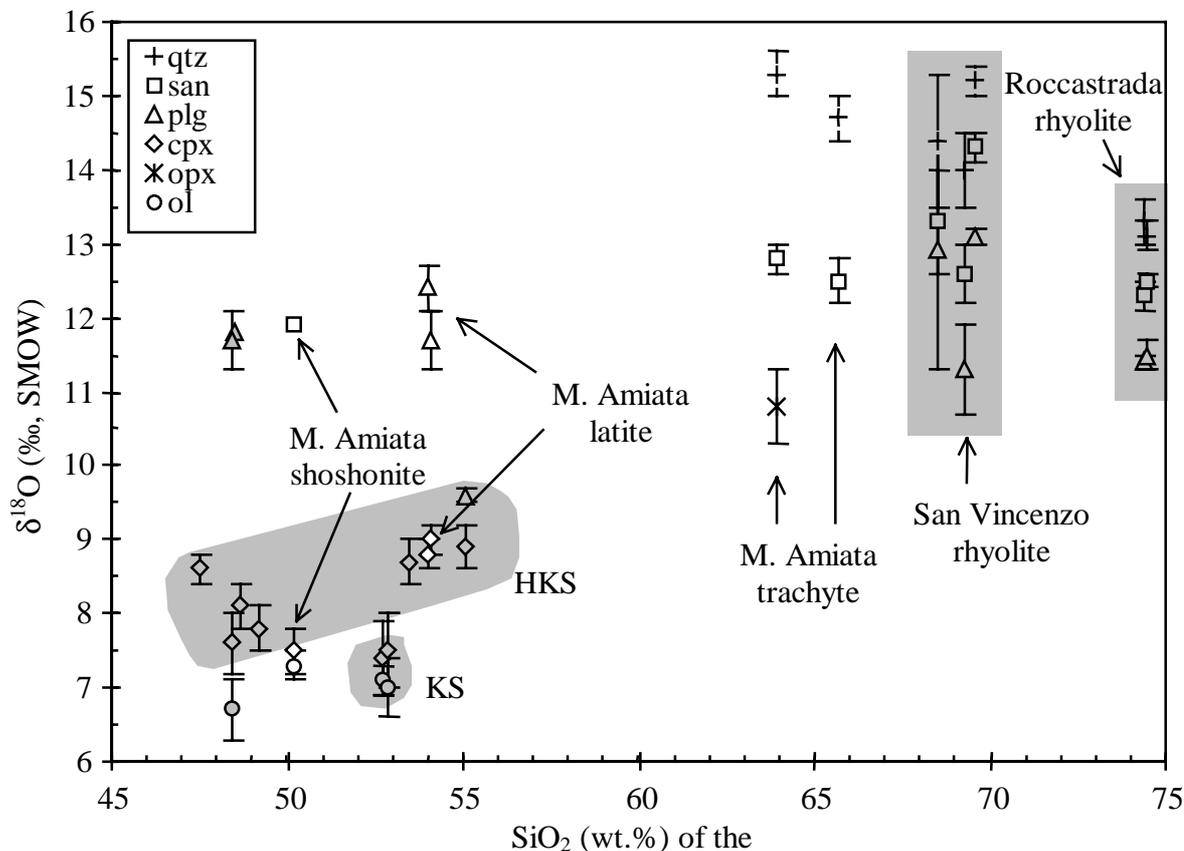

Fig. 4-24:  $\delta^{18}\text{O}$  values of phenocrystals vs.  $\text{SiO}_2$  content of the bulk rock. Monte Amiata phenocrystals are open symbols. Mineral data from the Vulsinian mountains (HKS and KS), San Vincenzo and Roccastrada are filled with gray. Gray fields represent the composition of the rhyolites from Roccastrada and San Vincenzo as well as the composition of clinopyroxenes from the HK series and the K series rocks from the Vulsinian mountains.

The trachytes display similar  $\delta^{18}\text{O}$  values for sanidines with 12.5 ‰ (AMT 9701) and 12.8 ‰ (AMT 9702), respectively. These values correspond to oxygen isotope ratios of Roccastrada sanidines (12.3 - 12.5 ‰) and to one rhyolite sample from San Vincenzo (SVC 9702: 12.6 ‰). Quartz phenocrystals have high  $\delta^{18}\text{O}$  values of 14.7 and 15.3 ‰. Fractionations between quartz and sanidine are too large for magmatic temperatures (Zheng 1993). Therefore a xenocrystic origin of the quartz must be assumed, as has been found by Balducci & Leoni (1981) in some  $\text{SiO}_2$  rich volcanic rocks from Monte Amiata. On the other hand the biotite of sample AMT 9701 is in isotopic equilibrium with the sanidines. The temperature can be calculated to 850 °C using the equations of Zheng (1993). In contrast orthopyroxenes of the sample AMT 9702 display a different behaviour. They show an oxygen isotope range of 10.1 -

11.2 ‰, which indicate an isotopic disequilibrium between the individual orthopyroxenes. Thus orthopyroxenes are also xenocrystals. In general high  $\delta^{18}\text{O}$  values of the phenocrystals from the trachytes indicate a crustal anatexis origin of these rocks.

From two latites (AMT 9704 A, B) and the shoshonitic xenolith clinopyroxenes could be analyzed. The shoshonite contains the lowest  $\delta^{18}\text{O}$  value with 7.4 ‰, whereas the latites display higher values with 8.8 ‰ and 9.0 ‰, respectively.  $\delta^{18}\text{O}$  values of clinopyroxenes from the shoshonite agree well with the oxygen isotopic composition of the less evolved rocks from the Vulsinian mountains: KS 7.4 - 7.5 ‰, HKS 7.6 ‰. Even clinopyroxenes of the latites are in the range of the Vulsinian mountains. Fractionations between clinopyroxene and feldspar for the latites and the shoshonite are too large for igneous processes (Chiba et al. 1989, Zheng 1993). Therefore a secondary process, at lower temperatures than the crystallization temperature, has obviously affected the oxygen isotope ratios of the feldspars. This explanation is supported by the wide range of the plagioclase composition of the sample AMT 9704 B with 11.1 - 12.0 ‰.

The present data agree with one analysis of Taylor & Turi (1976), who analyzed a quartz latite with 12.36 ‰ for the bulk rock and 12.67 ‰ for a K-feldspar.

## 5 Discussion

In this chapter constraints on the petrogenesis of the central Italian rocks are discussed on the basis of the results of this study. First the tectonic setting of the mantle derived rocks is described. In the following parts of this chapter the petrogenesis is discussed on the basis of bulk rock chemistry, mineral chemistry, and oxygen isotope composition. Additionally radiogenic isotope data, which kindly have been carried out for selected samples by Prof. Peccerillo, University of Perugia (personal information), are also taken into account. In the last part of this chapter a model of the petrogenesis of the central Italian rocks is set in a broader geodynamic context of the central Mediterranean region developed by Peccerillo & Panza (1999).

### 5.1 Tectonic Setting

Geochemical fingerprints of igneous rocks can be used to discriminate between different tectonic settings. These geochemical characteristics will briefly be described in the following section especially for the mantle melts.

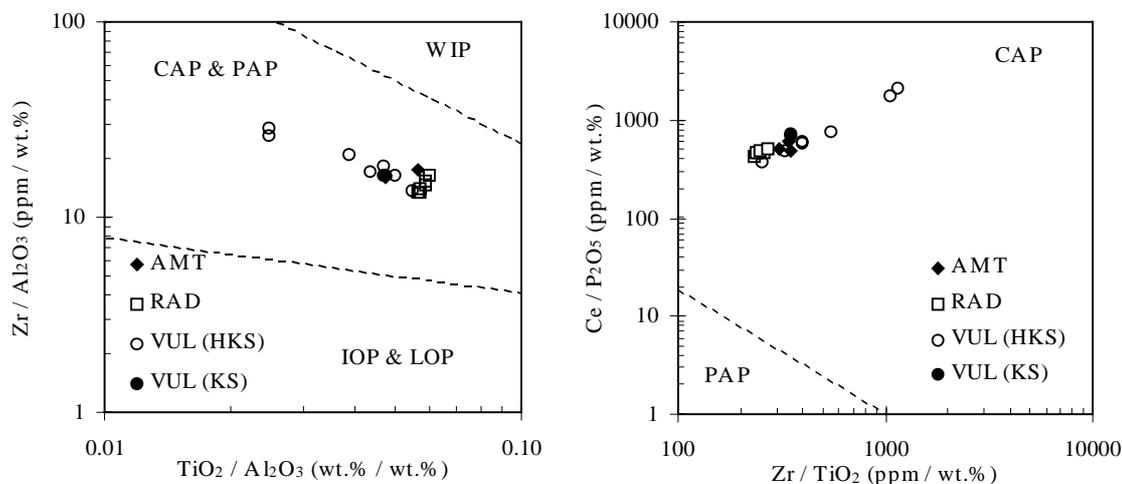

Fig. 5-1: Discrimination diagrams for potassic volcanic rocks from different tectonic settings according to Müller et al. (1992). Circles are HKS rocks and squares are KS rocks. Abbreviations: CAP = continental arc potassic rocks, IOP = initial oceanic arc potassic rocks, LOP = late oceanic arc potassic rocks, PAP = postcollisional arc potassic rocks, WIP = within-plate potassic rocks.

The mantle derived rocks display geochemical characteristics reinforcing the association of these rocks with a subduction zone. One characteristic feature is the trace element distribution shown in chapter 4.1.2, which is typical for subduction related rocks (Pearce 1983, White 1997/1998, Wilson 1995). However the multi element diagram is not sufficient to define the tectonic setting for potassic rocks exactly (Müller et al. 1992). Other chemical features are low

Zr concentrations combined with high Nb contents pointing to either a subduction or a post-collision tectonic regime of petrogenesis (Thompson & Fowler 1986).

Müller et al. (1992) developed a flow-diagram to discriminate different tectonic settings of potassic rocks using their geochemical composition. Intermediate  $Zr / Al_2O_3$  and  $TiO_2 / Al_2O_3$  ratios combined with high  $Ce / P_2O_5$  and  $Zr / TiO_2$  ratios point to a continental arc setting of the Vulsinian rocks (fig. 5-1). For lamproites or lamproitic rocks the situation is more complicated (Mitchell & Bergman 1991). But the multi element pattern also indicate a subduction related genesis.

