

Investigation of the Amorphization of iron and
austenitic stainless steel films by supersaturation with
Boron, Carbon, Nitrogen and Oxygen

Dissertation
zur Erlangung des Doktorgrades
der Mathematisch-Naturwissenschaftlichen Fakultäten
der Georg-August-Universität zu Göttingen

vorgelegt von
Salvatore Cusenza
aus Wolfsburg - Deutschland

Göttingen 2008

D 7

Referent: Prof. Dr. Peter Schaaf

Korreferent: Prof. Dr. Reiner Kirchheim

Tag der mündlichen Prüfung: 14.11.2008

Physics is like sex - sure, there is some practical results we get from it, but that's not the reason why we do it.

Richard P. Feynman

3.1	Viscosity (η)-temperature (T) dependence corresponding to crystallization and vitrification of a metallic melt.	27
3.2	Temperature dependence of enthalpy H and specific heat C_p corresponding to crystallization and vitrification of a metallic melt.	28
3.3	Illustration of atomic arrangements in an amorphous solid and the corresponding radial distribution function $\rho(r)$	28
4.1	Principle setup of a planar magnetron system.	31
4.2	Three different mechanisms for reactive sputter deposition: (a) at the target, (b) in the plasma volume, (c) at the substrate.	32
4.3	Principle setup of the PLD system (left) and typical PLD plasma (right).	33
4.4	Principle setup of the FEL system used at the Jefferson lab.	34
4.5	Quadrupole splitting for a 3/2 to 1/2 transition. The magnitude of quadrupole splitting Δ is shown.	36
4.6	Magnetic splitting of the nuclear energy levels.	36
4.7	Process scheme of the internal conversion for ^{57}Fe	37
4.8	Mechanical drawing of the CEMS detector.	37
4.9	Typical XAFS spectrum for Fe. The XANES and EXAFS regions are identified. $\mu(E)$ is shown with the smooth background function $\mu_0(E)$ and the edge step $\Delta\mu_0(E_0)$	38
4.10	Visualization of the so-called Bragg equation. Maximum scattered intensity is only obtained when the phase shifts add to a multiple of the incident wavelength λ	38
4.11	Laue diffraction geometry.	39
4.12	Vectorial display of the Laue diffraction geometry.	39
4.13	The $\theta/2\theta$ geometry. The x-ray tube is operated in the line focus mode; the plane of the figure is the scattering plane.	39

4.14	The GIXRD geometry. The x-ray tube is operated in the line focus mode; the plane of the figure is the scattering plane.	40
4.15	The wavelength λ of the electrons as a function of the accelerating voltage.	41
4.16	The wavelength λ of the electrons as a function of the accelerating voltage.	41
4.17	Schematics of the IONAS accelerator.	43
4.18	Schematics of the RNRA process.	43
5.1	top: GIXRD (2° incidence angle) pattern of the ARMCO-Iron sputter target; bottom: $\theta - 2\theta$ pattern of the AISI 316 sputter target.	45
5.2	(a) Transmission Mössbauer spectrum of the original ARMCO-Iron sputter target; (b) CEM spectrum of the original AISI 316 sputter target. The corresponding distributions of the hyperfine fields $p(B)$ are given on the right.	45
5.3	Angular scans of ARMCO-Iron sputter target: (top) coercitive field H_C ; (middle) relative remanence M_r/M_s ; (bottom) magnetization energy density E_s/M_s	46
6.1	Sputtering-yield Y of Fe, C and the sum of both elements in dependence of the Ar^+ ion energy.	47
6.2	The $\text{Fe}_{50}\text{C}_{50}$ Magnetron sputter target.	47
6.3	Growth rate g as a function of the Ar gas flow j_{Ar} for the room temperature deposition.	48
6.4	GIXRD (2°) spectra of the inert sputtered samples. The Ar gas flows are given in the graphs.	48
6.5	Peak position and peak width of the first broad peak in the XRD spectra of the reactive sputtered stainless steel films.	48
6.6	Mössbauer spectra of the inert sputtered FeC films.	49
6.7	Hysteresis curve of the inert deposited FeC film sputtered at 50 sccm Ar gas flow.	50
6.8	STM pattern for the FeC sample sputtered at 140 sccm Ar gas flow.	50
6.9	Autocorrelation of the STM image as shown in Fig. 6.8	50
6.10	Power-spectral density diagram derived from the line scan, which is shown in Fig. 6.9. The parameters of the Gauss multi-peak fit are given in the graph.	50
6.11	FeC film after deposition. The numbers indicate the positions of the RBS measurements.	50
6.12	Mean concentrations as derived from the RBS fitting routine.	51
6.13	Poisoning of the target as a function of the sputter yields of Fe and C at fixed $E_{\text{Ar}^+} = 400$ eV. The black dashed line corresponds to the $\text{Fe}_{50}\text{C}_{50}$ stoichiometry.	51
6.14	RBS spectra of the target before (black) and after (red dashed) sputtering.	51
6.15	Growth rate g as a function of the CH_4 gas flow j_{CH_4} for the room temperature deposition.	52
6.16	GIXRD (2°) spectra of the carburized films. The CH_4 gas flows are given in the graph.	52
6.17	Peak position and peak width of the first broad peak in the XRD spectra of the reactive sputtered stainless steel films.	53
6.18	Angular scans of (left) 0.01 sccm CH_4 and (right) 0.10 sccm CH_4 gas flow. The coercive field H_C (top) and the relative remanence M_R/M_S (bottom) are shown.	53
6.19	Mössbauer spectra of the reactive sputtered AISI 316 films. The numbers in the graphs represent the methane gas flow.	54
6.20	RBS spectra of the reactively sputtered films. The CH_4 flow is given in the graph.	55

6.21	Carbon content in the reactively sputtered films as derived from the RBS analysis versus the CH ₄ gas flow.	55
6.22	AFM measurement (left) and cross section analysis (right) of the sample sputtered with a CH ₄ gas flow of 0.01 sccm. The cross section analysis (right bottom) shows the line from which the roughness and the cluster-size were derived.	55
6.23	Raman results for the amorphous soft ferromagnetic carburized AISI 310 and AISI 316 films.	56
6.24	Mössbauer spectra of vacuum annealed AISI 316 film sputtered with a magnetron power of 100 W and 0.01 sccm methane. Exposition time and temperature are given.	56
6.25	GIXRD (2° incidence angle) spectra of the post-vacuum annealed samples sputtered with a magnetron power of 100 W and 0.01 sccm methane. Annealing temperature and time are given.	57
6.26	SEM pictures of the post-vacuum annealed samples: a) 1 h at 973 K, b) 10 h at 973 K and c) 120 h at 973 K.	57
6.27	Raman measurements of the post-vacuum annealed samples.	57
6.29	GIXRD (2° incidence angle) spectra of the as-carburized samples sputtered with a magnetron power of 100 W and 0.01 sccm methane. The substrate temperatures are given.	58
6.30	Angular scans of the film sputtered at 673 K with 0.1 sccm CH ₄ gas flow. The polar diagrams of the coercive field H_C (left) and the relative remanence M_R/M_S (right) are shown.	58
6.28	CEM spectra of carburized AISI 316 films sputtered with a magnetron power of 100 W and 0.01 sccm methane at two temperatures: T = 298 K (top), T = 673 K (bottom). On the right hand side, the hyperfine field distribution $p(B)$ and the quadrupole splitting distribution $p(\Delta)$ are shown.	59
6.31	Corrosion tests of AISI 310 (a) and AISI 316 (b) sputtered films. All samples were sputtered at a magnetron power of 100 W, inert-sputtered sample with 12 sccm Ar gas flow, carburized samples with 0.01 sccm CH ₄ gas flow. Temperatures are given in the graphs.	60
6.32	Peak width of the first amorphous peak in dependence of the carbon content of reactive sputtered stainless steel films.	61
6.34	FIM pattern of the amorphous and soft ferromagnetic film (sputtered at 298 K at 0.01 sccm CH ₄).	62
6.33	TEM pattern of the amorphous and soft ferromagnetic film (sputtered at 298 K at 0.01 sccm CH ₄). a) and b) dark field pattern, c) SAD pattern and d) HR-TEM of the film.	63
6.35	DSC curve of the amorphous and soft ferromagnetic film (sputtered at 298 K at 0.01 sccm CH ₄) measured at a heating rate of 10 K/s. the arrow refers to the glass transition temperature T_g	63
6.36	Fine-structure oscillations weighted with k^2 factor of: a) γ -(Fe,Cr,Ni) (bulk AISI 316), b) α -Fe, c) Fe ₃ C and the reactive magnetron-sputtered sample deposited with 0.01 sccm CH ₄	64
6.37	BFT moduli of bulk AISI 316 (solid) and the amorphous and soft ferromagnetic film (sputtered at 298 K at 0.01 sccm CH ₄) (dashed line) measured at the Fe K-edge (top) and at the Ni K-edge (bottom).	64
6.38	XRD pattern of the reactive magnetron-sputtered film deposited at 0.01 sccm CH ₄ gas flow.	65
6.39	Median hyperfine field B_{hf} in dependence of the carbon content of reactive sputtered stainless steel films.	65
6.40	Crystal structure of trigonal Ni ₃ C phase: space group R -3 c (167), $a = 4.5530 \text{ \AA}$, $c = 12.9200 \text{ \AA}$	66
6.41	Growth rate g as a function of the N ₂ gas flow j_{N_2} for the room temperature deposition (line is only to guide the eye).	68

6.42	GIXRD (2°) spectra of the nitrided films. The N_2 gas flows are given in the graph; the peaks of the ZnS-type (Fe,Cr,Ni)N phase are indexed.	68
6.43	Peak position and peak width of the first broad peak in the XRD spectra of the reactive sputtered stainless steel films.	69
6.44	Mössbauer spectra of the reactive sputtered AISI 316 films. The numbers in the graphs represent the nitrogen gas flow.	70
6.45	Angular scans of the reactive sputtered films with: (top) 0.01 sccm N_2 and b) (bottom) 0.05 sccm N_2 gas flow. The polar diagrams of the coercive field H_C are shown left and the relative remanence M_R/M_S at the right.	71
6.46	RBS spectra of the reactively sputtered films. The N_2 flow is given in the graph.	71
6.47	Nitrogen content in the reactively sputtered films as derived from the RBS analysis versus the N_2 gas flow.	71
6.48	RNRA depth-profiling results of the as-nitrided samples. The N_2 gas flow are given in the graph.	72
6.49	^{111}In PAC perturbation spectra along with their Fourier transforms for measurements of the as-nitrided samples: a) (top) PAC measurement of the as-nitrided sample sputtered at 0.05 sccm N_2 gas flow and b) (bottom) PAC measurement after 2 hours of post vacuum annealing treatment performed at $T_a = 973\text{ K}$. All presented spectra are recorded at 298 K.	73
6.50	Dependency between Martens hardness and nitrogen content including data from [132], [133]. The N values are obtained from the RNRA analysis.	73
6.51	Peak width of the first amorphous peak and reactive gas flow in dependence of the nitrogen content of reactive sputtered stainless steel films.	74
6.52	Growth rate g as a function of the O_2 gas flow j_{O_2} for the room temperature deposition (line is only to guide the eye).	75
6.53	GIXRD (2°) spectra of the oxidized films. The O_2 gas flows are given in the graph.	75
6.54	Mössbauer spectra of the reactive sputtered AISI 316 films. The numbers in the graphs represent the oxygen gas flow.	76
6.55	Peak position and peak width of the first broad peak in the XRD spectra of the reactive sputtered stainless steel films.	77
6.56	Angular scans of the deposited film sputtered at 1.00 sccm O_2 gas flow. The polar diagrams of the coercive field H_C (top) and the relative remanence M_R/M_S (bottom) are shown.	77
6.57	RBS spectra of the reactively sputtered films. The O_2 flow is given in the graph.	77
6.58	Oxygen content in the reactively sputtered films as derived from the RBS analysis versus the O_2 gas flow.	78
6.59	^{111}In PAC perturbation spectra along with their Fourier transforms for measurements: a) (top) PAC measurement of the as-oxidized sample sputtered at 1.00 sccm O_2 gas flow and b) (bottom) PAC measurement after 2 hours of post vacuum annealing treatment performed at $T_a = 973\text{ K}$. All presented spectra are recorded at 298 K.	79
6.60	Dependency between Martens hardness and oxygen content. The Oxygen values are obtained from the RBS analysis.	79
6.61	Peak width of the amorphous peak and reactive gas flow in dependence of the oxygen content of reactive sputtered stainless steel films.	80
6.62	Normalized gas flow in dependence of the radius of the reactive gas atoms. The parameters for the exponential decay fitting routine are given in the graph.	81