## 5.2 Evidence from Bulk Rock Major and Trace Element Chemistry

In the Roman Province, of which the northern part is formed by the Vulsinian mountains, two different mantle derived rock types generally can be distinguished, the HK and the K series. The less evolved rocks of both series display high Mg values and transitional metal concentrations similar to a MORB source indicating a genesis by partial melting of a mantle source without assimilation of crustal material. In addition high  $Al_2O_3$  and CaO contents point to a fertile mantle. The high enrichment of LILE and LREE points to an involvement of crustal material. It cannot be produced, however, by assimilation of crustal material during uprise of a mantle melt through the crust. Such an assimilation would dilute the transitional metal concentration and would decrease the Mg values of the less evolved rocks. In addition mantle derived rocks from the Roman Province display a higher enrichment of LILE and LREE than crustal anatectic rocks like the rhyolites from Roccastrada. Thus an assimilation of crustal material would also result in a dilution of LILE and LREE. The only explanation of the uncommon crustal signature of the Roman Province volcanic rocks is a contamination of the mantle source. The possible mechanism for this contamination process is the penetration of the mantle by fluids or melts with a crustal signature generated in a subducted slab. The source of the LILE and LREE could be the sediments of the subducted crust. The exact composition of the sediments is not known but marly sediments have been suggested by several authors (Beccaluva et al. 1991, Conticelli & Peccerillo 1992, Peccerillo 1985 and 1999, Peccerillo & Panza 1999, Rogers et al. 1985). A contamination of the mantle is also supported by trace element signatures like the Ta / Yb and Th / Yb ratios of the Vulsinian rocks. During magmatic processes Th and Ta behave similar but both elements are decoupled during dehydration and melting processes in a subducted slab. Th together with the other LILE is enriched in the generated fluid or melt. These fluids or melts can penetrate the mantle wedge above the subducted slab. They react with the mantle and consequently the mantle is enriched in LILE like Th and LREE. Therefore the melts generated by this modified mantle contain a higher Th / Yb ratio at the same Ta / Yb ratio of MORB than an unmodified mantle.

A contamination of the mantle with a fluid or melt would result in a reaction producing a chemically and mineralogically modified mantle. A possible reaction is the formation of a veined mantle (Foley 1992a, b) with phlogopite as an important new phase because phlogopite is a carrier of K and other LILE as well as H<sub>2</sub>O (Wendlandt & Eggler 1980a, b, Wyllie & Sekine 1982). Melting of such a modified mantle could produce the uncommon potassic to ultrapotassic mantle melts of the Roman Province. The combined melting of veins and wall rocks in varying proportions can produce a relatively wide span of different potassic and ultrapotassic rocks. The exact composition of the mantle, whether it is composed of peridotites (Peccerillo & Manetti 1985, Kamenetsky et al. 1995) or pyroxenites (Rogers et al. 1985), is still a matter of debate.

The major difference between the rocks of the HK and the K series is their content of K and Si. HK rocks are more enriched in K and more depleted in Si than K series rocks. This difference is caused by changes of the melting parameters. Either the HKS source contains more phlogopite than the source of the KS (Rogers et al. 1985) or HKS melts were produced under higher pressure and X<sub>CO<sub>2</sub></sub> of a fluid phase (Peccerillo 1994). Additionally the ratio of melted vein to melted wall rock is important for the melt composition (Foley 1992b) as well as the composition as possibly involved fluids (Foley et al. 1986).

In order to explain the range of volcanic rocks from the Vulsinian mountains from potassic trachybasalts to phonolites, magmatic processes modifying the melt composition as well as differences in the mantle composition has to be taken into account. Kamenetsky et al. (1995) suggested the existence of a continuous spectrum of different primary melts for the Vulsinian mountains. Even the mantle composition for only one volcano seems to be very complex (Conticelli et al. 1991). For example Conticelli et al. (1991) found three different source regions for the late stage eruptions of the Latera Volcano. One mantle source is identical with the source for KS rocks but the HKS source may be divided into a high Ba and a low Ba portion. Generally besides different source compositions for single volcanoes mantle melts are changed by processes within the crust. Processes like assimilation and fractional crystallization, as observed for individual volcanoes (Conticelli et al. 1991, Holm et al. 1982, Turbeville 1993), are not sufficient to generate the whole spectrum of evolved rocks (Conticelli et al. 1991, Kamenetsky et al. 1995). More complex processes like refilling + tapping + crystal fractionating + assimilation (Conticelli et al. 1997) are necessary to produce the whole range of volcanic rocks.

The second important group of mantle derived melts are the lamproites from the Tuscan Province. The igneous rocks from Orciatice and Montecatini Val di Cecina belong to this rock group. The Torre Alfina rocks differ slightly from the lamproites but they can also be assigned to this group. Thus the petrogenesis of the lamproites and the Torre Alfina rocks is discussed

together. Compared to the less evolved rocks from the Vulsinian mountains the lamproites also contain high Mg values, ferromagnesian and compatible elements supporting a mantle origin. The pattern of transitional elements is similar to MORB, which also points to a melt generation in the mantle. In contrast to the Roman Type rocks the  $\text{Al}_2\text{O}_3$ , CaO and  $\text{Na}_2\text{O}$  contents are low and V as well as Sc are moderately concentrated. Thus the source of the lamproites must be a residual mantle, which suffered a basaltic melt extraction. But the lamproites show the highest enrichment of LILE and LREE of all mantle derived rocks in central Italy. The trace element pattern – the high LILE / HFSE and LREE / HREE ratios – suggest the involvement of crustal material. Any assimilation of crustal material within the crust would dilute the concentrations of compatible and ferromagnesian elements and would lower the Mg values so that crustal assimilation could not produce the composition of the lamproites. The crustal signature of the lamproites thus must be a feature of the mantle source. Like the mantle beneath the Roman Province, the mantle beneath Tuscany could be contaminated by crustal material, which was incorporated into the mantle by a subducted slab. The reaction of the crustal material with the mantle could also produce a phlogopite containing veined mantle (Foley 1992b).

Summarizing the mantle source of the lamproites is a residual, metasomatized mantle. High  $\text{SiO}_2$ , high MgO lamproites can be generated by partial melting of such a mantle under special physico-chemical conditions (Arima & Edgar 1983). High  $\text{SiO}_2$  contents point to a partial melting at low pressure and under high  $\text{H}_2\text{O}$  activity (Wendlandt & Eggler 1980a, b, Arima & Edgar 1983). The pressure can be estimated to a maximum of about 10 – 15 kbar (Foley 1992b) or about 12 kbar (Edgar & Vukadinovic 1992), which is in accordance with an upper mantle origin.

The small variations in the composition of the Orciatice lamproites can be generated by crystal fractionation in a shallow level environment (Conticelli et al. 1992), whereas the Montecatini Val di Cecina lamproites suffered a more complex history of crustal assimilation, low pressure crystallization and squeezing processes during the late stage crystallization (Conticelli et al. 1992). The Torre Alfina rocks of type A represent mantle melts, which are relatively unaffected by crustal assimilation or fractional crystallization (Conticelli 1998). On the other hand the differences of type B lavas to type A rocks can be explained by assimilation of crustal material (Conticelli 1998, Peccerillo 1994). This explanation is supported by the high abundance of crustal xenoliths in type B lavas.

The last group of mantle derived melts in central Italy are the transitional rocks, which were sampled at Radicofani. Their high Mg values and high MgO, Cr, and Ni concentrations of the less evolved rocks clearly point to a mantle origin. Extensive fractional crystallization and crustal assimilation for the less evolved rocks can be excluded (Poli et al. 1984). Chemically

they are mixtures between Roman Province type and lamproitic melts. Mixing the two endmembers with different proportions can thus produce the observed range of volcanic rocks from Radicofani (Peccerillo 1994). On the basis of trace elements Peccerillo (1994) suggested a Roman type melt similar to the KS rocks from Ernici – a volcanic region lying in the transition zone between the Roman and the Campanian Province – as the Roman type endmember. On the basis of this study it can not be decided, whether the Roman type endmember belongs to the K or the HK series.

Rocks from the Vulsinian mountains, from Radicofani, and the lamproitic rocks from the Tuscan Province represent mantle derived melts. On the other hand the situation in central Italy is complicated by the occurrence of crustal anatectic rocks, which frequently occur in the Tuscan Magmatic Province. Representatives for crustal anatectic rocks are the rhyolites from Roccastrada. Their chemical composition is typical for melts generated by partial melting of metapelitic rocks (Green 1976). Metapelitic rocks form large parts of the Paleozoic basement of central Italy (Giraud et al. 1986, Taylor & Turi 1976). The residue may be characterized by biotite, quartz, cordierite, and feldspar (Giraud et al. 1986). But the relatively high enrichment of K, Rb, Pb, U, and Th cannot result from partial melting of this metapelitic material (Giraud et al. 1986). Because of the homogeneity of these rhyolites an additional process of enrichment like hydrothermal systems can be excluded. Giraud et al. (1986) suggested that the metapelitic source has been contaminated by fluids generated in the deeper crust, which are possibly related to a subducted slab, and which might also have contaminated the mantle beneath central Italy.

Another occurrence of crustal anatectic rocks are the rhyolites from San Vincenzo. Using the major and trace element composition of the bulk rocks these rocks could also be produced by partial melting of metapelitic basement rocks, which had been contaminated by fluids like the Roccastrada rhyolites (Feldstein et al. 1994, Ferrara et al. 1989, Giraud et al. 1986, Taylor & Turi 1976). As shown in chapter 5.4 the petrogenesis of the San Vincenzo rhyolites is, however, more complicated than the genesis of the Roccastrada rhyolites.

Hybrid rocks have been sampled at the Monte Amiata and represent mixtures between crustal anatectic rocks and mantle derived mafic rocks. The petrographic composition ranges from latites to trachytes with mafic shoshonitic inclusions in trachytes. These inclusions already point to a mixing between mafic and acidic melts. The most mafic rocks are the shoshonitic inclusions mentioned above. The trace element signature of these shoshonites is similar to the less evolved rocks from the Vulsinian mountains. But a matter of debate is whether the mafic melts belong either to the HK series or to the K series. Peccerillo et al. (1987) favoured the KS melts, whereas Poli et al. (1984) and van Bergen (1985) preferred the HKS melts. The

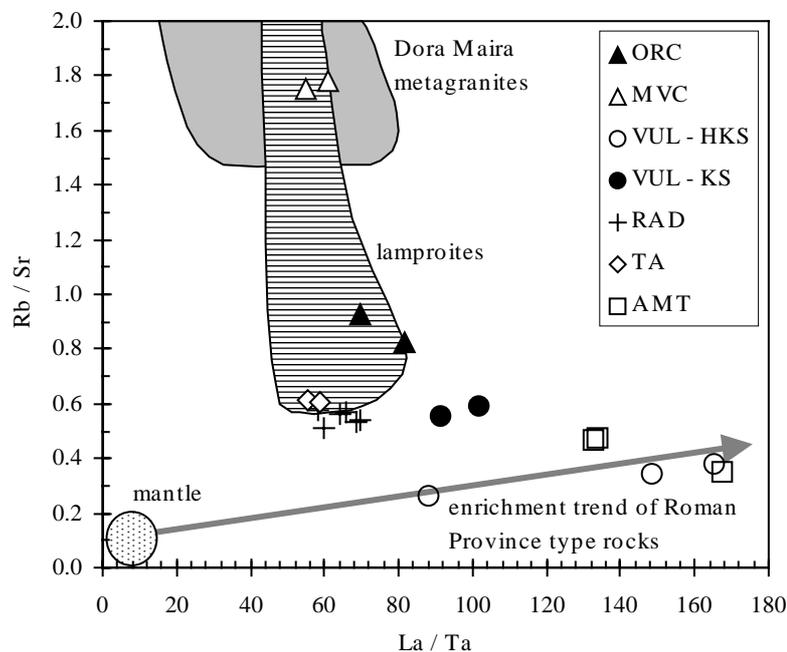

chemical composition of the bulk rock rather indicates KS melts as mafic melts of the Monte Amiata volcano.

For the acidic rocks, the trachytes, a petrogenesis of partial melting of metapelitic material is assumed (Giraud et al. 1986, Innocenti et al. 1992, Pinarelli 1991). However the high concentrations of K, Rb, Pb, Li and REE requires a further source of these elements (Giraud et al. 1986). Giraud et al. (1986) explained this with a mixing of a pure crustal anatectic melt similar in composition to San Vincenzo and Roccastrada rhyolites with a mantle derived melt of a K series composition. A contribution of about 15 - 30 % of mantle melt is necessary to produce the trace element signatures of the acidic rocks from Monte Amiata (Giraud et al. 1986, Innocenti et al. 1992). The crustal melt endmember is believed to be similar to the Roccastrada or San Vincenzo rhyolites (Giraud et al. 1986). But the trace element signature of the trachytes rather indicate a composition corresponding to the San Vincenzo rhyolites. However the metapelitic basement of central Italy displays a large variability so that crustal anatectic rocks from Tuscany shows a large variability. Thus the exact composition of the crustal anatectic endmember of the Monte Amiata volcano is not known.

Summarizing, the Monte Amiata rocks can be generated by mixing of a mantle and a crustal anatectic melt. Mantle melts correspond to the mantle melts of the Vulsinian mountains, probably the K series melts. Crustal anatectic melts are generated by partial melting of metapelitic rocks. Neither pure mantle melts nor pure crustal melts occur at the Monte Amiata.

A major aspect to understand the variability of different rocks in central Italy is the composition of the mantle source beneath central Italy and the different metasomatic agents for the mantle source. Summarizing two different mantle derived rocks can be distinguished, the Roman Type melts from the Vulsinian mountains and the mantle derived melts from the Tuscan Province occurring as lamproites. Using trace element ratios it can be tested whether the mantle beneath the Tuscan and the Roman Province were metasomatized by the same agent or not. Rb and Sr as well as La and Ta behave similar during partial melting of a mantle source and fractional crystallization of a melt. Thus different Rb / Sr and La / Ta ratios indicate a different source composition and consequently differently composed metasomatic agents. In fig. 5-3 these element ratios are shown. The lamproite composition can be explained by mixtures of a mantle derived with crustal derived material similar to the Dora Maira metagranites (Peccerillo 1999). The Roman Province rocks display another enrichment trend with higher La / Ta ratios and lower Rb / Sr ratios. Marly sediments are suggested as a possible contaminant (e.g. Beccaluva et al. 1991, Peccerillo 1999). The mafic endmembers of the Monte Amiata volcano lie in the enrichment trend of the Roman Province rocks thus supporting a Roman type melt as a mafic endmember. Rocks from Radicofani show

intermediate trace element ratios between Roman Province type and lamproitic melts indicating a petrogenesis by mixing of both melt types. Because of the relatively low Rb / Sr ratios Torre Alfina rocks can represent either pure lamproitic melts or lamproitic melts

slightly influenced by Roman Province type melts.

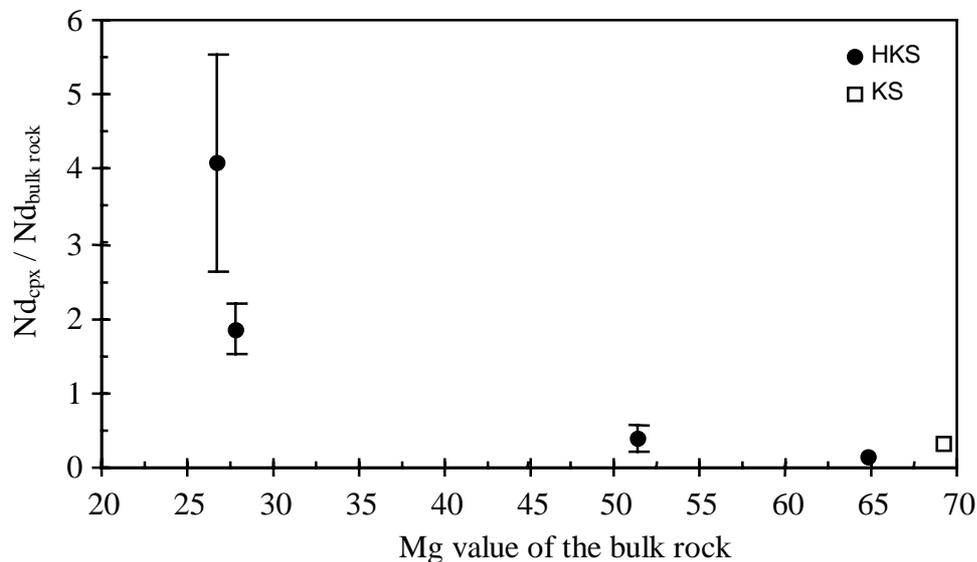

*Fig.5-3: Rb / Sr vs. La / Ta diagram for mafic rocks of central Italy (Mg values > 60) after Peccerillo (1999). The arrow displays the enrichment trend of the Roman type rocks. Mafic rocks from Monte Amiata are identical with the Roman type rocks. The lamproite - field can be generated by a mixing of material similar to Dora Maira metagranites and mantle material. Rocks from Torre Alfina and Radicofani lie in the lamproite field and between the lamproite field and the Roman Province enrichment trend, respectively. Primary mantle values are taken from McDonough & Sun (1995).*

### 5.3 Evidence from the Chemical Composition of Minerals

Mineral chemistry of selected rock samples has been analyzed using representative samples for every petrogenetic rock type.

The compositions of olivines and clinopyroxenes from the less evolved rocks of the Vulsinian mountains support a mantle derived origin of the rocks. Their composition is in accordance with their bulk rock composition and typical for Roman Province K rich rocks. As mentioned in chapter 5.2 the compositional range of the Vulsinian rocks can only be explained by complex processes like refilling + tapping + crystal fractionating + assimilation (Conticelli et al. 1997). These processes are reflected in the structure of the minerals. Some clinopyroxenes show oscillatory zoning, which indicate a complex history of the melts with changing pressure

and temperature conditions or melt compositions. Magma mixing is indicated by chemically different inherited cores within the clinopyroxenes. In addition melt inclusions in clinopyroxenes point to a rapid growth of the minerals, which is sometimes interrupted by processes of resorption.

*Fig. 5-4: Enrichment of Nd in clinopyroxenes - Nd concentrations are normalized to the bulk rock concentration - vs. the Mg values of the bulk rock. Filled circles are clinopyroxenes from HKS open squares from KS. For symbols without an error bar, the error is within the symbol size.*

Another remarkable feature is the increasing REE content of clinopyroxenes with decreasing Mg values or increasing evolving stage of the rocks. The change of REE concentrations is not only caused by higher REE concentrations of the bulk rock. Figure 5-4 shows the Nd concentrations of the clinopyroxenes normalized to the bulk rock versus the Mg values of the bulk rock. The less evolved rocks have lower  $REE_{cpx} / REE_{bulk\ rock}$  ratios than the more evolved rocks. During a magmatic evolution of a melt, especially fractional crystallization, the partition coefficient  $D_{cpx/melt}$  of the REE increases because the physicochemical conditions and the chemical composition of the melt change (Dobosi & Jenner 1999, Francalanci et al. 1987). The Al concentration of the melt and the clinopyroxenes have a major influence on the partition coefficient. Increasing Al contents in the melt and the clinopyroxenes induce an increase of the partition coefficient. But the partition coefficient does not depend on the Al content linearly (Lundstrom et al. 1998, Schosnig & Hoffer 1998). A positive trend of an increase of Al in the bulk rock and in the clinopyroxenes can also be observed in the Vulsinian samples.

In some rocks from the Vulsinian mountains phlogopites can be observed displaying dissolution processes at their mineral rim. This points to a xenocrystalline origin. The

chemical composition of the phlogopites like low Ti contents and high K / Al ratios indicate a high pressure origin (Foley 1990). Thus phlogopites may be of mantle origin and also indicate a metasomatized mantle beneath central Italy.

The forsteritic rich olivines of the lamproites also indicate a mantle origin for this rock type. Their chemical composition, especially the enrichment of LREE compared to HREE, reflect the chemical composition of the bulk rock. Clinopyroxenes of the Orciatico lamproites display only a minor zoning pointing to a small interaction of the melts with the crust. Changes of the chemical composition of the primary melt by assimilation of crustal material should also affect the composition of the clinopyroxenes. Compared to the Vulsinian micas the chemical composition of lamproitic phlogopites suggest a formation under relatively low pressures and high temperatures (Conticelli et al. 1992, Foley 1990, Trönnnes et al. 1985). However phlogopites from the lamproites reflect the conditions of crystallization of the melts whereas the phlogopites from the Vulsinian rocks probably are xenocrystals from the mantle source. Thus the phlogopites from the lamproites give only an indirect indication of the mantle and the primary melt composition of the Tuscan Province. In order to produce a phlogopite-sanidine-clinopyroxene containing lamproite the mantle source had to be melted at low pressures.

In summary mineral compositions of the Vulsinian and lamproitic rocks support the petrogenetic model based on bulk rock chemistry.

Another important piece of evidence for a petrogenetic model are peridotitic xenoliths embedded in the Torre Alfina lavas. Their olivines have a chemical composition, e.g. low CaO and high MnO contents, which is typically for a high pressure origin. Additionally the peridotitic xenolith contains spinels as the Al bearing phase indicating a mantle origin. Clinopyroxenes from the xenoliths contain relatively high REE concentrations pointing to a metasomatically enriched mantle. An important mineral of the peridotitic xenoliths are phlogopites with a typical mantle composition (Conticelli & Peccerillo 1990) indicating a metasomatically enriched mantle. Therefore the peridotitic xenolith strongly indicates an metasomatically enriched mantle beneath the Tuscan Province, which is in accordance with the bulk rock chemistry of the lamproites. Phlogopites are the K, LILE and REE carrier in the metasomatically enriched mantle beneath central Italy.