7.1	Different stainless steel STPLD targets in comparison to a conventional stainless steel PLD target (right). The red lines indicate the laser scan area. As indicated in SS/BN 50:50 STPLD target, for ultra-thin films a scan area of 4 mm (4 mm stainless steel/4 mm C) and 8 mm (8 mm stainless steel/8 mm C) for thin-films were used.	83
7.4	TEM pattern of the NaCl-type FeC grain and its FFT on the right hand.	84
7.2	(top) HR-TEM pattern of a grain. (bottom) diffraction pattern of this grain. The orientation of the reflexes are given in the graph.	84
7.3	Fine Fe and C multilayer system surrounding a metallic glassy grain observed by TEM and its FFT of that area (right).	84
7.5	GIXRD (2°) spectra of the STPLD films deposited at 298 (top) and 823 K (bottom). The temperatures and reflexes are given in the graph.	85
7.7	Median hyperfine field B_{hf} in dependence of the carbon content.	85
7.6	Mössbauer spectra of the STPLD deposited FeC films at 298 K (top) and 823 K (bottom).	86
7.8	RBS spectra of the STPLD films deposited at 298 and 823 K.	86
7.9	GIXRD (2°) spectra of the RPLD film. The reflexes are given in the graph.	87
7.10	CEM spectrum of the RPLD sample. The CH_4 /chamber pressure is given in the graph.	88
7.11	RBS spectra of the RPLD films. The CH_4 /chamber pressure is given in the graph.	88
7.12	Growth rate g as a function of the CH_4 /chamber pressure for the room temperature deposition.	89
7.15	Mössbauer spectra of the reactive sputtered AISI 316 films. The numbers in the graphs represent the methane gas flow.	90
7.13	GIXRD (2°) spectra of the carburized RPLD films. The CH_4 /chamber pressure are given in the graph.	90
7.14	Peak position and peak width of the first broad peak in the XRD spectra of the RPLD stainless steel films.	90
7.16	RBS spectra of the RPLD films. The CH_4 /chamber pressure is given in the graph.	91
7.17	Carbon content in the RPLD films (as derived from the RBS analysis) versus the CH_4 /chamber pressure.	91
7.18	Dependency between Martens hardness and carbon content (as derived from the RBS analysis).	92
7.19	Growth rate g as a function of the carbon area fraction for the room temperature STPLD deposition.	92
7.22	Mössbauer spectra of the STPLD stainless steel films. The numbers in the graphs represent the stainless steel/carbon area fraction of the STPLD targets.	93
7.23	Polar diagrams of the coercive field H_C and the relative remanence M_R/M_S for the STPLD 90:10 (left), the 60:40 (middle) and the 50:50 sample (right).	94
7.26	TEM pattern of the STPLD 9010 sample. Left: overview of the sample; middle: HR-TEM image of film/interface region; right: HR-TEM image of the surface region.	95
7.20	GIXRD (2°) spectra of the STPLD films. The stainless steel/carbon area fractions are given in the graph.	95
7.21	Peak position and peak width of the first broad peak in the XRD spectra of the STPLD stainless steel films.	95
7.24	RBS spectra of the STPLD films. The stainless steel/carbon area ratios are given in the graph.	95

7.25	RBS depth profile of the STPLD 90:10 sample.	96
7.27	Comparison between conventional and modified 60:40 STPLD films: Mössbauer spectra (top); TEM pattern (middle) and RBS spectra with calculated depth profile (bottom). . .	98
7.28	Comparison between conventional and modified 50:50 STPLD films: Mössbauer spectra (top); TEM pattern (middle) and RBS spectra with calculated depth profile (bottom). . .	99
7.29	GIXRD (2° incidence angle) spectrum of the post-vacuum annealed STPLD film. Phase, annealing temperature and time are given in the graph.	100
7.30	CEM spectrum of the post-vacuum annealed 90:10 STPLD film.	100
7.31	TEM patterns of the post-vacuum annealed 90:10 STPLD film.	100
7.32	RBS spectra of the post-vacuum annealed and as-deposited 90:10 STPLD film. the depth profile of the post-vacuum annealed can be found at the bottom	101
7.33	GIXRD (2° incidence angle) spectrum of the 90:10 STPLD film deposited with an substrate temperature of 673 K.	101
7.34	CEM spectrum of the 90:10 STPLD film deposited with an substrate temperature of 673 K.102	
7.35	RBS spectra of the 90:10 STPLD film deposited at 298 and 673 K. The depth profile of the film deposited at 673 K can be found at the bottom.	102
7.36	TEM patterns of the 90:10 STPLD sample deposited at 673 K. Left: overview of the sample; right: HR-TEM pattern.	103
7.37	X-ray reflectivity pattern of the 50:50mod STPLD film.	103
7.38	RBS spectra of the 50:50, 50:50mod and 50:50modwob STPLD film deposited at 298 K. The depth profile of the 50:50modwob STPLD film can be found at the bottom.	104
7.39	EDX-time to space correlation diagram of the 90:10 STPLD film. The dashed line corresponds to the situation, in which the laser spot hits the graphite layer of the target. . . .	105
7.40	EDX-time to space correlation diagram of the 50:50 STPLD film. The dashed line corresponds to the situation, in which the laser spot hits the graphite layer of the target. . . .	105
7.41	Ion distribution of the plasma ions of the 90:10 target.	105
7.42	Ion distribution of the plasma ions of the 50:50 target.	106
7.43	RBS spectra of the Aluminum bulk material and the Al/C 60:40mod STPLD film deposited at 298 K. The depth profile of the Al/C 60:40mod STPLD film can be found at the bottom.106	
7.44	RBS spectra of the Titanium bulk material, the Ti/C 90:10 and the Ti/C 60:40mod STPLD films deposited at 298 K. The depth profile of the Ti/C 90:10 and of the Ti/C 60:40mod STPLD film can be found at the middle/bottom.	107
7.45	Dependence between multilayer thickness and atomic number at constant carbon content. Here, the thicknesses of SS/C, Al/C and Ti/C 60:40mod samples are summarized.	107
7.46	Implantation profiles calculated by SRIM for stainless steel samples containng 1, 3 and 6 at.% boron.	108
7.47	Growth rate g as a function of the boron-nitride area fraction for the room temperature STPLD deposition.	108
7.48	RBS spectra of AISI 316 samples implanted with 1, 3 and 6 at.% boron.	109
7.49	GIXRD (2°) spectrum and peak analysis of the AISI 316 sample implanted with 6 at.% boron.	109
7.50	Polar diagrams of the coercive field H_C (top) and the relative remanence M_R/M_S (bottom) of AISI 316 sample implanted with 1 at.% boron.	109

7.51	Mössbauer spectra of the implanted AISI 316 films. The numbers in the graphs represent the implanted boron concentration.	110
7.52	Peak position and peak width of the first broad peak in the XRD spectra of the STPLD films.	110
7.53	GIXRD (2°) spectra of the carburized films. The stainless steel - boron nitride area fractions are given in the graph.	111
7.54	Mössbauer spectra of the STPLD stainless steel films. The numbers in the graphs represent the stainless steel/boron-nitride fraction of the STPLD targets.	112
7.55	Polar diagrams of the coercive field H_C (top) and the relative remanence M_R/M_S (bottom) of SS/BN 90:10 STPLD sample.	113
7.56	RBS spectra of the STPLD films. The stainless steel/boron-nitride area ratios are given in the graph.	113
7.57	TEM pattern of the SS/BN 80:20 STPLD film. The two numbers in the pattern indicate the position, where the histograms were taken.	113
7.58	Histograms taken from the positions shown in the SS/bn 80:20 TEM pattern.	114
8.1	Light microscope images of the FEL surface processed stainless steel samples. Top: AISI 310; bottom AISI 316.	117
8.2	GIXRD (2°) spectra of the FEL nitrided films. The stainless steel - boron nitride area fractions are given in the graph.	117
8.3	Mössbauer spectra of FEL nitrided AISI 310 and AISI 316 samples.	118
8.4	RBS spectra of the FEL nitrided AISI 310 and AISI 316 samples.	118
8.5	Hardness-depth profiles of the FEL nitrided AISI 310 and AISI 316 samples.	118

List of Tables

2.1	Fe-O crystal structure data.	24
2.2	Fe-B crystal structure data.	25
2.3	Chemical composition of AISI 316. All numeric data are given in wt.%.	25
4.1	Set of parameter for the FEL surface processing: P is the power, $f_{p,micro}$ the frequency of the micro-pulse, \emptyset_{focus} the diameter of the FEL radiation and $\aleph_{sh,i}$ the track displacement of the laser radiation for steel i	34
4.2	Parameters of the electron beam in the ESRF storage ring	38
4.3	Parameters of all RBS measurements at the IONAS facility in Göttingen	42
5.1	Fitting results of the MOKE analysis. χ^2 and χ_{red}^2 represent the values of the statistical significance tests.	46
6.1	Gas flow j , deposition time t , real film thickness d (as measured by Rutherford Backscattering Spectrometry (RBS) after deposition) and derived growth rate $g = \frac{d}{t}$ for the deposited films. All samples were deposited at 298 K with a magnetron power of 100 W and a target-substrate distance of 2 cm.	48
6.2	Mössbauer fitting results of the sputtered FeC samples, deposited at room temperature with a magnetron power of 100 W (f - area fraction (error), mean values of $\langle\delta\rangle$ - isomer shift, $\langle\Delta\rangle$ - the quadrupole splitting for the paramagnetic subspectra, $\langle\epsilon\rangle$ the quadrupole splitting for the magnetic subspectra, B - hyperfine field).	49
6.3	Gas flow j , deposition time t , real film thickness d (as measured by Rutherford Backscattering Spectrometry (RBS) after deposition) and derived growth rate $g = \frac{d}{t}$ for the deposited carburized films. All samples were deposited at 298 K with a magnetron power of 100 W and a target-substrate distance of 10 cm.	52
6.4	Mössbauer fitting results of the carburized AISI 316 samples, deposited at room temperature with a magnetron power of 100 W (f - area fraction (error), mean values of $\langle\delta\rangle$ - isomer shift, $\langle\Delta\rangle$ - the quadrupole splitting for the paramagnetic subspectra, $\langle\epsilon\rangle$ the quadrupole splitting for the magnetic subspectra, B - hyperfine field).	53
6.5	Mössbauer results for the vacuum annealed sample deposited with 0.01 sccm methane flow (δ - isomer shift, Δ - the quadrupole splitting for the paramagnetic subspectra, ϵ the quadrupole splitting for the magnetic subspectra, B - hyperfine field, Γ - line width (HWHM), f - area fraction).	57
6.6	Raman results of the vacuum-annealed samples	58
6.7	CEM results of AISI 316 films, deposited at 673 K with a magnetron power of 100 W and 0.01 sccm CH ₄ flow (f - area fraction (error), mean values of δ - isomer shift, $\langle\Delta\rangle$ - the quadrupole splitting for the paramagnetic subspectra, $\langle\epsilon\rangle$ the quadrupole splitting for the magnetic subspectra, B - hyperfine field).	59