Clinopyroxenes of the host rocks from Torre Alfina have a chemically intermediate composition between Tuscan lamproites and Vulsinian rocks emphasizing the transitional character of these rocks. The mineralogical composition and mineral chemistry supports a transitional character of the Torre Alfina lavas. The bulk rock chemistry and the mineral chemistry, especially the absence of plagioclases and the composition of sanidines, display a lamproitic affinity of these rocks.

In contrast to the Torre Alfina rocks the Radicofani lavas show a different affinity. They also belong to the transitional rock type but their mineralogy – olivines, clinopyroxenes, and plagioclases as major phases as well as the lack of phlogopites and sanidines - is more close to the Vulsinian rocks. The mineral composition is intermediate between lamproites and Roman Province type rocks, too. This can be shown especially for the clinopyroxenes. Si and Al contents are similar to the Vulsinian rocks but Ca deficiency is similar to the clinopyroxenes from the lamproites. Generally the mineral chemistry of the Radicofani rocks support the transitional character and the closeness to the Roman Province type rocks, as it is reflected by the bulk rock chemistry.

Besides the mantle derived melts, crustal anatectic rocks are the second important rock type in central Italy. The rhyolites of Roccastrada and San Vincenzo are dominantly generated by partial melting of metapelitic rocks. This conclusion has been drawn using bulk rock composition. The mineral chemistry reflects this genesis. For a crustal anatectic melt the minerals have a common composition. Especially cordierite xenocrystals from San Vincenzo supports the petrogenesis by partial melting of a metapelitic source. Comparing the chemical composition of the phenocrystals, differences between the Roccastrada and San Vincenzo rhyolites can be observed, e.g. biotites from Roccastrada are MnO rich and MgO poor whereas biotites from San Vincenzo show the opposite behaviour, which may result from heterogeneities of the crustal composition of central Italy. Summarizing mineral chemistry is in accordance with the petrogenetic model based on the bulk rock chemistry.

Finally the hybrid rocks from Monte Amiata have to be discussed. From the bulk rock composition mixing of a mantle melt with a crustal melt has been concluded. The crustal melt has a composition similar to the San Vincenzo rhyolites whereas the mantle melt is similar to the Roman Province type rocks, especially the K series rocks. Minerals from a shoshonitic xenolith reflect the mafic endmember, minerals from a trachyte the SiO<sub>2</sub> rich endmember and minerals from a latite an intermediate representative. The chemical composition of clinopyroxenes and phlogopites from the shoshonite is similar to the Vulsinian rocks. Therefore the mineral chemistry supports a genetic model of a Roman type melt as a mafic endmember for the Monte Amiata hybrid rocks. On the other hand minerals of the trachytes are similar in composition as the minerals from the San Vincenzo rhyolites. A crustal source similar to the San Vincenzo rocks is thus likely. The intermediate latites can be produced by mixing of the two endmembers. In general the mineral chemistry supports the conclusions drawn on the basis of the bulk rock chemistry.

Summarizing the mineral chemistry of all rock samples investigated, the results support the petrogenetic models deduced from whole rock data presented. Additionally a better knowledge of the processes during crystallization can be obtained such as a changing

distribution coefficient of REE in clinopyroxenes depending on the composition of clinopyroxenes and melt.

#### 5.4 Evidence from the Oxygen Isotope Ratios

Oxygen isotope ratios of the phenocrystals have been analyzed to characterize the original isotopic composition of the melts. Using bulk rock analyses oxygen isotope ratios may have been changed by secondary processes like hydrothermal alteration. A secondary alteration of the isotopic ratios has been observed in some rock samples; e.g. plagioclases of the groundmass are not in isotopic equilibrium with clinopyroxenes or olivines as the liquidus phases. Thus the analyses of the first crystallizing minerals will give a better estimate of the original composition of the rocks.

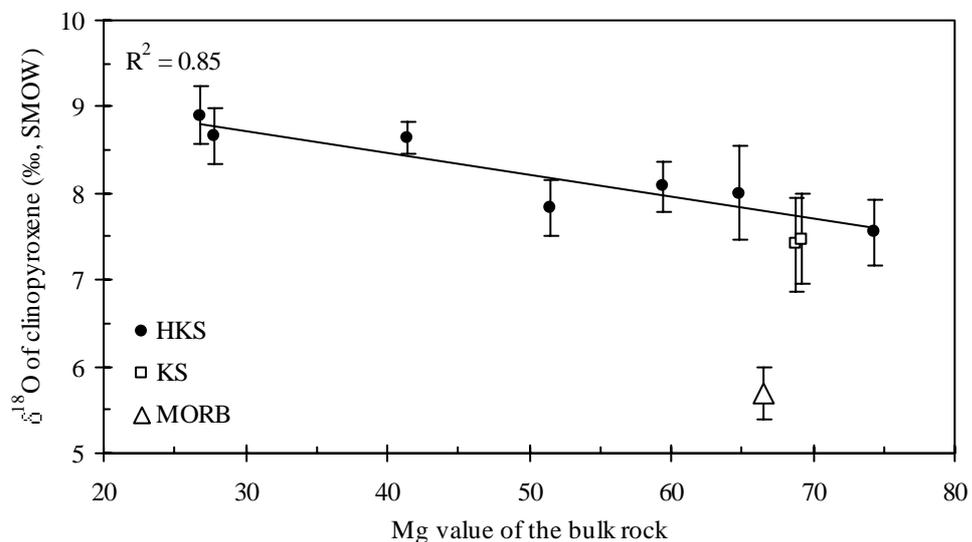

Fig. 5-5:  $\delta^{18}\text{O}$  values of clinopyroxenes vs. Mg values of the bulk rock. For comparison a MORB value (Hoefs 1997, Schilling et al. 1983, White 1997/1998) is shown.

Oxygen isotope ratios of clinopyroxenes from the Vulsinian rocks range from 7.4 - 8.9 ‰. An increase of the  $\delta^{18}\text{O}$  values with decreasing Mg values of the bulk rock can be explained by fractional crystallization and assimilation of crustal material (fig. 5-5). However an increase of 1.3 ‰ of the oxygen isotope ratios with an increase of 6.7 wt.%  $\text{SiO}_2$  of the bulk rock is too high for a fractional crystallization process alone (Hoefs 1997). Because of that assimilation of crustal material during the uprise of the melt has to occur.

In order to increase the oxygen isotope ratios, assimilation of carbonatitic material has been suggested (Varekamp & Kalamarides 1989) as it is observed at other localities in central Italy (Peccerillo 1998). If the oxygen isotope ratios are affected by assimilation of carbonates the  $\delta^{18}\text{O}$  values should be positively correlated with the CaO content of the bulk rock. But the

contrary is observed (fig. 5-6). Therefore the assimilation of large amounts of carbonatitic material can be excluded. An explanation of the observed negative correlation may be a combination of fractional crystallization of clinopyroxenes or anorthite rich plagioclases and assimilation of SiO<sub>2</sub> rich crustal material.

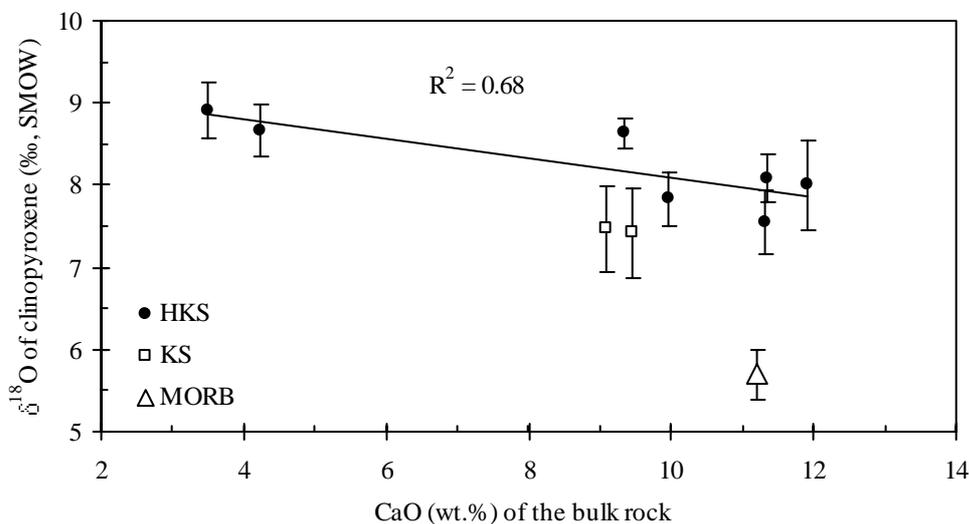

Fig. 5-6:  $\delta^{18}\text{O}$  values of clinopyroxenes vs. CaO content of the bulk rock. For comparison a MORB value (Hoefs 1997, Schilling et al. 1983 and White 1997/1998) is shown.

The composition of the primitive mantle melts from the Vulsinian mountains can be estimated from the data of the less evolved rocks. These rocks show  $\delta^{18}\text{O}$  values of 7.4 - 7.6 ‰ for clinopyroxenes and 6.7 ‰ for olivines. Thus the mantle source or the mantle melts should have  $\delta^{18}\text{O}$  values of about 6.7 ‰. This is in agreement with Turi et al. (1986) and Ferrara et al. (1986b), who stated that the mantle source is similar in composition with the Alban hills mantle source of about 6.5 - 7.0 ‰. The estimated primary range of mantle melts from the Vulsinian mountains of 7.8 - 9.4 ‰ from Holm & Munksgaard (1982) seems to be too high. Summarizing the mantle source must be enriched in <sup>18</sup>O but to a lesser degree than Holm & Munksgaard (1982) or Rogers et al. (1985) suggested.

Only one lamproite sample displays no secondary alteration of the olivines, so that only few oxygen isotope data are available. These few olivines have high  $\delta^{18}\text{O}$  values of 7.2 ‰. The  $\delta^{18}\text{O}$  differences between olivines and sanidines of the groundmass can be explained by secondary alteration of the groundmass. Because of low oxygen diffusion coefficients in olivine the  $\delta^{18}\text{O}$  values should represent the original values of the melt. Thus the source of the lamproites must be enriched in <sup>18</sup>O.

The oxygen isotopic composition of the peridotitic xenolith from Torre Alfina gives strong evidence for an <sup>18</sup>O enriched mantle. As shown in chapter 4.1.4 olivines of the peridotitic xenolith contain the lowest values in the core and the highest at the boundary to the host rock.

Oxygen isotope ratios of the olivines in the core are up to 7 ‰ whereas typical mantle olivines have an oxygen isotopic composition of about 5.2 – 5.4 ‰ (Hoefs 1997, Matthey et al. 1994). Oxygen diffusion in olivines is low, so that the enrichment of the olivines could not occur during uprising of the melt. Conticelli (1998) has calculated the uprising of the Torre Alfina melts from the mantle source to the surface to be about several hours. A minimum time of 350 ka to 1.6 Ma is required for diffusion of oxygen from the outer part of the xenolith into the core using the diffusion coefficients of Cherniak & Lanford (1989), Jaoul et al. (1980), Ryerson et al. (1989), and Yurimoto et al. (1992).

Phenocrystals from Radicofani rocks are characterized by a homogeneous composition. Their values are in accordance with a mixing model of lamproites and Roman type melts.

Comparing the different genetic types the  $\delta^{18}\text{O}$  values of olivines are identical within the reproducibility ( $\pm 0.3\text{‰}$ ) of the LA-SIRMS: Orciatico lamproite 7.2 ‰, Roman Province HK series 6.7 ‰, Roman Province K series 7.0 - 7.1 ‰ and Radicofani 7.1 - 7.4 ‰. Compared to olivines from an unaffected mantle these values are too high and clearly indicate an  $^{18}\text{O}$  enriched mantle beneath central Italy.

On the basis of the bulk rock and mineral chemistry data the rhyolites from Roccastrada and San Vincenzo have been explained as crustal anatectic melts. The crustal source had to be enriched by fluids in order to produce the high K, Rb, Pb, U, and Th contents. For the Roccastrada rhyolites oxygen isotope data of the phenocrystals support a crustal anatectic origin. Oxygen isotope ratios are typically for crustal derived rocks (Hoefs 1997) and minerals like the quartzes, sanidines, and plagioclases are in isotopic equilibrium to each other. This is also true for the San Vincenzo type A rhyolites. But type B rhyolites indicate oxygen isotopic disequilibrium among the phenocrystals.

Oxygen isotopic characteristics of the San Vincenzo rhyolites are supported by Sr isotopes (Ferrara et al. 1989). Phenocrystals of type A rocks are in Sr isotopic equilibrium to each other whereas group B rocks also show a Sr isotopic disequilibrium among the minerals. Therefore a genetic model for the San Vincenzo rhyolites has to explain the inhomogeneous composition of the group B rocks. Feldstein et al. (1994) have calculated that the inhomogeneity can not be produced by large assimilation of crustal material. Thus the heterogeneity has to be due to magma mixing. Magma mixing has also been suggested by Ferrara et al. (1989), Peccerillo et al. (1987) and Serri et al. (1993), which is supported by mafic inclusions and andesitic xenoliths in the rhyolites (Ferrara et al. 1986a, b; 1989). A possible model for this process is a layered or stratified magma chamber, where a more mafic magma underlies the rhyolitic magma (Feldstein et al. 1994). The mafic magma has to be differentiated to a latitic melt, so that mixing between a latitic and a rhyolitic melt can produce the variability of Sr isotope ratios without changing the major elements of the

rhyolites (Feldstein et al. 1994). Consequently the rhyolites of group A originated from parts of the magma chamber, where no mixing between mantle and crustal melts occurred. In contrast sources of the phenocrystals within group B rhyolites are (I) small amounts of assimilated crystals from the wall rock, (II) minerals crystallized from the pure anatectic rhyolitic melt, (III) minerals crystallized from a mixture of the rhyolitic and the latitic melt and (IV) phenocrystals of the mantle melt itself, e.g. clinopyroxenes and orthopyroxenes (Feldstein et al. 1994). In order to prohibit a reequilibration of Sr isotopes the residence time for the phenocrystals probably has to be less than 10 ka in the mixed melt. Using diffusion coefficients of Eiler et al. (1992, 1993) and Fortier & Giletti (1989) the inhomogeneity in oxygen isotope ratios would also be preserved. Therefore the model can explain both the Sr isotope and the oxygen isotope heterogeneity. On the other hand the nature and source of the mantle melt has not been clarified yet. Peccerillo et al. (1987) suggested a calc alkaline subcrustal melt akin to the mantle melts of the Roman Province. Contrary Feldstein et al. (1994) argued for a basaltic melt. But the mafic inclusions are characterized by relatively low Sr isotope ratios and high Nd isotope ratios (Innocenti et al. 1992, Ferrara et al. 1989), which do not agree with the values of the Roman Province rocks (Ferrara et al. 1986a, b) nor to the values of the lamproites from Orciatice or Montecatini (Conticelli et al. 1992).

Besides bulk rock and mineral chemistry data oxygen isotope ratios of phenocrystals from the Monte Amiata rocks support a model of mixing of a crustal anatectic and a mantle derived melt. Using the SiO<sub>2</sub> content of the bulk rock and oxygen isotope ratios (fig. 4-17, chapter 4.3.4) the mafic endmember has a similar composition as the Vulsinian melts and the crustal endmember is similar to the San Vincenzo rhyolites.

## 5.5 Combined Oxygen and Strontium Isotopic Data

In fig. 5-7 a schematic diagram of  $\delta^{18}\text{O}$  vs.  $^{87}\text{Sr} / ^{86}\text{Sr}$  for the central Italian rocks is shown. The data are compiled from Ferrara et al. (1985, 1986b), Giraud et al. (1986), Holm & Munksgaard (1982), Innocenti et al. (1992), Poli et al. (1984), Taylor & Turi (1976), Vollmer (1976) and this work. Oxygen isotopic compositions are shown for rocks prior to a secondary alteration of the groundmass.

Two different mantle compositions can be observed. The first one is the mantle beneath the Vulsinian mountains with a  $\delta^{18}\text{O}$  value of about 6.7 ‰ and a  $^{87}\text{Sr} / ^{86}\text{Sr}$  ratio of less than 0.712. In contrast the lamproites have higher  $^{87}\text{Sr} / ^{86}\text{Sr}$  ratios (> 0.714) but similar  $\delta^{18}\text{O}$  values of about 7.2 ‰.

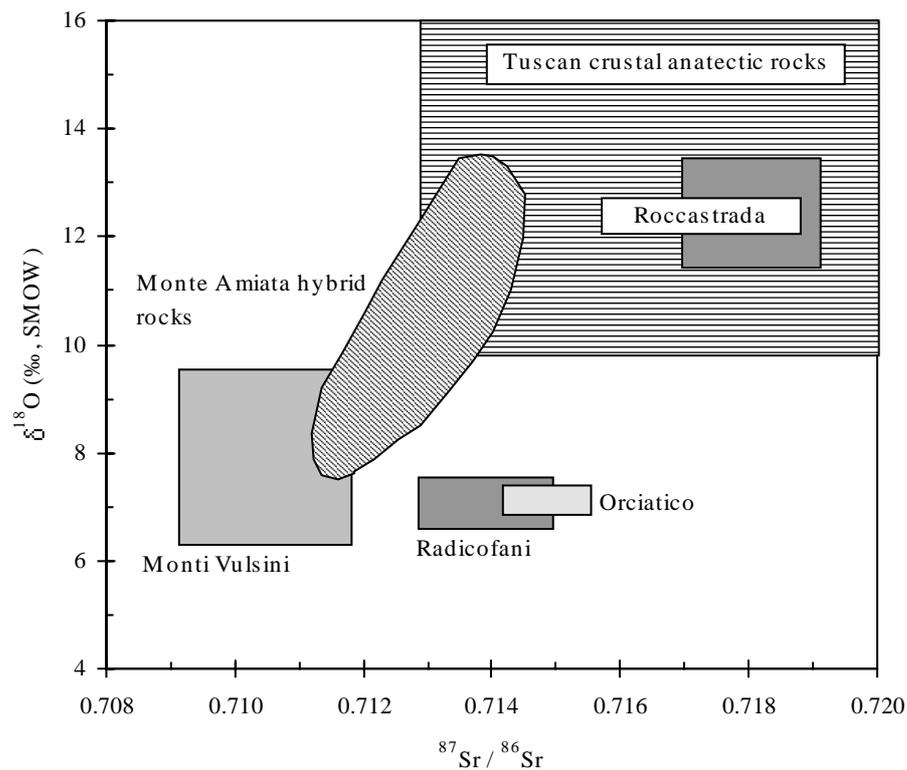

Fig. 5-7:  $\delta^{18}\text{O}$  values vs.  $^{87}\text{Sr}/^{86}\text{Sr}$  (i) of central Italian magmatic rocks.  $\delta^{18}\text{O}$  values are estimated for melts prior to a possible secondary low temperature alteration. Orciatico lamproites show the  $\delta^{18}\text{O}$  values, which are estimated for the rocks prior to a secondary alteration of the groundmass. Data are compiled from Ferrara et al. (1985, 1986b), Giraud et al. (1986), Holm & Munksgaard (1982), Innocenti et al. (1992), Poli et al. (1984), Taylor & Turi (1976), and this work.

From the Torre Alfina rocks only olivine phenocrystals could be analyzed. These phenocrystals show a large range of  $\delta^{18}\text{O}$  values. For the high oxygen isotope ratios of the groundmass (13.1 ‰) a secondary alteration must be taken into account. Therefore the Torre Alfina rocks have not been plotted in the diagram. If similar  $\delta^{18}\text{O}$  compositions of the Torre Alfina rocks and the lamproites is assumed then they lie in the lamproite field because Sr isotope ratios agree with the Sr isotope ratios of the lamproites.

The rocks from Radicofani display a relatively large variability of Sr isotopic ratios but a low variability of oxygen isotopes. This relationship is not a sign of source contamination (James 1981) but a result of mixing between two mantle melts with different Sr isotopic and similar O isotopic compositions. A mixing of a mantle and a crustal melt as it is proposed by Ferrara et al. (1986b) can not explain the composition of the Radicofani rocks.

$\delta^{18}\text{O}$  values and  $^{87}\text{Sr}/^{86}\text{Sr}$  ratios of the rhyolites from Roccastrada are typical for crustal anatectic rocks in Tuscany. The San Vincenzo rhyolites display a more complex pattern.

Generally their  $^{87}\text{Sr} / ^{86}\text{Sr}$  ratios are higher than 0.720 with  $\delta^{18}\text{O}$  values higher than 11 ‰. But some rhyolites with low  $^{87}\text{Sr} / ^{86}\text{Sr}$  occur (Innocenti et al. 1992).

The Sr and O isotopic data from Monte Amiata confirm a petrogenetic model of a mixing between crustal anatectic and Vulsinian melts.

## 5.6 Radiogenic Isotopic Data

In this subchapter radiogenic isotopes from the literature are compiled and discussed with regard to a few new data from the rocks investigated. The analyses of the radiogenic isotope ratios have kindly been carried out by A. Peccerillo (personal communication). In fig. 5-8 and 5-9 ratios of  $^{143}\text{Nd} / ^{144}\text{Nd}$  vs.  $^{87}\text{Sr} / ^{86}\text{Sr}$  and  $^{206}\text{Pb} / ^{204}\text{Pb}$  vs.  $^{87}\text{Sr} / ^{86}\text{Sr}$  are shown.