6.8	Hardness, Young modulus and C-content of carburized AISI 310 films, where E is the elastic modulus and ν the poisson ratio	60
6.9	Hardness, Young modulus and C-content of carburized AISI 316 films, where E is the elastic modulus and ν the poisson ratio	60
6.10	Carbide Formation Ability (CFA) of AISI steels. The lattice constants a are also given.	62
6.11	Fit results for the Fe k-edge.	64
6.12	Fit results for the Ni k-edge.	64
6.13	A list of used alloying elements and selected properties: r is the atomic radius; $R_{i/j}$ is the ratio (R) of the solute atom radius to the solvent atom radius; R_N^* is the radius ratio, where the subscript N specifies the particular coordination number; σ^{e^-} is the electronic configuration and CFA the Carbide Formation Ability.	66
6.14	Gas flow j , deposition time t , real film thickness d (as measured by Rutherford Backscattering Spectrometry (RBS) after deposition) and derived growth rate $g = \frac{d}{t}$ for the deposited nitrided films. All samples were deposited at 298 K with a magnetron power of 100 W and a target-substrate distance of 10 cm.	68
6.15	Mössbauer fitting results of the nitrided AISI 316 samples, deposited at room temperature with a magnetron power of 100 W (f - area fraction (error), mean values of $\langle\delta\rangle$ - isomer shift, $\langle\Delta\rangle$ - the quadrupole splitting for the paramagnetic subspectra, $\langle\epsilon\rangle$ the quadrupole splitting for the magnetic subspectra, B - hyperfine field).	69
6.16	Hyperfine interaction parameters of the single line analysis of the as-sputtered samples shown in Fig. 6.44 e) and f). Hyperfine parameters: δ is the isomer shift, QS the quadrupole splitting, Γ the line width (HWHM), and RA the relative area.	71
6.17	PAC interaction parameters of the annealed amorphous and soft ferromagnetic phase at 973 K for 2 hours shown in Fig. 6.49 b). Hyperfine parameters: ν_Q is the quadrupole interaction frequency, δ the damping of ν_Q , η the asymmetry parameter, and RA the relative area.	72
6.18	Hardness, Young modulus and N-content of nitrided AISI 316 films, where E is the elastic modulus an ν the poisson ratio	72
6.19	Gas flow j , deposition time t , real film thickness d (as measured by Rutherford Backscattering Spectrometry (RBS) after deposition) and derived growth rate $g = \frac{d}{t}$ for the deposited oxidized films. All samples were deposited at 298 K with a magnetron power of 100 W and a target-substrate distance of 10 cm.	75
6.20	Mössbauer fitting results of the nitrided AISI 316 samples, deposited at room temperature with a magnetron power of 100 W (f - area fraction (error), mean values of $\langle\delta\rangle$ - isomer shift, $\langle\Delta\rangle$ - the quadrupole splitting for the paramagnetic subspectra, $\langle\epsilon\rangle$ the quadrupole splitting for the magnetic subspectra, B - hyperfine field).	78
6.21	PAC interaction parameters of the annealed amorphous and soft ferromagnetic phase at 973 K for 2 hours shown in Fig. 6.59 b). Hyperfine parameters: ν_Q is the quadrupole interaction frequency, δ the damping of ν_Q , η the asymmetry parameter, and RA the relative area.	78
6.22	Hardness, Young modulus and O-content of oxidized AISI 316 films, where E is the elastic modulus an ν the poisson ratio	79
6.23	Summary of the synthesization parameters of the new amorphous and soft ferromagnetic phase: R is the theoretical calculated radius, R_I the ionic or van-der-Waals radius, R_C the covalent radius, $\sigma_{50:50}$ the structure of stoichiometric FeX phase (where X represent the reactive gas atom), $T_{\sigma_{50:50}}$ the temperature at which the stoichiometric phase can be formed and Λ the amorphization parameter.	82

7.1	Deposition temperature T_{dep} , laser energy, number of pulses $\#$, real film thickness d (as measured by Rutherford Backscattering Spectrometry (RBS) after deposition) and derived growth rate $g = \frac{d}{t}$ for the deposited STPLD films.	83
7.3	Hyperfine interaction parameters of the single line analysis of the STPLD FeC film deposited at 823 K. Hyperfine parameters: δ is the isomer shift, QS the quadrupole splitting, Γ the line width (HWHM), and RA the relative area.	85
7.2	Mössbauer fitting results of the STPLD deposited FeC films: (f - area fraction (error), mean values of $\langle\delta\rangle$ - isomer shift, $\langle\Delta\rangle$ - the quadrupole splitting for the paramagnetic subspectra, $\langle\epsilon\rangle$ the quadrupole splitting for the magnetic subspectra, B - hyperfine field).	86
7.4	Results of the RBS analysis of the STPLD deposited films.	86
7.5	Mössbauer fitting results of the RPLD film, deposited at room temperature: (f - area fraction (error), mean values of $\langle\delta\rangle$ - isomer shift, $\langle\Delta\rangle$ - the quadrupole splitting for the paramagnetic subspectra, $\langle\epsilon\rangle$ the quadrupole splitting for the magnetic subspectra, B - hyperfine field).	88
7.6	Total chamber pressure j , deposition time t , real film thickness d (as measured by RBS after deposition) and derived growth rate $g = \frac{d}{t}$ for the carburized RPLD films. All samples were deposited at 298 K with a laser energy of 5 mJ/cm ² and a target-substrate distance of 7.5 cm.	89
7.7	Mössbauer fitting results of the RPLD films, deposited at room temperature with a laser energy of 5 J/cm ² (f - area fraction (error), mean values of $\langle\delta\rangle$ - isomer shift, $\langle\Delta\rangle$ - the quadrupole splitting for the paramagnetic subspectra, $\langle\epsilon\rangle$ the quadrupole splitting for the magnetic subspectra, B - hyperfine field).	91
7.8	Hardness, Young modulus and C-content of RPLD AISI 316 films, where j is the CH ₄ /chamber pressure, E the elastic modulus and ν the poisson ratio.	92
7.9	Deposition time t , real film thickness d (as measured by TEM after deposition) and derived growth rate $g = \frac{d}{t}$ for the STPLD films. All samples were deposited at 298 K with a laser energy of 5 mJ/cm ² and a target-substrate distance of 7.5 cm.	92
7.10	Mössbauer fitting results of the STPLD stainless steel samples, deposited at room temperature with a laser energy of 5 J/cm ² (f - area fraction (error), mean values of $\langle\delta\rangle$ - isomer shift, $\langle\Delta\rangle$ - the quadrupole splitting for the paramagnetic subspectra, $\langle\epsilon\rangle$ the quadrupole splitting for the magnetic subspectra, B - hyperfine field).	94
7.11	Mössbauer fitting results of the 60:40, 60:40mod, 50:50 and 50:50mod STPLD samples, deposited at room temperature with a laser energy of 5 J/cm ² (f - area fraction (error), mean values of $\langle\delta\rangle$ - isomer shift, $\langle\Delta\rangle$ - the quadrupole splitting for the paramagnetic subspectra, $\langle\epsilon\rangle$ the quadrupole splitting for the magnetic subspectra, B - hyperfine field).	97
7.12	Mössbauer fitting results of the STPLD stainless steel samples, deposited at room temperature (90:10 _{ad}) and after post-vacuum annealing (90:10 _{pva}): f - area fraction (error), mean values of $\langle\delta\rangle$ - isomer shift, $\langle\Delta\rangle$ - the quadrupole splitting for the paramagnetic subspectra, $\langle\epsilon\rangle$ the quadrupole splitting for the magnetic subspectra, B - hyperfine field.	101
7.13	Mössbauer fitting results of the 90:10 STPLD stainless steel samples, deposited at room temperature and at 673 K (f - area fraction (error), mean values of $\langle\delta\rangle$ - isomer shift, $\langle\Delta\rangle$ - the quadrupole splitting for the paramagnetic subspectra, $\langle\epsilon\rangle$ the quadrupole splitting for the magnetic subspectra, B - hyperfine field).	102
7.14	Implantation fluences for stainless steel samples containing 1, 3 and 6 at.% for different implantation energies. The samples are labeled as 1P, 3P and 6P.	108
7.15	Deposition time t , real film thickness d (as measured by RBS after deposition) and derived growth rate $g = \frac{d}{t}$ for the STPLD films. All samples were deposited at 298 K with a laser energy of 5 mJ/cm ² and a target-substrate distance of 6.5 cm.	108

7.16	Mössbauer fitting results of the boron implanted AISI 316 samples, deposited at room temperature (f - area fraction (error), mean values of $\langle\delta\rangle$ - isomer shift, $\langle\Delta\rangle$ - the quadrupole splitting for the paramagnetic subspectra, $\langle\epsilon\rangle$ the quadrupole splitting for the magnetic subspectra, B - hyperfine field).	111
7.17	Mössbauer fitting results of the boron implanted AISI 316 samples, deposited at room temperature (f - area fraction (error), mean values of $\langle\delta\rangle$ - isomer shift, $\langle\Delta\rangle$ - the quadrupole splitting for the paramagnetic subspectra, $\langle\epsilon\rangle$ the quadrupole splitting for the magnetic subspectra, B - hyperfine field).	114
8.1	Mössbauer results for FEL nitrated stainless steel samples (δ - isomer shift, Δ - the quadrupole splitting for the paramagnetic subspectra, ϵ the quadrupole splitting for the magnetic subspectra, B - hyperfine field, Γ - line width (HWHM), f - area fraction). . . .	118

Chapter 1

Introduction

Iron and iron-based alloys have been used by mankind for at least 3,000 years. Its outstanding position in modern society results from its numerous beneficial criteria including the abundance and low cost of iron, its main constituents, manufacturing ability and its recyclability. After several millennia and extensive research, one may think that developments in iron-based alloys are part of the past and its properties have already been developed and exploited to its maximum, but in the last four decades, the development of metastable alloys has attracted the research society: the class of amorphous materials and metallic glasses.

These alloys exhibit a large variety of compositions and provide atomic configurations which are different from their crystalline alloys and reveal various interesting properties, such as good tribological, magnetic and unique chemical properties [1–4].

In Fig. 1.1 the progress in amorphous phase formation is shown, which has finally lead to the development of bulk metallic glasses (BMGs) [5] and which are based on certain late transition metals such as Pd, Pt, Ln (=lanthanide series) and Zr.

In contrast to Fe-based alloys, these new class steels are very expensive due to the huge demand of Pd, Pt and Zr by the manufacturing car industry, which led to a price for Pt and Pd of approximately \$900.00 and \$190.00 an ounce, respectively; and this will not be the end of the line. Stock market predicts a Pd price of \$450.00 in one year and \$1100.00 in three years [6]. In opposition, iron costs \$0.53 an ounce. Thus, the amorphization of Fe-based alloys and the formation of metallic glasses based on conventional steels would be desirable.

Small additions of alloying elements such as boron, oxygen, carbon, or nitrogen, have crucial influence on the deformation behavior, on the mechanical and tribological properties of steel. The modification of the steel properties are originated in strong interactions between interstitial alloying atoms and defects such as vacancies, interstitials and grain boundaries [7, 8]. Thus, it is necessary to determine in more detail the effects of individual alloying elements on the Fe and steel properties.

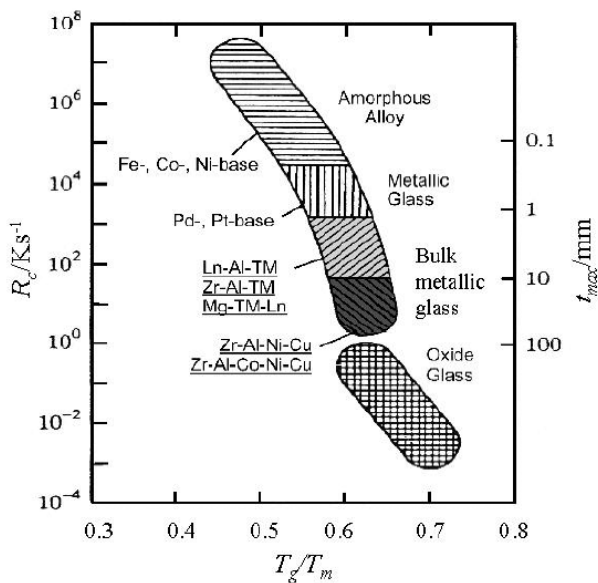

Figure 1.1: Relation between the critical cooling rate (R_C) for glass formation, the maximum sample thickness (t_{max}) and the ratio of liquidus and melting temperature (T_l/T_m) [5].

One of the more recent works, which attempts to develop a theoretical model of the binary Fe-C/Fe-N system, was published by Byeng-Joo Lee [9, 10]. By using a modified embedded-atom method (MEAM) [11], which is said to be highly applicable to multi-component systems, he calculated an interatomic potential for the Fe-C/Fe-N binary system and predicted the physical properties of a hypothetical NaCl-type FeC/FeN phase.

This was the impulse to investigate the Fe-C system for high-carbon concentrations to get a comprehensive sketch of carbide formation and to be able to amorphize conventional steels of the AISI 3xx family and not those late-transition-Fe-based steels as mentioned in the literature [12–14].