In general a continuous change in the isotopic composition of the mantle melts from the Roman Province, the Southern Latium Transition Zone (Ernici - Roccamonfina), the Campanian Province (Stromboli - Vesuvius) and the Monte Vulture can be observed with a northward decrease of  $^{143}\text{Nd} / ^{144}\text{Nd}$  and  $^{206}\text{Pb} / ^{204}\text{Pb}$  ratios and an increase in  $^{87}\text{Sr} / ^{86}\text{Sr}$  ratios (data summarized by Innocenti et al. 1992, Peccerillo 1999, Peccerillo & Panza 1999, Vollmer 1976, see fig. 5-8, 5-9). This regional distribution may be caused by a change of the amount of fluids or melts, metasomatizing the mantle, or by a change of the composition of the fluids or melts.

As in the  $\delta^{18}\text{O}$  vs.  $^{87}\text{Sr} / ^{86}\text{Sr}$  diagram (fig. 5-7) three different groups can be distinguished in central Italy. The first group are the Roman Province melts, the second group are the Tuscan anatectic rocks and the third group are the lamproites.

The radiogenetic isotope ratios diagrams also show, that mantle sources between the Tuscan Province and the Roman Province are different and that the lamproites can not be generated by mixing of Roman Province melts or mantle domains with crustal material from Tuscany.

The similarity of the radiogenic isotope ratios between the Torre Alfina rocks and the lamproites confirm the genetic model, that the Torre Alfina rocks are lamproites. Even the Radicofani rocks, which from mineral and bulk rock chemistry are a mixture of lamproitic melts and Roman Province melts, lie in or near the lamproite field.

For Monte Amiata only few Nd and Pb isotopic data are available (Innocenti et al. 1992) but these data support a model of mixing between Roman Province and crustal melts.

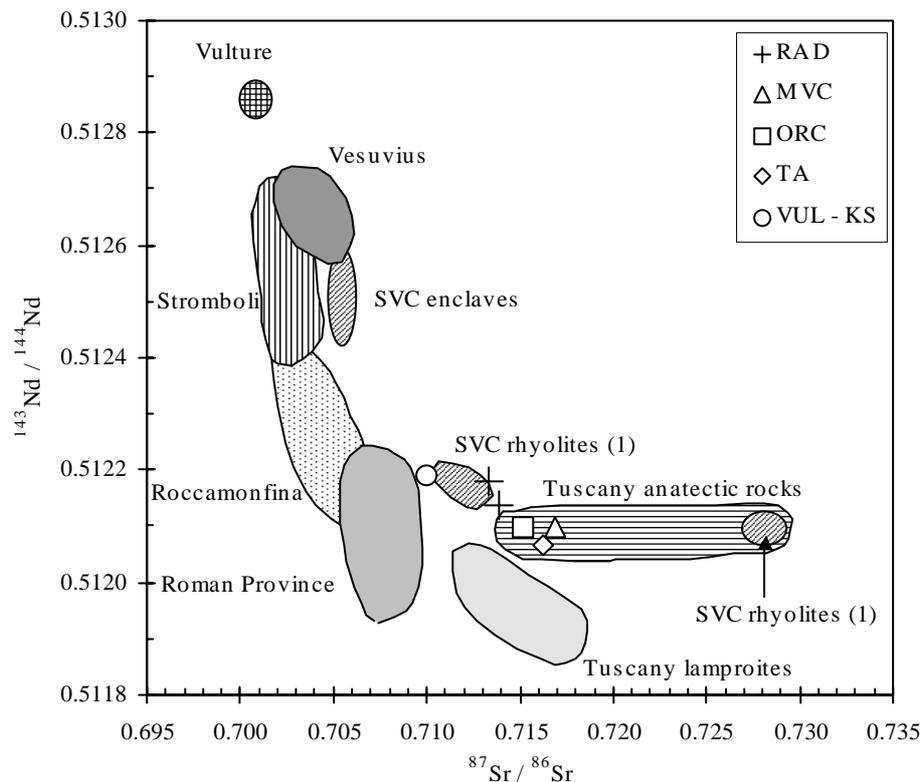

Fig. 5-8:  $^{143}\text{Nd} / ^{144}\text{Nd}$  vs.  $^{87}\text{Sr} / ^{86}\text{Sr}$  ratios for igneous rocks from Italy (RAD: Radicofani, MVC: Montecatini Val di Cecina, ORC: Orciatico, TA: Torre Alfina, VUL-KS: Monti Vulsini K series, SVC: San Vincenzo, SVC rhyolites (1): rhyolites with a low  $^{87}\text{Sr} / ^{86}\text{Sr}$  ratio, SVC rhyolites (2): rhyolites with a high  $^{87}\text{Sr} / ^{86}\text{Sr}$  ratio, SVC enclaves: mafic enclaves in the rhyolites). Data are summarized from Innocenti et al. (1992) and Peccerillo & Panza (1999). The new data are represented by symbols (Peccerillo, personal information, see tab. A-22).

Rhyolites from Roccastrada agree with the Tuscan anatectic rocks, but San Vincenzo rhyolites display a different behaviour. They are not plotted in the diagram because Pb isotope ratios are not available. Mafic inclusions have very high  $^{143}\text{Nd} / ^{144}\text{Nd}$  ratios. Thus the mafic melt, which influenced the group B rhyolites, must be different from the Roman and the Tuscan mantle melts. This may indicate a heterogenic composition of the mantle beneath the Tuscan Province.

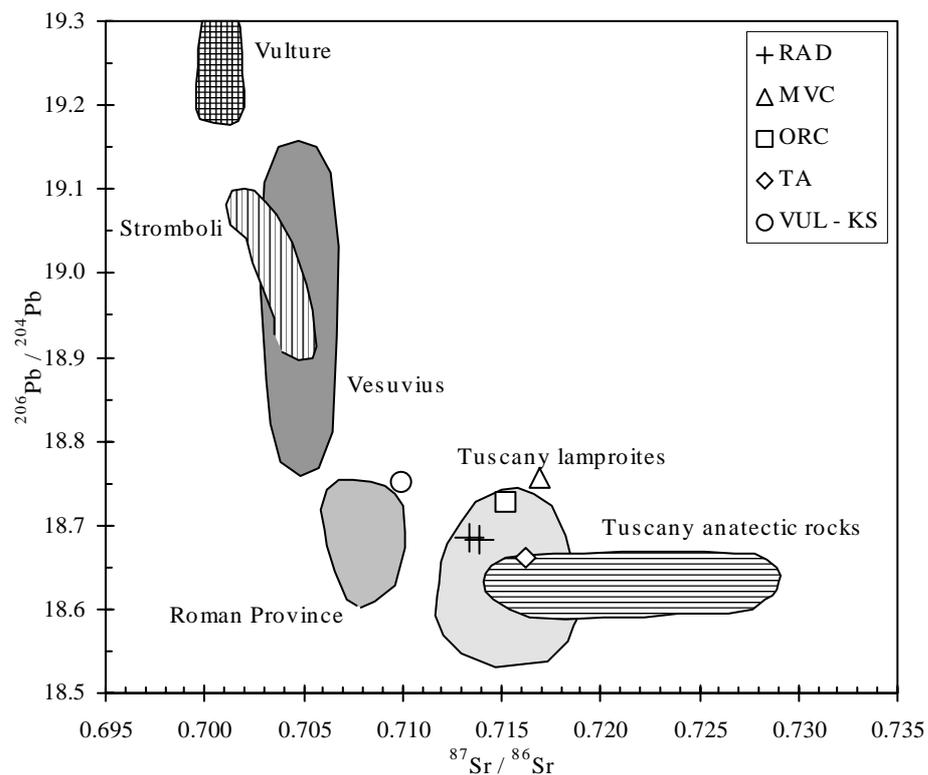

Fig. 5-9:  $^{206}\text{Pb} / ^{204}\text{Pb}$  vs.  $^{87}\text{Sr} / ^{86}\text{Sr}$  ratios for the igneous rocks from Italy (RAD: Radicofani, MVC: Montecatini Val di Cecina, ORC: Orciatice, TA: Torre Alfina, VUL-KS: Monti Vulsini K series). Data are summarized by Peccerillo & Panza (1999) and Vollmer (1976). Additional isotopic analyses (symbols) were carried out at the University of Perugia (Peccerillo, personal information, see tab. A-22).

## 5.7 Petrogenesis and Geodynamic Model

In this section the petrogenesis of the central Italian igneous rocks is set in a broader geodynamic model. The complex petrological and geochemical situation of the Tertiary and Quaternary magmatism in central Italy and on the Italian peninsular has often been described but without a consideration of the geodynamic situation of the Mediterranean region. On the other hand the magmatic evolution in Italy in relation to the geodynamic situation has been investigated but without an explanation of the geochemical and petrological composition of the single magmatic zones or provinces in Italy. Recently Peccerillo (1999) and Peccerillo & Panza (1999) have developed a combined petrological and geodynamic model of the Italian magmatism. The petrogenetic results of this study are tested whether they confirm this model or not.

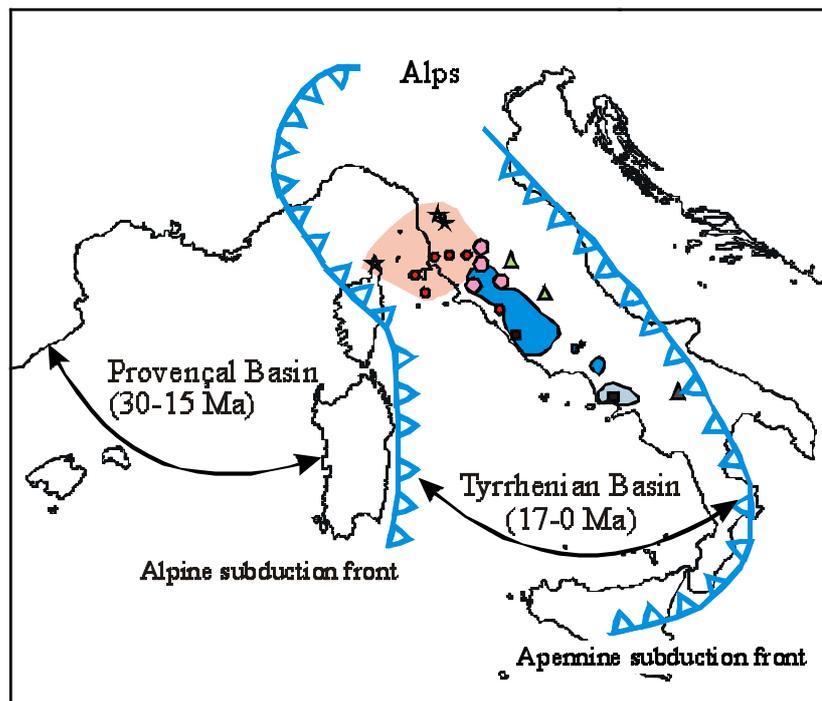

Fig. 5-10: Schematic distribution of magmatism on the Italian peninsular (modified after Peccerillo 1999): Three provinces are shown: I) in the northern part the Tuscan Province (bright red) with lamproites (stars) and crustal anatectic rocks (red circles); II) in the central part the Roman Province (dark blue field), transitional rocks (big, bright red circles) and kamafugitic rocks (green triangles); III) in the southern part the Campanian Province (bright blue field) and the Mount Vulture (black triangle). Subduction fronts are plotted as lines, the Alpine subduction front in the western part and the present Apennine front in the eastern part (Gueguen et al. 1997). The arrows indicate backarc extension.

In central Italy two general trends of eruption ages can be observed. Rock ages decrease from west to east and from north to south (e.g. Peccerillo et al. 1987, Innocenti et al. 1992, Serri et al. 1993). The oldest rocks are the crustal anatectic rocks and lamproites with an age of older than 6 and about 4 Ma, respectively (e.g. Peccerillo et al. 1987, Innocenti et al. 1992). The igneous rocks from the islands lying west of central Italy display a higher age, e.g. the lamproites from Corsica are 14 - 15 Ma old (e.g. Peccerillo et al. 1987). Generally the Roman Province rocks are younger than 0.6 Ma (e.g. Peccerillo et al. 1987). A geodynamic model has to explain the different compositions of the rocks including the differences between the mantle compositions beneath the Tuscan and Roman Province as well as the sequence of ages. Villemant & Fledoc (1989) dated on the basis of Th-U disequilibrium investigations an age of about 300 ka for the metasomatism of the Vico volcano mantle source, Roman Province. Therefore the metasomatism of the Roman Province type rocks on the Italian peninsular is temporally related to the eruption age of the rocks without a large time gap. But on the other hand such implications are not given for the metasomatism of the lamproitic mantle source. In

this case the metasomatic event must not necessarily be related to the eruption age but may be older (Peccerillo 1999, Peccerillo & Panza 1999).

The Tuscan lamproites display an almost identical composition to lamproitic rocks from the western Alps and from Corsica (Mitchell & Bergman 1991, Peccerillo 1999). Therefore the source of these lamproites must be similar in composition. Furthermore all lamproites are sited east of the Alpine collision front (Gueguen et al. 1997, Peccerillo 1999). The geochemical and geological data indicate a similar source with a corresponding evolutionary history of these lamproites (Peccerillo 1999). Furthermore a possible mantle contaminant may be rocks with a similar composition like the Dora Maira metapelitic rocks (Peccerillo 1999). For these rocks Tilton et al. (1989) have shown a deep subduction to a depth of about 100 km and suggested that rocks with a similar composition had been the contaminant of the mantle source of the Spanish lamproites. The Spanish lamproites from the Murcia-Almeria region complete the tectonic view of a similar genesis of lamproites from the western Mediterranean region including Tuscany. The Spanish lamproites are situated on the south - the African side - of the Alpine front (e.g. Mitchell & Bergman 1991).

As mentioned before the lamproitic rocks in the central Mediterranean region - Corsica and Tuscany - and in the western Alps are located east of the Alpine front and thus on the overriding plate during the collision of the Apulia-Africa and European plates (Rehault et al. 1989). During upper Cretaceous the oceanic crust of the European plates were subducted under the overriding Apulia-Africa plate (Rehault et al. 1989). As a consequence pelitic sediments could possibly be subducted beneath the Apulia plate and contaminate the mantle beneath the Apulian plate. After collision of the Apulia with the European plate subduction of the European plate ceased and parts of the Apulia-Africa plate overthrust the European plate. Then the Apulia plate started to be subducted beneath Europe (Rehault et al. 1989). During subduction of the Apulian plate induced by a higher density of the Apulian lithosphere compared to the underlying asthenosphere (Malinverno & Ryan 1986) the subducted slab rolled back into a southern direction in the western Mediterranean area and into an eastern direction in the middle Mediterranean region (Malinverno & Ryan 1986). Today subduction occurs beneath the Italian peninsula (e.g. Gueguen et al 1997, Marson et al. 1995). Because the roll back of the subducted slab is faster than the movement of the African plate in the European direction, extension occurs in the central Mediterranean region resulting in the opening of the Provençal and Tyrrhenian basin (Malinverno & Ryan 1986). During the anticlockwise rotation of the arc, the Corsica-Sardinia microplate were detached from the European continent and were translated to its recent position (Keller et al. 1994). This tectonic movement can explain the sequence of the emplacement of lamproitic rocks in the middle Mediterranean region. 42 Ma ago lamproitic rocks in the western Alps were formed in an

extensional regime. A subduction related genesis of the Alpine lamproitic rocks was suggested by Venturelli et al. (1984b). Then 14 - 15 Ma ago the lamproites from Corsica were produced and finally 4 Ma ago the Tuscan lamproites (Civetta et al. 1978, Peccerillo et al. 1987). Source of the lamproites are preserved parts of the metasomatized Apulian lithospheric mantle. Partial melting of this mantle part was triggered by two factors. The vacant space by rolling back of the lithospheric part of the Apulia plate was replaced by the upwelling hot asthenospheric mantle (Keller et al. 1994). Thus a high heat flow beneath the Provençal and Thyrrhenian basin as well as beneath central Italy was produced (Della Vedova et al. 1991). The second factor is the extensional stress regime in parts of the central Mediterranean region and of the Italian peninsular (e.g. Carmignani et al. 1994, Montone et al. 1995, Keller et al. 1994). Increasing temperature and decreasing pressure resulted in a partial melting of the lamproitic mantle source.

In contrast the Roman Province magmatism is related to the subduction of the Apulian plate itself. The sinking Apulian plate beneath Italy may be the source of the metasomatic agents - fluids or melts - generated by marly metasediments. This metasomatic agent raised upwards in the upwelling mantle material and contaminated it. Metasomatism and partial melting can not have occurred with a long time gap (Villemant & Fledoc 1989). Therefore the magmatism of the Roman Province is directly related to the metasomatic event.

Partial melting of the Tuscan basement resulting in the crustal anatectic rocks like the Roccastrada and San Vincenzo rhyolites was related to the same extensional tectonic situation like the generation of the lamproites. Reasons for crustal melting are the high heat flow and the extension in Tuscany (Carmignani et al. 1994, Montone et al. 1995, Keller et al. 1994). Furthermore fluids mobilized in the mantle support the melting (Civetta et al. 1978). These fluids can be the contaminant of the crustal rocks like the Roccastrada rhyolites resulting in an enrichment in LILE like K, Rb, Li, and Th. Additionally for the crustal derived melts with a contribution of mantle melts, like the rocks from Monte Amiata and the San Vincenzo group B rhyolites, the mantle melt itself can also heat up the surrounding crustal rocks.

The sequence of the eruptions in central Italy - southeast decreasing ages - can be explained by a continuous southeast movement of the extensional regime (Montone et al. 1995, Keller et al. 1994). In contrast the southwards decrease of the eruption ages within the Roman and Campanian Province should be related to the ages of metasomatism of the mantle sources (Peccerillo & Panza 1999).

The present mantle reconstruction beneath the Italian peninsular has been described by Peccerillo & Panza (1999). Beneath the Tuscan Province the upper part of the mantle consists of an old metasomatically veined restitic soft lid approximately metasomatized during the Alpine subduction. This lithospheric mantle part is the source of the lamproitic melts like the

rocks from Orciatice, Montecatini Val di Cecina and Torre Alfina. Lithospheric roots of the Apulia plate underlie this region. In the Roman Province this soft lid of a metasomatically veined restitic mantle also occurs. But this part is underlain by a fertile mantle of asthenospheric origin. It is probably contaminated by Ca rich marly sediments. This fertile metasomatized mantle is the source region of the Roman Province type rocks. The differences between the undersaturated HK series and the K series can result from a lower pressure regime of melting for the K series. The volcano of Radicofani is thus located above a mantle region where both mantle types melted, the metasomatically veined restitic part and the fertile mantle part. This produced the transitional rocks from Radicofani. However the variability of the composition within the HK and the K series (Conticelli et al. 1991) points to a heterogeneous mantle composition beneath the Roman Province. Therefore the mantle beneath the Roman Province is not homogeneously metasomatized but probably display lateral and vertical heterogeneities.

## 6 Conclusions

Tertiary to Quarternary mantle derived igneous rocks of Italy are characterized by a crustal signature of the trace elements and isotope ratios as well as a potassic to ultrapotassic composition. The reason for the crustal signature is a matter of debate, whether crustal assimilation or source contamination occurred and to which degrees these two processes influenced the mantle derived rocks.

This investigation has focussed on central Italy because this region is of special interest. Within a narrow area a large diversity of different igneous rocks can be observed. In this area two different magmatic provinces overlap - the Roman Magmatic Province in southern central Italy with the Vulsinian mountains and the Tuscan Magmatic Province. The Tuscan Magmatic Province is characterized by lamproites, crustal anatectic rocks as well as hybrid rocks from crustal and mantle derived melts and transitional rocks between Roman type rocks and Tuscan lamproites.

In central Italy three different types of mantle derived rocks can be distinguished. These are the Roman Province type rocks from the Vulsinian mountains, the lamproites and the transitional rocks. For the whole mantle beneath central Italy a metasomatic enrichment of LILE like K, LREE,  $^{18}\text{O}$ ,  $^{87}\text{Sr}$ , and  $^{206}\text{Pb}$  is assumed.

Lamproites from the Tuscan Province are mantle derived melts. They are produced by partial melting of a metasomatically overprinted depleted mantle source. Characteristics of the mantle source are high contents of LILE, LREE, and high  $\delta^{18}\text{O}$  values and high  $^{87}\text{Sr}/^{86}\text{Sr}$  values. Metasomatic agents had a composition similar to the Dora Maira metagranites. An alpine age of the metasomatism has been suggested by Venturelli et al. (1984b) and thus the metasomatism could be a consequence of the subduction of the African plate beneath the European plate.

Roman Province type rocks occurring at the Vulsinian mountains are also mantle derived melt type. The mantle source of these rocks is a fertile mantle, which was metasomatized by fluids or melts rich in LILE, LREE,  $^{18}\text{O}$ , and  $^{87}\text{Sr}$ . The oxygen isotope composition of the mantle source is about 6.7 – 7.6 ‰ and thus lower than Holm & Munksgaard (1982) proposed. Therefore the oxygen isotopic composition of the Vulsinian mountains mantle source is similar to volcanic regions of the Roman Province lying south (Ferrara et al. 1985, Turi et al. 1986). The oxygen isotope composition of the Roman Province mantle seems to be homogeneous. The metasomatic agents were produced recently during the subduction of the Apulian plate beneath central Italy. The source of the metasomatizing melts or fluids are mainly sediments. These melts penetrated the mantle beneath the Roman Province producing a veined mantle. The major carrier of the LILE, especially K, and LREE is probably phlogopite.