As a matter of fact, a cubic FeC phase, which was prepared by means of pulsed laser deposition (PLD), was found and its parameters were found

very close to those as predicted by Lee. Otherwise, the magnetron-sputtering technique exposed as unsuitable to form cubic FeC structures and various carbides were observed instead.

However, reactive magnetron-sputtering showed the formation of an amorphous and soft ferromagnetic phase in a wide range of the processing parameters and for different reactive gases (e.g. CH₄, N₂ and O₂). These films exhibit quasi-metallic glass behavior and the origin and magnitude of magnetism was deduced from a disordered Ni₃C phase for carburized/nitrided films, and from a disordered NiFe₂O₄ for oxidized films.

Also PLD revealed interesting film properties: whereas films synthesized by reactive PLD showed the same physical properties as those synthesized by reactive magnetron-sputtering, inert PLD from pre-combined targets revealed a self-organized structure, which could be controlled by the processing parameters.

As mentioned at the beginning, iron and steel are still topics in advanced research and were under the focus to develop "high tech" materials with newer and better properties.

In the following chapter 2, a brief review on the binary phase diagrams of the used systems will be shown. Chapter 3 will give a short introduction to the metallic glass formation by defining the principal conditions to retain an amorphous structure and presenting a theory of metallic glass formation. In Chapter 4, the synthesization of the films (4.1) and the analyzing methods will be discussed. The analyzing methods section is subdivided into three parts: 1) the phase analysis section, where the methods of Mössbauer Spectroscopy, Extended X-ray Absorbtion Fine-Structure, X-ray diffraction and Transmission Electron Microscopy and 2) the chemical composition analysis section, where Rutherford-Backscattering Spectrometry and Resonant Nuclear Reaction Analysis are explained. In the last section 3), other methods such as PAC, MOKE, AFM/STM, Raman spectroscopy and corrosion tests are summarized.

Chapter 5 to 8 will report on the experimental results of the targets and starting materials (chapter 5), the magnetron-sputtered films (chapter 6), the pulsed laser deposited films (chapter 6) and on the laser surface treated samples (chapter 8). The conclusions of the work and the outlooks for future developments and investigations will be drawn in Chapter 9.

Chapter 2

Relevant phase diagrams and structures

The subject of this work is the synthesis of amorphous iron/stainless steel films prepared via magnetron sputtering and pulsed laser deposition. As it will be shown, during magnetron sputtering and pulsed laser deposition, carbon, nitrogen, oxygen and boron are incorporated into the deposited films. As a consequence, the formation of different carbides, nitrides, oxides and borides are observed. Therefore, this section explains the various phase diagrams and properties of the used materials.

2.1 The Fe-C and Fe-N System

A study of the microstructure of all Fe-based alloys, such as steels, usually starts with the metastable binary Fe-C phase diagram, which is illustrated in Fig. 2.1.

At the low-carbon end of the metastable Fe-C

Figure 2.1: The Fe-C phase diagram [15].

phase diagram, one can distinguish ferrite (α -Fe),

which can at most dissolve ~ 0.1 at.% C at 740°C , and austenite (γ -iron), which can dissolve ~ 9 at.% C at 1154°C . The much larger phase field of γ -Fe (austenite) compared with that of α -Fe (ferrite) indicates clearly the considerably greater solubility of carbon in γ -Fe (austenite). The hardening of carbon containing Fe films, such as carbon steels and many alloy steels, is based on this difference in the solubility of carbon in α -Fe (ferrite) and γ -Fe (austenite).

At the carbon-rich side of the metastable Fe-C phase diagram cementite (θ - Fe_3C) can be found. Of less interest, except for highly alloyed steels, is the δ -ferrite at the highest temperatures.

At ambient pressure, body-centered cubic (BCC) ferrite is stable from all temperatures up to 912°C , when it transforms into face-centered cubic (FCC) austenite. It reverts to ferrite at 1394°C . This high-temperature ferrite is labeled δ -Fe, even though its crystal structure is identical to that of α -ferrite. The δ -ferrite remains stable until it melts at 1538°C .

Also other metastable phases, such as ϵ/θ - Fe_2C , χ - Fe_5C_2 , Fe_7C_3 , Fe_2OC_9 and Fe_2C_6 have been reported [16,17].

Regions with mixtures of two phases (such as ferrite+cementite, austenite+cementite, and ferrite+austenite) are found between the single-phase fields. At the highest temperatures, the liquid phase field can be found, and below this are the two-phase fields (liquid+austenite, liquid+cementite, and liquid+ δ -ferrite).

Similar to carbon, nitrogen also occupies interstitial sites in the Fe lattice. There are five equilibrium solid phases in the Fe-N system, which is shown in Fig. 2.2 [15].

The phases are: α -Fe(N), γ -Fe(N), γ' - Fe_4N , ζ - Fe_2N and ϵ - Fe_3N . In the α -Fe, the maximum nitrogen solubility is ~ 0.4 at.% at 592°C , but it can reach ~ 10.3 at.% at 650°C in the γ -Fe. The stoichiometric γ' - Fe_4N phase exists in a narrow re-

Figure 2.2: The Fe-N phase diagram [15].

gion that extends up to 680°C and crystallizes in a cubic structure. The hexagonal ϵ -Fe_xN phase is stable and crystallizes with structures similar to the ϵ -Fe_xC carbide in a large compositional range. The metastable α'' -Fe₁₆N₂ and the body-centered tetragonal martensite phases has been reported as well [17].

2.2 The Fe-O System

Figure 2.3: The Fe-O phase diagram [15].

The stable Fe-O system consists of five solid phases [15]: (1) the terminal BCC solid solution with a narrow range of composition denoted as α -Fe(O) or δ -Fe(O), with the temperature designations used below 912°C and above 1394°C, respectively; (2) the terminal FCC solution denoted as austenite or γ -Fe, with a narrow range of composition extending approximately from 912°C to 1394°C, the stable temperature range of γ -Fe; (3) the FCC oxides,

denoted as FeO, Fe_{1-x}O, Fe_xO, FeO_{1+x} or FeO_x, wustite, with broad range of compositions, which may possibly can be subdivided into regions of differing types or degrees of order; (4) Fe₃O₄ denoted as magnetite, which is monoclinic and almost stoichiometric below -149°C and is FCC above -149°C, with a range of compositions largely broadened at high temperatures; and (5) the rhombohedral oxide Fe₂O₃, called hematite, which is almost stoichiometric at low temperatures, but has an excessive broadened range of compositions at high temperatures.

The most important phases of the Fe-O phase diagram (Fig. 2.3) and its parameters can be found in Table 2.1.

Table 2.1: Fe-O crystal structure data.

Phase	Composition [at% O]	Space group	lattice constant [nm]

in the corrosion process.

There are four different stainless steels: austenitic, ferritic, martensitic and combined austenitic-ferritic steels.

In this work, AISI 316 is used, its composition can be obtained in Table 2.3. It is an austenitic stainless

Table 2.3: Chemical composition of AISI 316. All numeric data are given in wt.%.

C	Si	Mn	Cr	Mo	Ni
≤ 0.07	≤ 1.0	≤ 2.0	16.5-18.5	2.0-2.5	10.0-13.0

steel, antiferromagnetic and its Neel temperature is -149.5°C [20]. Its FCC structure is influenced by its Ni content, which exceeds the γ -stabilizing Ni content of 8 at.% [19, 21]. The ternary phase diagram of the Fe-Cr-Ni compound can be seen in 2.5.

2.4 The Fe-Cr-Ni System

Figure 2.5: Fe-Cr-Ni phase diagram at 900°C [18].

In metallurgy, stainless steel is defined as a steel alloy with a minimum of 11.5 wt.% Cr content [19]. Higher Cr contents and other alloying elements such as Ni and Mo increase the corrosion resistance of these steel. The most important factor for corrosion resistance is known in the Cr content in the film due to the formation of Cr-rich oxides on the surface of the steel. This oxide/passive layer separates the material from any medium and constrains processes such as mass transport, transpassive reactions and chemical conversions, which are involved

Chapter 3

Amorphization of metals

In the last decades it has become clear, that nano- and non-crystalline alloys can exhibit many potential advantages to their equivalent or similar crystalline phases, such as higher strength and hardness, better magnetic properties, better corrosion resistance and low material costs [4, 14, 22]. This led to a new group of materials: bulk amorphous alloys (also known as BMGs: bulk metallic glasses). This chapter will give a short introduction to the metallic glass formation by defining the principal conditions to retain an amorphous structure and presenting a theory of metallic glass formation.

3.1 Metallic glass formation

The term metallic glass refers to a non-crystalline solid phase and represents the ultimate state of solid metastability and can be obtained from solidification of a liquid, from the vapor phase, deposition from a chemical solution or an electrolyte and by high-energy ion- or neutron bombardment of crystalline materials are also included [3]. In its original sense it is formed by continuous cooling of a liquid. A glass lacks three-dimensional atomic periodicity beyond a few atomic distances and show diffuse halos in X-ray, electron and neutron diffraction and no sharp diffraction contrast in high-resolution electron microscopy. Different approaches have been made to give a physical definition of metallic glasses. The first one concentrates on carefully chosen experimental observations - the phenomenological approach - whereas the second regards the construction of atomistic models - the theoretical approach.

The first approach of a metallic glass defines a vitrified melt as a frozen liquid, or at least largely so [23]. Some alloys, with specific ranges in their composition, can be cooled down below the melting temperature T_m . This effect is called undercooling of the melt. The heterogeneous nucleants of the alloy were increasingly delayed for kinetic reasons, whereas the recalescence decreases by en-

Figure 3.1: Viscosity (η)-temperature (T) dependence corresponding to crystallization and vitrification of a metallic melt.

hancing the undercooling which finally leads to a steady suppression of crystallization. Initially, this allows a refinement of microstructure and ends in the extension of solute solubility and in the formation of metastable phases. If the cooling rate is high enough, crystallization can be suppressed due to insufficient nucleation, which finally leads to a continuously increase of the viscosity of the melt. This is illustrated in Fig. 3.1.

At the so-called glass transition temperature T_g , the atomic configuration becomes homogeneously frozen, after starting from the equilibrium state. This structurally freezing to glass state is defined at a viscosity of 10^{13} Poise and is the so-called kinetic arrest and is highly cooling-rate dependent. At T_g , the volume-enthalpy-temperature dependency decrease non-discretely, which can be seen in Fig 3.2.

During vitrification, the change in the specific heat of the undercooled liquid increases with falling temperature, as well as the crystalline state. According to the free volume model of atomic transport [24], glass transition corresponds to the absence of free volume.

The second definition of a glass is reported by

Figure 3.2: Temperature dependence of enthalpy H and specific heat C_p corresponding to crystallization and vitrification of a metallic melt.

Cargill et al. [25], in which the glass is described by a combination of an experimental determined radial distribution function (RDF) and of a theoretical RDF of a dense random packing (DRP) model proposed by Bernal [26].

The RDF is defined by:

$$\varrho(r) = \sum_R \frac{nR}{n} \delta(r - R) \quad (3.1)$$

where r is the vector between two atoms. It can be obtained by X-ray or neutron diffraction measurements or NMR spectroscopy and gives information about the nearest and next-nearest neighbour atoms lying in a spherical coordination shell as shown in Fig. 3.3 [27].

The DRP is considered to be the first realistic model of liquid structure. The model demonstrates that an aperiodic structure with a physical density comparable to that of a crystal by physically packing many small spheres inside a large spherical volume. Bernal then studied the local topology of several atomic configurations which were unseen in crystalline structures.

The absence of crystallization upon undercooling is explained on the basis of a standard nucleation theory [28]. In this theory, a homogenous nucleation mechanism, which is responsible for the formation of the solid phase, is considered to be hindered by a large energy barrier. This barrier was approved by Frank [29] and is originated in the development of local short-range order structures (mostly with an icosahedral form) of a metallic undercooled melt, which are incompatible with long-range periodicity. As a consequence, several attempts were made to confirm this model, but not till Kelton et al. in 2003 were demonstrating the first experimental evidence between the local order of the liquid and the nucleation barrier upon undercooling [30].

Figure 3.3: Illustration of atomic arrangements in an amorphous solid and the corresponding radial distribution function $\varrho(r)$.

3.2 Theory of metallic glass formation

An approach to determine the so-called glass forming ability (GFA) of a system was proposed by Inoue et al. [31]. Inoue suggested the following rules for the GFA of an alloy:

1. A good metallic glass former is a multicomponent system with more than three elements.
2. The alloying elements must have a relative ratio of the atomic radii larger than 12 %, which provides dense packing of different elements and, thus, atomic rearrangement can be hindered.
3. The constituents must have a large negative heat of mixing, which is an indication of the tendency of two chemical species to combine and to form a metallic compound. On the contrary, if the enthalpy of mixing is positive the tendency of mutual avoidance is enhanced and the alloy may show phase separations.

An alloy which satisfy Inoue's rules should have a large GFA. These rules can be discussed in terms of

thermodynamics, kinetics and structural point of views.

From thermodynamics, a large GFA is obtained under the condition of low Gibbs free energy $\Delta G(T)$ for the transformation from the liquid to the solid phase. These low values can be obtained, if the values for enthalpy ΔH_f and entropy ΔS_f of fusion in the Gibbs relation

$$\Delta G = \Delta H_f - T\Delta S_f \quad (3.2)$$

have its minimum. In multicomponent alloy systems, ΔS_f is expected to be large. An increase of ΔS_f causes an increase of the DRP which is also favorable for a decrease of ΔH_f and an increase of the solid/liquid interfacial energy.

From kinetics, Cohen and Turnbull [32] derived a relation between the rate of homogeneous nucleation frequency, I_v , and the reduced undercooling temperature $\Delta T_r = (T_l - T)/T_l$ as follows:

$$I_v = \frac{k_n}{\eta(T)} \exp(-16\pi\alpha^3\beta/3T_r\Delta T_r^2) \quad (3.3)$$

where k_n is a kinetic constant, $\eta(T)$ the shear viscosity at temperature T (which is inversely related to the atomic diffusivity D) and T_r the reduced temperature T/T_l . Respectively, α and β are dimensionless parameters and are related to the liquid/crystal interfacial energy σ and to ΔS_f , thus:

$$\begin{aligned} \alpha &= (N\bar{V}^2)^{1/3}\sigma/\Delta H_f \\ \beta &= \Delta S_f/R \end{aligned} \quad (3.4)$$

where N is the Avogadro's number and \bar{V} the molar volume of the crystal. From the equation for I_v it is evident for given temperature and viscosity of a melt that I_v decreases precipitously as the magnitude of $\alpha\beta^{1/3}$ increases and, thus for high temperatures, I_v becomes dominated by the reduced glass temperature T_{rg} as indicated in Fig. 3.1.

As T_{rg} is increased, η is increases rapidly with ΔT_r . As a consequence, the $I_v - T_r$ peak is rapidly lowered and shifted to higher T_r . Thus, nucleation can be avoided easier and the volume in which a single nucleation can be avoided increases. For alloys with $T_{rg} = 0.5$, droplets would vitrify with a diameter of about $60 \mu m$ [3] for cooling rates of 10^6 K/s.

A related kinetic approach was taken by Uhlmann [33] and was generalized for all metallic systems by Davies et al. [34]. According to the Johnson-Mehl-Avrami treatment of transformation kinetics [35, 36], the fraction of a transformed phase x in time t is given by:

$$x \sim \pi I_v u_c^3 t^4 / 3 \quad (3.5)$$

where u_c is the crystal growth velocity and can expressed as:

$$u_c = \frac{kT_f}{3\pi a_0^2 \eta} [1 - \exp(-\Delta T_r \Delta H_f / RT)] \quad (3.6)$$

f is the fraction of sites at the crystal surfaces where atomic attachment can occur ($= 1$ for close packed crystals and $0.2 \Delta T_r$ for faceted crystals) and a_0 the mean atomic diameter.

In contrast to the kinetic model mentioned above, wherein I_v was based on the Hoffman model for free enthalpy of crystallization ($\Delta G = T_r \Delta T_r \Delta H_f$), here I_v is given by:

$$I_v = \frac{kT\bar{N}_v}{3\pi a_0^3 \eta} \cdot \exp\left(\frac{-1.07}{\Delta T_r^2 T_r^3}\right) \quad (3.7)$$

The pre-exponential constants in equations 3.6 and 3.7 are derived on the assumption that the atomic diffusivity is identical to cross the liquid-nucleus and liquid-crystal interfaces and related to η through the Stokes-Einstein equation. \bar{N}_v is the average atomic volume concentration.

From a structural point of view, the presence of elements with different atomic sizes (about 12%) in a multicomponent system which have large negative heats of mixing causes an increase of RDP in the undercooled liquid. As a consequence, a large liquid/solid interfacial energy is achieved and is hindering an atomic arrangement of the constituent elements on a long-range scale which suppresses crystalline phase nucleation and crystal growth, respectively [37–39].

Chapter 4

Deposition of thin films and experimental methods

4.1 Film Deposition

In this section, the synthesization techniques of the deposited films were discussed, which were fabricated by magnetron sputtering and pulsed laser deposition. In this work, a planar magnetron is used which is equipped with a radio-frequency bias generator (Plasma Products RF5S, 13.56 MHz). The PLD chamber was self-assembled as described in 3.1.2 and using a Siemens XP2020 XeCl excimer and a Quantel Brilliant Nd:Yag laser system.

4.1.1 Magnetron sputtering

The sputtering phenomenon has been known since 1852 and exploited for deposition of films and is now one of the most extensively used techniques for the deposition of films and coatings. Sputter deposition methods used today have a common simple processing aim: to generate and maintain a desired plasma and to establish a bias or electric field for the acceleration of ions to the electrode or to the target which is then being bombarded.

The principle setup of a planar magnetron

The magnetron target is based on the work carried out by Penning more than 70 years ago [40] and a lot of work had been done to develop this concept since then. Today, the planar magnetron is the most widely used target assembly, but it was not introduced until the early 1970s by Chapin [41]. Sputter deposition of thin films as functional and protective layers has increased in the last decade which can be ascribed to the development of high-performance magnetron cathodes. In comparison to conventional diode sputtering, the magnetron cathode provides higher deposition rates at a lower operating pressure accompanied by an increased quality

Figure 4.1: Principle setup of a planar magnetron system.

of the films (better adherence and greater uniformity over large areas).

The principle setup of planar Magnetron in its simplest form is shown schematically in Figure 4.1 [42]. It consists of the target material backed by permanent magnets that provide a toroidal confinement field with the field lines forming a closed tunnel on the target surface. The field strength is chosen to provide effective confinement for electrons while allowing heavier ions considerable freedom.

Secondary electrons were emitted from the target during the sputtering process. These are accelerated across the cathode dark space towards the highly charged plasma, which has the form of the so-called Debye sphere. The propagation of the electrons is affected by the Lorentz force and one component of their motion is a helical path about the magnetic field lines. The electrons which propagate along these helical lines in the middle of the target are reflected due to the higher density of field lines and were affected by a repulsive electric field. After reflection the electrons eventually reach the perimeter of the target where the field lines again intersect the surface. An anode placed in this re-

gion effectively collects these electrons and prevents a drift of the electrons to the substrate. A second component of their propagation is a drift from one field line to another resulting in a toroidal tunnel on the surface of the target. The combined motion gives an extended path length resulting in a large number of collisions of the electrons with gas atoms. The ions which are affected by the same Lorentz force as the electrons were - de to their higher mass - not so hardly influenced in their resulting propagation to the substrate.

Reactive sputtering

In contrary to inert sputtering, reactive sputtering is identified with the process, where neutral, excited, or ionized gaseous species react with the sputtered particles from the target or with particles at the substrate [43]. Thus, a variety of thin films and compounds, such as oxides, nitrides, and carbides etc. can be deposited by introducing a mixture of reactive gas (e.g. O_2 , N_2 , or CH_4 etc.) and inert gas (e.g. Ar or He) with desired stoichiometries (depending on the processing parameters) can be formed. The mechanism of the sputtering gas interaction is not fully understood, but different models have been introduced. In Figure 4.2 the common mechanism model of L. Holland is shown [44].

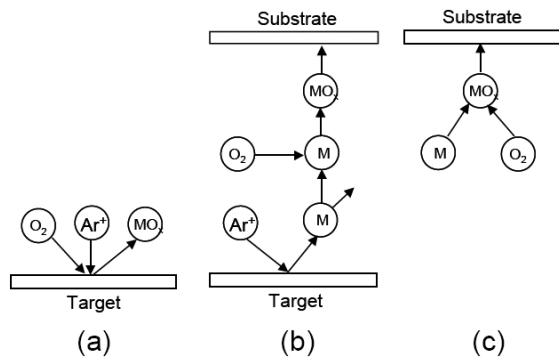

Figure 4.2: Three different mechanisms for reactive sputter deposition: (a) at the target, (b) in the plasma volume, (c) at the substrate.

4.1.2 Pulsed Laser Deposition (PLD)

Pulsed Laser Deposition (PLD) is conceptually and experimentally a relatively simple technique and is enjoying great popularity in the last years. The laser radiation hits direct the target located in a

vacuum chamber at an inclination angle of e.g. 45° with respect to the normal of a substrate-holder.

The impact of the laser radiation on the target surface results in various processes including melting, evaporation, and ablation of the target material with production of a plasma due to excitation and ionization of the species ejected from the target by the laser radiation. All these processes are triggered by conversion of the optical energy into thermal, chemical, and mechanical energy. The ablated material is deposited on a substrate positioned on a heatable substrate holder.

The principle setup of the used PLD system is displayed in Fig. 4.3.

During deposition, a fine control of the film thickness can be achieved by the number of pulses. Thus, a fast response in exploiting new material systems is a unique feature of PLD among other deposition techniques. The most important feature of PLD is that the stoichiometry of the target can be retained in the deposited films. The extremely high heating rate of the target surface (10^8 K/s) caused by the pulsed laser irradiation leads to the congruent evaporation of compounds from the target irrespective of the sublimation point of the target constituent elements.

In spite of the advantages of PLD, some drawbacks have been identified in using this technique. One of the major restriction is the formation of droplets due to splashing from the target. The size of the droplets are usually a few microns. In general, such droplets have to be avoided otherwise they greatly affect the growth as well as the properties of the films. Another restriction is the narrow angular distribution of the species, which are generated by the adiabatic expansion of the laserinduced plasma. In general some solutions have been proposed, such as the inserting a shadow mask to block off the particulate and rotating both target and substrate in order to produce uniform films. On the other hands, the features previously mentioned limit the use of PLD in producing large area thin films that PLD has not yet been fully deployed in industry. Recently remedial measures, in order to produce a larger uniform film, have been developed to minimize these restrictions in PLD, for instance, the simultaneous movements of target and substrates (using a robotic/automated/ positioning mechanisms) in combination with the use of certain power density distribution yielding a special angular distribution of the laser induced vapourplasma. In addition, various targets may be used to increase the versatility of laser radiation to deposit large area thin films.

Figure 4.3: Principle setup of the PLD system (left) and typical PLD plasma (right).

4.1.2.1 Description of physical phenomena during PLD processing

The vaporisation threshold, viz. the minimum laser intensity necessary for bulk material evaporation can be described by the equation:

$$I_{vap} = \frac{c_p \rho \sqrt{\pi \chi} (T_{vap} - T_0)}{2(1 - R) \sqrt{\tau_{las}}} \quad (4.1)$$

where C_p , ρ and χ are the heat capacity, specific mass, and the thermal diffusivity of the target material, R the reflectivity of the surface of the target, T_{vap} the vaporization temperature and T_0 the ambient temperature. Note, this formula is only valid for a laser pulse with a rectangular temporal shape of duration τ_{las} .

To get thin layers of high quality, particle/droplet formation has to be avoided. Two main factors for particle/droplet formation during laser evaporation are: 1) the separation of surface defects under thermal shock and 2) splashing of liquid material due to superheating of subsurface layers, which appears for fast heating rates. To avoid superheating, the laser intensity must be lower than that intensity, which is needed to evaporate a mass volume with a depth of $\delta_{th}/2$ (the heat diffusion length is defined as $\delta_{th} = \sqrt{2\chi t}$). This gives an upper limit for laser intensity to be applied in a PLD process. The superheating threshold is given by [45]

$$I_{th} = \frac{\rho \Delta H_{vap}}{\alpha t_r} \quad (4.2)$$

where α is the absorption coefficient, t_r the relaxation time of hot electrons on the surface, ΔH_{vap} the enthalpy change per mass unit including latent heat for fusion and vaporization and heating from ambient temperature to the vaporization point.