The differences of K and HK series rocks are the chemical composition of the bulk rock. The isotopic composition, especially the oxygen isotopes, are similar. Thus the K and HK series rocks were probably produced in a roughly homogeneously composed mantle but under different pressure conditions with a lower pressure for the KS and a higher pressure for the HKS rocks. The range from less to highly evolved rocks from the Vulsinian mountains can be produced by fractional crystallization and crustal assimilation processes or more complex processes like refilling + tapping + crystal fractionating + assimilation (Conticelli et al. 1997). However large assimilation of carbonatic material in order to produce the high oxygen isotope ratios can be excluded. Although the general composition of the mantle beneath the Roman Province is homogeneous, variations in the composition could be observed by (Conticelli et al. 1991) leading to the conclusion that for every volcano the source composition had to be determined and that the source compositions for the single volcanoes of the Vulsinian mountains differ slightly.

Comparing both mantle sources from the Tuscan and Roman Province the following differences and common grounds can be observed. Prior to metasomatism the mantle of the Tuscan Province was depleted whereas the Roman Province mantle was fertile. The metasomatic agents were differently composed producing different radiogenic isotope characteristics for the two mantle sources. But their oxygen isotopic compositions are probably similar ranging between 6.5 – 7.5 ‰. The metasomatism of the Tuscan mantle is an old one of an Alpine age, whereas the metasomatism of the Roman mantle is relatively young. Lamproitic melts were generated in the mantle at low depth (lithospheric mantle) whereas the KS rocks from the Roman Province were generated at an intermediate depth and the HKS rocks at greater depths.

The third group of mantle derived melts are transitional rocks between Tuscan and Roman Type melts. Two different volcanoes have been sampled. The Torre Alfina volcano has a great geochemical affinity to the lamproites. But particularly clinopyroxenes display an influence of Roman type melts in the genesis of the Torre Alfina lavas. The peridotitic xenolith clearly indicates an metasomatically overprinted and  $^{18}\text{O}$  enriched mantle beneath central Italy.

The other transitional rocks are the volcanic rocks from Radicofani. They are also a mixture of lamproitic and Roman type melts but with a stronger affinity to the Roman type melts. These rocks display a large variability in Sr isotope ratios and a homogeneous composition of oxygen isotope ratios. A combination of these two isotopic systems is often used to distinguish between crustal assimilation and source contamination (James 1981) – a large range of Sr and a small range of oxygen isotope ratios is interpreted as source contamination. But in this case the two endmembers of the Radicofani rocks have different Sr isotope ratios and similar oxygen isotope ratios, so that the previous interpretation cannot be used for these

rocks. The generation of the transitional rocks can be explained by a transition zone between the Roman and the Tuscan mantle. The Roman Province mantle underlies the Tuscan Province mantle in this zone. Generated melt in the Roman Province mantle raised up and mixed with melts in the Tuscan mantle with different degrees producing the rocks from Torre Alfina and Radicofani.

In the Tuscan Province acidic crustal anatectic rocks also occur like the rhyolites from Roccastrada and San Vincenzo. Their chemical compositions point to an enriched crustal source. The enriching agents for the Roccastrada and parts of the San Vincenzo rhyolites (group A) were probably fluids derived from the mantle. The oxygen isotope ratios are common for crustal anatectic rocks. However the San Vincenzo group B rhyolites are assumed to be influenced by a mantle derived melt. The mixing of mantle and crustal melts is preserved by the oxygen isotope and Sr isotope (Ferrara et al. 1989) heterogeneities of the phenocrystals.

Hybrid rocks between crustal and mantle melts occur at Monte Amiata. The crustal melts are similar to the San Vincenzo rhyolites whereas the mantle endmember is similar to the K series rocks from the Vulsinian mountains.

## 8 Appendix

### Abbreviations

ab	albite
ac	acmite
an	anorthite
av.	Average
b.d.l.	below detection limit
bio	biotite
cel	celsian
cpx	clinopyroxene
EMPA	electron beam microprobe analysis
en	enstatite
excimer	excited dimer
fa	fayalite
FeO <sub>tot</sub>	total iron content expressed as FeO
fo	forsterite
fs	ferrosilite
HFSE	high field strength elements
HKS	high potassic series (rocks from Vulsinian mountains, Roman Province)
HREE	heavy rare earth elements
ICP-MS	inductively coupled plasma - mass spectrometry
IR	infra-red
KS	potassic series (rocks from Vulsinian mountains, Roman Province)
LA	laser ablation
LA-ICP-MS	laser ablation - inductively coupled plasma - mass spectrometry
LILE	large ion lithophile elements
LREE	light rare earth elements
n.a.	not analyzed
Mg#	Magnesium-number; defined as $\text{molar Mg} / (\text{Mg} + \text{Fe}_{\text{tot}})$
MORB	mid ocean ridge basalt
Nd-YAG	Neodymium-Yttrium-Aluminium-Garnet
ol	olivine
opx	orthopyroxene
or	orthoclase
phl	phlogopite
plg	plagioclase
ppm	parts per million, equal to mg / kg
qtz	quartz
REE	rare earth elements (La to Lu)
s	standard deviation
san	sanidine
SIRMS	stable isotope ratio mass spectrometry
SMOW	standard mean ocean water
tsch	Tschermak's molecule
UV	ultra-violet
wo	wollastonite

Tab. A-1: Samples, localities and petrological classification.

Sample	Locality	Rock Type
VUL 9701	Monti Vulsini, Acquapendente	phonolite
VUL 9702	Monti Vulsini, Valento	phonotephrite
VUL 9703 A	Monti Vulsini, Selva del Lamone	shoshonite
VUL 9703 B	Monti Vulsini, Selva del Lamone	shoshonite
VUL 9704	Monti Vulsini, 2.5 km E' Viterbo	phonotephrite
VUL 9705	Monti Vulsini, 1.5 km E' Viterbo	phonotephrite
VUL 9706	Monti Vulsini, 1 km S' Bolsena	phonotephrite
VUL 9707	Monti Vulsini, 3 km E' Bolsena	tephriphonolite
Montefiascone	Monti Vulsini, Montefiascone	potassic trachybasalt
ORC 9701	200 m E' Orciatico	lamproite
ORC 9702	100 m E' Orciatico	lamproite
MVC 9701	50 m E' Montecatini Val di Cecina	lamproite
MVC 9702	250 m E' Montecatini Val di Cecina	lamproite
RAD 9701	Radicofani, 700 m N' top	basaltic andesite
RAD 9702 A	Radicofani, 50 m SW' top	basaltic andesite
RAD 9702 B	Radicofani, 50 m SW' top	basaltic andesite
RAD 9703	Radicofani, on the top	basaltic andesite
RAD 9705	2 km SW' Radicofani	basaltic andesite
RAD 9706	2 km SW' Radicofani	basaltic andesite
TA 9701	Torre Alfina, 300 m SSW' village	transitional rock between lamproites and Roman Province type rocks
TA 9702	Torre Alfina, 200 NNW' village	transitional rock between lamproites and Roman Province type rocks
ROC 9701	Roccastrada, Piloni	rhyolite
ROC 9702	5 km N' Roccastrada	rhyolite
SVC 9701	1.2 km ESE' San Vincenzo	rhyolite
SVC 9702	1.2 km E' San Vincenzo	rhyolite
SVC 9703	500 m NNE' San Vincenzo	rhyolite
AMT 9701	Monte Amiata, 400 m E' Castel del Piano	trachyte

---

Sample	Locality	Rock Type
AMT 9702	Monte Amiata, Prato Contessa	trachyte
AMT 9703 I	Monte Amiata, Prato Contessa	latite, xenolith
AMT 9703 II	Monte Amiata, Prato Contessa	shoshonite, xenolith
AMT 9704 A	Monte Amiata, Ermeata	latite
AMT 9704 B	Monte Amiata, Ermeata	latite

## **Acknowledgements**

I gratefully acknowledge Prof. Dr. J. Hoefs for the allocation of the very interesting project and for supporting me in both advice and discussions.

I am especially grateful to Prof. Dr. A. Peccerillo from the University of Perugia for the introduction in the regional geology and petrology of central Italy and for supporting the sampling. Prof. Dr. A. Peccerillo is also gratefully appreciated for helpful discussions and comments.

I thank Prof. Dr. S. F. Foley from the University of Greifswald for being the co-advisor.

Furthermore I thank Dr. J. Fiebig (LA-SIRMS), Dr. G. Hartmann (XFA), Dr. A. Kronz (EMPA), R. Przybilla (LA-SIRMS), and Dr. K. Simon (ICP-MS, LA-ICP-MS) for helpful discussions and technical advice. I also thank A. Reitz and E. Schiffcyzk for supporting me by common problems of laboratory working.

I thank B. Hagen (University of Bonn) for carrying out CO<sub>2</sub> LA-SIRMS analyses of phenocrystals from selected samples.

I am especially indebted to S. Schlabach for helping me at any problems.

This project was financially granted by the Deutsche Forschungsgemeinschaft (project no. Ho 375 / 16-1 and Ho 375 / 16-2).

## Curriculum Vitae

Date and place of birth: 4<sup>th</sup> of December 1969, Bremen (Germany)

1976-1990 Grundschule, Orientierungsstufe and Gymnasium in the municipality of Ganderkesee, school leaving exam: Allgemeine Hochschulreife

1990-1991 National service in Goslar and Delmenhorst

1991-1996 Study of mineralogy at the Georg-August Universität, Göttingen

1996 Diploma in Mineralogy

Advisor: Prof. Dr. H. Heinrichs, Co-advisor: Prof. Dr. J. Hoefs

Thesis for diploma: “Der Einfluß der Silikatverwitterung auf den Chemismus abgepreßter Porenlösungen von versauerten Böden (Harz, Solling)” (translated: “The Influence of Silicate Weathering on the Chemistry of Squeezed Pore Solutions from Acidic Soils (Harz mountains, Solling mountains)”)

1997-1999 Doctorate studies, scientific assistant at the Geochemisches Institut, University of Göttingen, in the project “<sup>18</sup>O-Zusammensetzung von Phenocrysten in Vulkaniten analysiert durch Laser-Evaporation”

2000 Thesis: “Volcanic Rocks from Central Italy: An Oxygen Isotopic Microanalytical and Geochemical Study”

Advisor: Prof. Dr. J. Hoefs, Co-advisor: Prof. Dr. S.F. Foley (University of Greifswald)

since July 2000 R & D manager at Merck KGaA, Darmstadt, Germany, in the department of research on pigments