For laser intensities slightly lower than the vaporization threshold, very low material sputtering rates

in vacuum result in a collision less than low density vapor in front of the target surface. Evaporation appears to be a thermal process. When the laser intensity increases, the vapor density rises and collisions occur in a zone onto the surface. This is the so-called Knudsen layer. Increasing the laser intensity leads to an increase of atom density and temperature in the Knudsen layer. The ionization degree rises. By increasing the laser intensity above the plasma ignition threshold, a fully ionized vapor plasma can be identified.

Laser heating of metals can be modeled by three basic processes: 1) the deposition of radiation energy on free electrons, 2) the energy exchange between electrons and lattice, and 3) the propagation of energy through media by free electron motion [45,46]. In the course of high power laser heating, where the metal is looked upon as a two-temperature system, the free electrons are heated to an effective temperature much higher than that of the lattice. As a result, large local temperature gradients arise between the electrons and the lattice. Subsequently, the transport of energy from the electrons to the lattice takes place by means of a relaxation mechanism and a heat transfer coupling coefficient between electron and phonon subsystem is considered.

4.2 Free Electron Laser surface processing

To compare the properties of thin films to those of surface treated films, Free Electron Laser (FEL) surface processing experiments at the Jefferson Lab were carried out. As well as synchrotron facilities, FELs were used in bioscience, chemistry, solid-state physics, advanced materials and basic research (also manufacturing, medical and military purposes are

Figure 4.4: Principle setup of the FEL system used at the Jefferson lab.

planned) due to their high-rated potential. These advantages include amongst others high peak and average power, bandwidth, beam quality and pulse brevity.

The main advantage of FELs are their ability to be tunable over a wide range of wavelengths, which opens their usage not only to basic research facilities. This tunability results from a basic difference between FELs to conventional lasers: whereas conventional lasers use electrons bounded in atoms or molecules, the FEL uses an beam of unbounded electron, which is accelerated nearly to speed of light. Using a magnetic device - called undulator - the electrons were conducted on a sinusoidal orbit. They are above the ground state and represent a population inversion. In the undulator the electron yield synchrotron radiation, which is shown in the schematics of the principle setup of the FEL in Fig. 4.4 [47]. This light initially emits spontaneously, but is bounced backwards between a pair of mirrors, just like in a conventional laser until it reaches saturation.

The specific photon energy is set by a resonance between the electrons' velocity and the electromagnetic wave: after each wiggle, the electrons slip back one optical wavelength. This allows a tunability by varying the input electron energy, where in contrast bound-electron-lasers are limited to discrete wavelengths via quantum mechanics.

The set of parameter for the surface treatment in this work are given in Table 4.1.

Table 4.1: Set of parameter for the FEL surface processing: P is the power, $f_{p,micro}$ the frequency of the micro-pulse, \emptyset_{focus} the diameter of the FEL radiation and $N_{sh,i}$ the track displacement of the laser radiation for steel i .

Parameter for the FEL surface processing	
P [W]	900
λ [μm]	1.64
$f_{p,micro}$ [MHz]	9.36 (in cw-mode)
\emptyset_{focus} [μm]	600
$N_{sh,AISI310}$ [mm]	1
$N_{sh,AISI316}$ [mm]	0.8

4.3 Experimental Methods

The following sections describe the experimental analyzing techniques, which are separated into the parts: phase analysis and chemical composition analysis. Each technique will be described briefly. For more detailed explanations, the specific literature will be reported.

4.3.1 Phase analysis

4.3.1.1 Mössbauer Spectroscopy

The technique of Mössbauer Spectroscopy is widely used in nuclear solid-state physics, materials science, biophysics and chemistry and bases on the homonymous Mössbauer effect, which was discovered in 1956 by R.L. Mössbauer [48–51]. He showed that nuclear radiation can be emitted and absorbed recoilless, if the atoms are placed in a solid state. Some of the principles, experimental setup, and special magnetic transitions are discussed in this section. Further details are described in the books [52–54].

The Mössbauer Effect A nucleus in an excited state with a mean life time τ emits γ -radiation. Its energy distribution can be described by the Breit-Wigner formula [54]:

$$I(E) = I_0 \cdot \frac{(\Gamma/2)^2}{(E - E_0) + (\Gamma/2)^2} \quad (4.3)$$

where E_0 is the transition energy and $\Gamma = \hbar/\tau$ is the resonance width ($E_0 = 14.4 \text{ keV}$, $\Gamma = 4.7 \text{ neV}$ for ^{57}Fe). The momentum of the γ -quantum is $p = \hbar k$. A free atom receive a recoil by an emitted γ -quantum. Its energy E_r can be modeled by $E_r = p_\gamma^2/2M = \frac{E_\gamma^2}{2Mc^2}$. The recoil energy is much larger than the natural line width Γ . If the emitting nucleus is in a solid, the whole matrix takes up the recoil, given that the mass of the matrix is 10^{20} times larger than a single, free atom. Thus, the contribution of the recoil energy becomes negligible. This yields in the Mössbauer effect, viz. the resonant nuclear emission and absorption. Nevertheless, the emission (or absorption) may also transfer energy to the lattice, which could results in phonon-interactions in the crystal. The probability that the emission takes place without inducing any phonons is named the Mössbauer-Lamb factor, or as analogon to x-ray diffraction, Debye-Waller factor f_D , which depends on the temperature T , the Debye

temperature θ_D of the crystal and the energy of the γ -quantum [55]:

$$f_D(T) = \exp(x) \quad (4.4)$$

$$x = \gamma \left[1 + 4 \left(\frac{T}{\theta_D} \right)^2 \cdot \int_0^{\theta_D/T} \frac{y}{\exp(y) - 1} dy \right]$$

where γ is $\frac{-3\hbar^2 k^2}{3Mk_B\theta_D}$. The probability of recoil free emission or absorption is 0.76 for ^{57}Fe in $\alpha\text{-Fe}$ at room temperature. Due to the high resolution involved in this process, the hyperfine interactions can be resolved by a Doppler gamma energy modulation

$$E(\nu) = E_0 \cdot \left(1 + \frac{\nu}{c} \right) \quad (4.5)$$

by moving the source relative to the absorber, or vice versa. The energy resolution of this movement allows the observation of the change of the energy levels resulting from electric or magnetic fields acting at the nucleus. These are the hyperfine interactions: the electric monopole interaction, the electric quadrupole interaction, and the magnetic dipole interaction which will be explained briefly in the next sections.

The isomer shift δ The electrical monopole interaction is the interaction of the nuclear charge Ze with the electron density, which leads to a change in the energy states in the source (s) and in the absorber (a) in comparison to a point charge. With the energy difference between the absorber and the source, $\delta = E_a - E_s$, the isomer shift is obtained [56]:

$$\delta = \frac{2}{5}\pi Ze^2 [|\Psi_a(0)|^2 - |\Psi_s(0)|^2] [R_e^2 - R_s^2] \quad (4.6)$$

where Ψ is the electron wave function, $e|\Psi_s(0)|^2$ the electron density and R_i the nuclear radius ($i = g \Rightarrow R$ in ground state, $i = e \Rightarrow R$ in excited state).

The quadrupole splitting Δ An electrical quadrupole moment of the nucleus, eQ , interacts with the electric field gradient tensor (EFG) acting at the nucleus, which leads to a splitting of the energy levels. The asymmetry parameter η is obtained by diagonalizing the EFG tensor. With the constraints for the electrical potential V : $|V_{zz}| \geq |V_{yy}| \geq |V_{xx}|$ and $V_{xx} + V_{yy} + V_{zz} = 0$ the asymmetry parameter can be written as:

$$\eta = \frac{V_{xx} - V_{yy}}{V_{zz}}. \quad (4.7)$$

Figure 4.5: Quadrupole splitting for a 3/2 to 1/2 transition. The magnitude of quadrupole splitting Δ is shown.

In the case of an isotope with a $I = 3/2$ excited state, such as ^{57}Fe or ^{119}Sn , only the excited state is split into two substates $m_I = \pm 1/2$ and $m_I = \pm 3/2$, which is shown in Fig. 4.5. By considering the formula for the energy shift given by Wertheim [56], which depends on spin I and magnetic quantum number m_I , the quadrupole splitting Δ can be derived as:

$$\begin{aligned} \Delta &= E_q(m_I = 3/2) - E_q(m_I = 1/2) \\ &= 1/2eQV_{zz}\sqrt{1 + \frac{1}{3}\eta} \end{aligned} \quad (4.8)$$

The magnetic splitting The magnetic moment μ of the nucleus interacts with a magnetic field B acting at the nucleus (nuclear Zeeman effect). This interaction leads to the splitting of the degenerated states. The state with spin I splits into $2I + 1$ magnetic sub-states with eigenvalues:

$$E_m = -\frac{\mu B m_I}{I} = -g_N \mu_N B m_I \quad (4.9)$$

where the magnetic quantum number m_I can hold the values $m_I = I, I - 1, \dots, -(I - 1), -I$. The magnetic moment μ is given by the Bohr magneton μ_N and the Landé factor g_N by:

$$\mu = g_N \mu_N I. \quad (4.10)$$

A closer look to the selection rule ($\Delta m = 0; \pm 1$) points that only six transitions are possible. This is illustrated in Fig. 4.6.

Mixed hyperfine interaction The previous mentioned formulae are not generally effective, if

Figure 4.6: Magnetic splitting of the nuclear energy levels.

electric quadrupole and the magnetic dipole interaction appear together. The more general case cannot be described any longer by closed analytic expressions. For Fe-compounds the condition $eQV_{zz}/4 \ll \mu_a B/I_a$ is frequently satisfied, so that the electric quadrupole interaction can be treated as small disturbance of the magnetic dipole interaction. The quantum-mechanical perturbation calculation first order yields in

$$E_q(m, \theta) = \frac{eQV_{zz}}{4} \frac{3m^2 - I(I+1)}{I(2I-1)} \frac{3\cos^2\theta - 1}{2} \quad (4.11)$$

where θ is the angle between the direction of the magnetic field and the predominant axis of the electric field gradient component V_{zz} .

Except the isomer shift, all these hyperfine parameters, are also found for Perturbed Angular Correlation (PAC) [57] and they are comparable with those observed by Mössbauer spectroscopy.

Internal conversion As internal conversion, the process in which an excited nucleus transmits its excessive energy to the orbital electron of the atom, is identified. If the amount of energy given to the orbital electron exceeds its binding energy, it leaves the atomic union. Therefore, x-rays are emitted as the atom attempts to restore its neutrality. Internal conversion usually competes with gamma radiation as an energy-shedding mechanism.

Internal conversion is schematically illustrated in

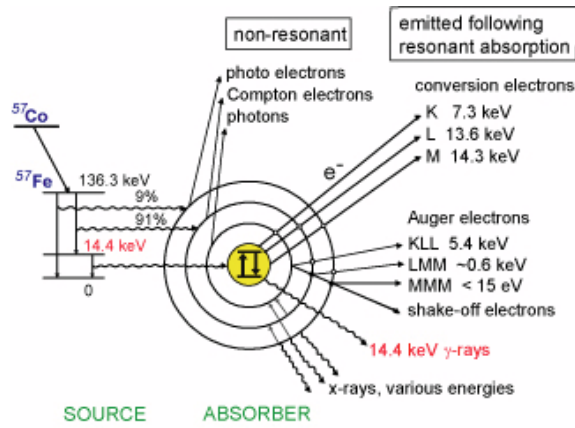

Figure 4.7: Process scheme of the internal conversion for ^{57}Fe .

Fig. 4.7 [58].

From this scheme, the different Mössbauer measuring proceedings can be derived: Transmission Mössbauer Spectroscopy (TMS), Conversion Electron Mössbauer Spectroscopy (CEMS) with an information depth of 150 nm [59], Conversion X-ray Mössbauer Spectroscopy (CXMS) with an information dept of 30-50 μm [59] and Auger Electron Mössbauer Spectroscopy (AEMS), which is very surface sensitive [60]. In this work, CEMS measurements were performed [61–63]. In Fig. 4.8 the schematics of the detector is shown and is described in [59]. A mixture of helium and methane is flow-

Figure 4.8: Mechanical drawing of the CEMS detector.

ing through the counting tube (94 Vol. % He and 6 Vol. % CH_4) to prevent a contamination of the test gas.

4.3.1.2 Extended X-ray Absorbtion Fine-Structure

X-rays are electromagnetic waves with energies ranging from ~ 500 eV to 500 keV. At this energy regime, a X-ray beam is absorbed by the photo-electric effect, if the beam traverse the solid. Absorbtion is primarily characterized by the absorbtion coefficient μ , which gives the probability that X-rays will be absorbed according to Beer's Law:

$$I = I_0 e^{-\mu t} \quad (4.12)$$

where I_0 is the X-ray intensity incident on a sample, t the sample thickness, I the intensity transmitted through the sample and where μ is given by $\mu \sim \frac{\rho Z^4}{AE^3}$. μ is a smooth function of energy, which depends on the sample density ρ , the atomic number Z , atomic mass A and the X-ray energy E . As well as for all electromagnetic waves, the intensity of X-rays is proportional to the number of photons. Due to the Z^4 dependence, the absorption coefficient for usual chemical compounds are very different, so that good contrast between different materials can be achieved for nearly any sample thickness and concentrations by adjusting the X-ray energy.

X-ray absorbtion fine structure (XAFS) is generally thought of in two distinct portions: the near-edge spectra (XANES) – typically within 30 eV of the main absorption edge, and the extended fine-structure (EXAFS) which contains information about the local atomic neighborhood. The basic physical description of these two regimes is the same, but important approximations and limits allow to interpret the extended spectra in a more quantitative way than those for the near edge-spectra.

EXAFS refers to the oscillations above the absorption edge [64]. Its fine structure function $\chi(E)$ is defined as:

$$\chi(E) = \frac{\mu(E) - \mu_0(E)}{\Delta\mu_0(E)} \quad (4.13)$$

where $\mu(E)$ is the measured absorption coefficient, $\mu_0(E)$ is a smooth background function representing the absorption of an isolated atom, and $\Delta\mu_0$ is the measured jump in the absorption $\mu(E)$ at the threshold energy E_0 , which can be seen in Fig. 4.9.

As mentioned above, EXAFS is understood in terms of photo-electron created wave behavior in the absorbtion process. Therefore, it is common to

Figure 4.9: Typical XAFS spectrum for Fe. The XANES and EXAFS regions are identified. $\mu(E)$ is shown with the smooth background function $\mu_0(E)$ and the edge step $\Delta\mu_0(E_0)$.

convolute the X-ray energy to the wave number k , which is defined as:

$$k = \sqrt{\frac{2m_e(E - E_0)}{\hbar^2}} \quad (4.14)$$

where E_0 is the absorption edge energy and m_e the electron mass. Thus, the fine structure function has the quantity $\chi(k)$ and decays quickly with k . As a result, $\chi(k)$ typically is often scaled by k , k^2 or k^3 . In this work, the spectra are multiplied with k^2 .

The oscillations correspond to quantum-interferences caused by the different near-neighbor coordination shells and can be described by the equation:

$$\chi(k) = \sum_j \frac{N_j f_j(k) e^{-2k^2 \sigma_j^2}}{k R_j^2} \sin[2k R_j + \delta_j(k)] \quad (4.15)$$

where $f(k)$ and $\delta(k)$ are the scattering properties of the next nearest-neighborhood, N the number of neighboring atoms, R the distance between two atoms, and σ^2 is the disorder in the neighbor distance. By getting the scattering amplitude $f(k)$ and phase-shift $\delta(k)$ from the experiments, a determination of N , R and σ^2 is possible. As a result of the μ dependency of $\chi(k)$, the fine structure function also depends on Z of the next-nearest atoms. Thus, EXAFS is also sensitive to atomic species of the neighborhood.

EXAFS experiments in this work were carried out at the European Synchrotron Radiation Facility (ESRF) (Grenoble), France) on the beamline BM29. The storage ring was operating at 6 GeV with an average current of 200 mA. The data were collected at room temperature in the 7000 - 7700 eV (Fe K-edge: $E_0 = 7112.0$ eV) and in the 8200 - 8900 eV

(Ni K-edge: $E_0 = 8332.0$ eV) energy range with 1 eV step in total electron yield (TEY) mode. The data analysis was performed with the HORAE software package [65–67]. For the sake of completeness, the main parameters of the electron beam in the storage ring are summarized in Table 4.2.

Table 4.2: Parameters of the electron beam in the ESRF storage ring .

Energy	GeV	6.03
Max. Current	mA	200
Horizontal Emittance	nm	4
Vertical Emittance (*min. achieved)	nm	0.025(0.010*)
Coupling (*min. achieved)	%	0.6 (0.25*)
Revolution frequency	kHz	355
Number of bunches		1 to 992
Time between bunches	ns	2.816 to 2.82

4.3.1.3 X-ray diffraction

X-ray diffraction (XRD) is a general characteristic of all waves and is referred to the rearrangement of the behavior of waves by its interaction with an object. It is used for structural analysis by revealing the phase difference Δ_i of the characteristic interference patterns of scattered X-rays photons at each lattice plain. The physical values derived from the patterns, such as position, shape and intensity provide detailed information on the structural properties of the examined specimen on atomic scales. Fig. 4.10 [68] indicates the condition for constructive interference, where the phase shift adds to a multiple of the incident wavelength .

By considering the trigonometric conditions, the

Figure 4.10: Visualization of the so-called Bragg equation. Maximum scattered intensity is only obtained when the phase shifts add to a multiple of the incident wavelength λ .

sum of phase difference lead to the Bragg equation [69, 70]:

$$n\lambda = \Delta_1 + \Delta_2 = 2d\cos(90^\circ - \theta) = 2d\sin\theta \quad (4.16)$$

where d is the distance of two parallel plains and θ the angle with respect to the incident X-ray beam of wavelength λ .

Another approach to explain diffraction is given by Laue [71] as seen in Fig. 4.11. The path difference of

Figure 4.11: Laue diffraction geometry.

rays scattering at points A and D is just $AB - CD$. If the incoming rays are in phase, the path difference must be some integral multiple of the wavelength for constructive interference to occur.

This lead to the first Laue equation:

$$(AB - CD) = a(\cos\alpha_n - \cos\alpha_0) = n_x\lambda \quad (4.17)$$

This result is valid for any scattered ray that makes an angle α_n with the unit cell axis. Thus the Laue condition is consistent with a cone of scattered rays centered about the a axis. This equation can be restated in vector terms. The repeat distance a , becomes a unit cell vector \mathbf{a} . Call a unit vector parallel to the incoming rays, \mathbf{k}_0 , and one parallel to the scattered rays, \mathbf{S} . There are then some simple vector dot products as seen in Fig. 4.12:

$$\begin{aligned} \mathbf{a} \cdot \mathbf{S} &= a \cdot \cos\alpha_n \\ \mathbf{a} \cdot \mathbf{S}_0 &= a \cdot \cos\alpha_0 \\ \mathbf{a}(\cos\alpha_n - \cos\alpha_0) &= \mathbf{a} \cdot (\mathbf{S} - \mathbf{S}_0) = n_x\lambda \end{aligned} \quad (4.18)$$

The $\theta/2\theta$ scan An often-used instrument for measuring Bragg reflections of thin films is the $\theta/2\theta$ diffractometer. In order to derive an information on the microstructure of an given sample, the measurement is set up to investigate position, shape and intensities of the reflections. The intensity function can be obtained by the square of the absolute value of the structure factor F_{hkl} multiplied with the polarization factor p :

$$\begin{aligned} I_{hkl}(Q) &= |F_{hkl}|^2 p \\ &= \prod_{i=1}^3 \frac{\sin^2(N_i a Q c_i / 2)}{\sin^2(a Q c_i / 2)} \end{aligned} \quad (4.19)$$

Figure 4.12: Vectorial display of the Laue diffraction geometry.

where $Q = \mathbf{S} - \mathbf{S}_0$, N_i is the normal vector and c_i vectors in reciprocal space.

The intensity variation that is associated with the reflection is given by the above mentioned equation, while the scattered intensity depends on the distance from the sample to the detector system. Therefore, the instrument should be configured in such a way, that the scan can measure the space around the sample by keeping the sample-detector distance constant. This measure ensures that any intensity variation is due to the intensity function and is not caused by a dependency of the sample-detector distance. The detector should accordingly move on a semicircle in 2-D, on a hemisphere in 3-D, respectively, with constant radius with the sample in the center of it. The geometry is shown in Fig. 4.13.

Figure 4.13: The $\theta/2\theta$ geometry. The x-ray tube is operated in the line focus mode; the plane of the figure is the scattering plane.

Grating Incidence X-ray diffraction The grating incidence measuring configuration is shown

in Fig. 4.14.

The angle between the incoming beam and the

Figure 4.14: The GIXRD geometry. The x-ray tube is operated in the line focus mode; the plane of the figure is the scattering plane.

sample surface is very small and amounts to only a few degrees. This angle is different from half the scattering angle and will be denoted as ω . The X-rays travel a maximum path of $l = \sin\omega$ within the layer, which might be a high multiple of the thickness t when the entrance angle is chosen very flat. For the investigation of a sample with attenuation coefficient μ a first criterion for ω should be $l = 1/\mu$, so that for the incidence angle the condition $\omega = \arcsin(\mu t)$.

To get an insight to the information depth of the penetrating beam, the GIXRD absorption factor $A_\omega = (1 - \exp(-\mu t k_\omega))$ and a machine dependant configuration factor k_ω has to be taken into account. By considering, that average information depth $\bar{\tau}_\omega$ is the weighted sum of all beams that differ by the amount of damping they undergo by being diffracted in various depths, $\bar{\tau}_\omega$ is obtained as [68]:

$$\bar{\tau}_\omega = \frac{1}{\mu k_\omega} + \frac{t}{1 - \exp(\mu t k_\omega)}. \quad (4.20)$$

In this work, ω was fixed to 2° . With the formula for $\bar{\tau}_\omega$ we get an information depth of $\bar{\tau}_\omega \approx 350$ nm.

The Bruker AXS D8 Advance diffractometer In this work, crystallographic analyses were performed using a Bruker AXS D8 diffractometer equipped with a Cu-K α source ($\lambda = 1.54$ Å), a Goebel mirror, a grazing incidence attachment mounted on an eulerian girdle, a soller-collimator system, a secondary monochromator (LiF) and a YAP-detector.

4.3.1.4 Transmission Electron Microscopy

The transmission electron microscopy is used in physics, chemistry, biology, in the medicine and in the engineering sciences for the clearing-up of most different questions. Examples are the exploration of the atomic structure of inorganic or organic materials, the illustration of biological objects with high lateral resolution or the visualization of the structure and the chemical composition of very fine-crystalline materials. The small wavelength of the electrons permits thereby a lateral resolution up to atomic dimensions.

Based on the de Broglie relationship, the wavelength λ of the electron is related to its momentum p through Planck's constant h :

$$\lambda = \frac{h}{p} \quad (4.21)$$

For an electron which experiences the accelerating voltage U_A , the equation from the relativistic energy theorem can be derived:

$$E = \sqrt{p^2 c^2 + m_0^2 c^4} = m_0 c^2 + e U_A$$

$$\Rightarrow p = \sqrt{2 m_0 e U_A \left(1 + \frac{e U_A}{2 m_0 c^2} \right)} \quad (4.22)$$

If one inserts the impulse into the previously mentioned relationship, the wavelength λ of an electron which experienced the accelerating voltage U_A , can be written as:

$$\lambda = \frac{h}{\sqrt{2 m_0 e U_A \left(1 + \frac{e U_A}{2 m_0 c^2} \right)}} \quad (4.23)$$

$$[nm] \approx \sqrt{\frac{1.5}{U_A [V]}}$$

Fig. 4.15 shows the wavelength λ of the electrons as a function of the accelerating voltage U_A .

At accelerating voltages of 200 kV and 300 kV, the wavelengths are of the magnitude 2.74(2) pm and 2.25(3) pm, respectively. Since the increase of the accelerating voltage has only a small contribution to the resolution, accelerating voltages of 200 kV are used in conventional TEMs. Theoretically, resolutions in the sub-nanometer scale can be achieved. Practically, only point resolutions of 0.12 nm and line resolutions of 0.10 nm were achieved for 1 MeV TEMs, which are called Ultra High Voltage Electron Microscopes (UHVEM) [72]. The limitations in resolution are given by spherical and chromatic aberration. World-wide, some working groups are resolving these limitations by electron-optical elements like the corrector for the spherical aberration

Figure 4.15: The wavelength λ of the electrons as a function of the accelerating voltage.

(“Cs-corrector”) or by holographic recording methods like off-axis electron holography and focus-series reconstruction.

The principle setup of a TEM Similar to a light microscope, a TEM can be divided into three components: 1) an illumination system, 2) the objective lens, and 3) the imaging system. The role of the illumination systems (condenser) is to transfer the electrons from the source to the specimen, which is realized in two different modes: a parallel or a convergent beam mode. The first one is used for TEM imaging and selected area diffraction (SAD), while the second one is used for imaging in a Scanning Transmission Electron Microscope (STEM), which are used for microanalysis and microdiffraction. As indicated above, the objective lens is the most important part of the TEM. It produces the first image of the sample in its image plane and the diffraction pattern in its back focal plane and its resolution depends primarily and sensitively on the aberration of the objective lens and secondary on the high voltage. Image or diffraction pattern can be selected with help of the intermediate lens, which images either the back focal plane or the image plane of the objective lens as seen in Fig. 4.16 [73]. Further magnification on the screen is performed by subsequent projector lenses.

A bright-field image (BF) is formed when only the direct beam is used for image formation. The objective aperture blocks all other beams to pass to the imaging system. A dark-field image (DF) is formed when the aperture is positioned to pass only some scattered electrons. The off-axis electrons are less accurately bent due to spherical aberrations of the objective lens which leads to a reduced image quality. To avoid this, the incident beam has to be tilted above the objective lens to keep the beam,

Figure 4.16: The wavelength λ of the electrons as a function of the accelerating voltage.

which is used for imaging, close and parallel to the optic axis.

The Philips CM 200-UT microscope In this work, transmission electron microscopy was carried out employing a Philips CM 200-UT microscope (200 kV acceleration voltage) and which is equipped with a Noran Energy Dispersive X-ray detector for STEM. The achieved point resolution was 0.187 nm, the resolving capacity 0.11 nm.

4.3.2 Chemical composition analysis

4.3.2.1 Rutherford Backscattering Spectrometry

Rutherford backscattering spectroscopy (RBS) is one of the most powerful techniques for measuring elemental depth profiles. It allows quantitative and nondestructive analysis with a reasonable depth resolution. In conventional RBS, He ions with energies in the range 1–4 MeV, are used as probes. Almost all ions penetrate deep inside the sample up to ca. 10 μm until they entirely lose their kinetic energy. During the penetration some ions collide with the target atoms and are subject to elastic Coulomb scattering (Rutherford scattering) between the projectile and the target nuclei and may be backscattered from the sample. The energy of the ion backscattered from the target atom depends on the target atom mass. This allows compositional analysis of a surface region of several micrometers by measuring the energy spectrum of the backscattered ions.

Kinematics of collisions When an ion is scattered from a target atom at an angle θ , the ratio of the scattered-ion energy E to the incident energy E_0 can be calculated using the laws of conservation of energy and momentum [74],

$$k = \frac{E}{E_0} = \frac{\sqrt{M_2^2 - M_1^2 \sin^2 \theta} + M_1 \cos \theta}{M_1 + M_2} \quad (4.24)$$

where M_1 and M_2 are masses of the incident ion and the target atom, respectively. The binding energy of the target atom and its thermal vibration are neglected in this derivation. These effects are negligibly small in collisions between ions with mega-electron volt energy and target atoms. It is clear that the energy ratio K , called the kinematic factor, is determined by the mass ratio M_2/M_1 and the scattering angle θ . The basic idea of RBS relies on this equation.

The Rutherford Cross-section The scattering cross-section σ is an effective area associated with the colliding particles. When projectile ions collide on a thin target film of thickness t , the scattering yield is given by [74]

$$Y_{tot} = \frac{Nt\sigma Q}{\cos \alpha} \quad (4.25)$$

where N is the volume density of the target atom, Q the number of incident ions, and α is the incident angle of the beam in respect to the normal vector

of the target.

In RBS, the ions scattered at a particular scattering angle θ are measured by a detector with a finite acceptance solid angle $\Delta\Omega$. The number of these ions can be calculated with an angular differential cross-section [74]

$$Y(\theta) = Nt \frac{d\sigma}{d\Omega} \frac{\Delta\sigma Q}{\cos \alpha}. \quad (4.26)$$

The differential cross-section for Coulomb scattering (Rutherford cross-section) is given by the Rutherford formula [74]:

$$\left(\frac{d\sigma}{d\Omega}\right)_R = \left(\frac{Z_1 Z_2 e^2}{4E}\right)^2 \times \frac{4 \cdot \left[\sqrt{M_2^2 - M_1^2 \sin^2 \theta} + M_1 \cos \theta\right]^2}{M_2 \sin^4 \theta \sqrt{M_2^2 - M_1^2 \sin^2 \theta}} \quad (4.27)$$

where Z_1 , Z_2 are atomic numbers of incident ion and target atom, respectively and E is the incident energy. This simple formula allows to extract quantitative data about abundances of elements from RBS spectra. The cross-section is proportional to Z_2^2 , indicating high sensitivity for heavy elements in RBS.

The IONAS Accelerator Facility RBS was performed at the 530 kV IONAS accelerator facility in Göttingen, which is described in [75, 76] and which is shown in Fig. 4.17. In Table 4.3, the parameters for all RBS measurements are given.

Table 4.3: Parameters of all RBS measurements at the IONAS facility in Göttingen .

Probe ion	He ²⁺
Ion energy	0.9 MeV
Beam current	10-15 μA
Beam spot size (focused)	2 mm ²
Detector	silicon surface barrier (SSB)
Detector resolution	12.5 keV (FWHM)
Scattering angle θ	165°
Depth resolution	~10 nm
Element range	> 4
Sensitivity	ca. 100 ppm for heavy elements in light hosts

4.3.2.2 Resonant Nuclear Reaction Analysis

As well as RBS, Resonant Nuclear Reaction Analysis (RNRA) is a powerful tool for depth profiling. In contrast to RBS, where all elements of an examined sample were instantaneously profiled via the scattering process, RNRA has a high sensitivity to one

Figure 4.17: Schematics of the IONAS accelerator.

specific element due to a nuclear reaction, in this case the $^{15}\text{N}(p, \alpha\gamma)^{12}\text{C}$ reaction [77]. the theory of RNRA is well discussed in [78, 79] and is ideal for nitrogen depth profiling [80–82]. The schematics of RNRA is shown in Fig. 4.18 [83].

The Yield of the 4.43 MeV emitted γ -ray can be

Figure 4.18: Schematics of the RNRA process.

described by:

$$Y(E_b) = \epsilon_{det} \Omega N_p \int_0^\infty \int_0^\infty \int_0^\infty C_N(z) g(E_b, E) f(E, E', z) \cdot \sigma(E') dE' dE dz \quad (4.28)$$

where ϵ_{det} is the efficiency of the detector, Ω the detector solid angle, N_p the number of incident protons and $C_N(z)$ the concentration profile of nitrogen atoms. The most important factors in the formula are $\sigma(E')$ and $f(E, E', z)$. the first one describes the resonance cross section at a proton energy E' , whereas the second one corresponds to the presence of a proton with initial energy E , after penetrating a depth of z by maintaining the energy E' .

The nitrogen depth profiles and the proton incidence energy define the observed γ -yield. Vice versa, the $C_N(z)$ of a binary compound $A_M B_n$ can be derived by a Fourier retransformation:

$$C_N = \frac{C_{st} Y_{\epsilon B}}{Y_{st\epsilon B} + C_{st} Y(\epsilon_B - \epsilon_A)} \quad (4.29)$$

where ϵ_A and ϵ_B describe the stopping power of element A and B, ϵ_{st} the stopping power of the calibration sample (here a magnetron sputtered TiN, 400 nm in thickness), C_{st} the nitrogen concentration of the calibration sample and Y, Y_{st} the γ -yield of $A_M B_n$ and of the calibration sample, respectively. the resulting stopping power of $A_M B_n$ is then derived by the Bragg rule [84].

By assuming a constant stopping power in an infinitesimal small depth-element, the analyzing depth can be derived by

$$z(E_i) = z(E_{i-1}) + \frac{2(E_i - E_{i-1})}{\epsilon(E_i) + \epsilon(E_{i-1})}. \quad (4.30)$$

The observed spectra were analyzed by the Win-RNRA fitting tool [85].

4.3.3 Other Methods

Perturbed angular correlation (PAC) spectroscopy was performed using ^{111}Cd atoms as PAC probe, which are populated by the 2.8 d EC decay of ^{111}In . A recent description of the method as applied in Göttingen can be found in [86]. Using a four detector set-up, 12 coincidence time spectra were recorded. Combining these spectra, the perturbation function $R(t)$ is derived, which is proportional to the angular correlation coefficient A_{22}^{eff} and the perturbation factor $G_{22}^i(t)$. The spectra were fitted by:

$$F(t) = A_{22}^i \cdot \sum_i f_i \cdot G_{22}^i(t) \quad (4.31)$$

with

$$G_{22}^i(t) = \sum_{n=0}^3 s_{2n}(\eta^i) \cdot \cos(g_n(\eta^i) \cdot \nu_Q^i t) \cdot \exp(-g_n(\eta^i) \cdot \delta^i t) \quad (4.32)$$

The fraction f^i of probe atoms is exposed to an electric field gradient (EFG) characterized by the quadrupole interaction frequency ν_Q^i and the asymmetry parameter η^i . Further information on the principles of PAC can be obtained in [57, 87].

Magneto-optical Kerr effect (MOKE) was used to investigate the ferromagnetic behavior of the samples. The MOKE measurements were conducted in longitudinal geometry at room temperature, using a polarization-compensator-sample-analyzer (PCSA) ellipsometer and a maximum external magnetic field of 0.15 T [88, 89]. The samples were mounted onto a rotationally motorized holder, so that magnetic anisotropy could also be analyzed by rotating the sample with respect to the direction of the magnetic field [90].

Atomic force microscopy (AFM) was performed on a Nanoscope III MultiMode AFM (Digital Instruments) whose maximum scan range is $80 \mu\text{m} \times 80 \mu\text{m}$. All samples were measured in tapping-mode.

Scanning tunneling microscopy (STM) was performed on a Nanosurf Easyscan II STM (nanoScience Instruments) whose maximum lateral scan range is 1 micron.

Raman spectroscopy was carried out on a self-assembled device. An argon laser with a wavelength of 514.5 nm was used, together with a Dilor XY triple monochromator. The optics track was assigned to the so-called macro-Raman optics in which the laser beam is aligned in grazing incident mode. The emitted Raman radiation was mapped by a CCD camera.

Corrosion resistance tests used a combination of two galvanic cells. The sputtered films were used as working electrodes, a platinum and kalomel electrode as counter- and as reference-electrode, respectively. 1-molar Na_2SO_4 was used as electrolyte and the voltage was varied from -2 to $+2$ V by means of a potentiostat [91].

Nanoindentation measurements were performed on a Fischerscope HV100 with a Vickers diamond. The maximum indentation force was set from 2 to 5 mN. Five positions were measured for each sample and the mean values are reported [92].

Chapter 5

Targets and starting materials

In this section, the physical properties of the used targets are specified.

The original ARMCO-Iron (purity 99.96 %) and

Figure 5.1: top: GIXRD (2° incidence angle) pattern of the ARMCO-Iron sputter target; bottom: $\theta - 2\theta$ pattern of the AISI 316 sputter target.

AISI 316 targets have a body-centered cubic (bcc, α) and face-centered cubic (fcc, γ) structure, respectively, in contrast to inert magnetron-sputtered thin AISI 316 films, which exhibit only an α -structure when deposited below 678 K [93]. This is readily seen in Fig. 5.1, where the XRD patterns of ARMCO-Iron and AISI 316 are shown.

The bcc structure of the original ARMCO-Fe target and the fcc structure of the original AISI 316 target are extracted in Fig. 5.1a) and b). The lattice constants obtained are $a = 0.2881(1)$ nm for the bcc ARMCO target and $a = 0.3592(1)$ nm for the fcc stainless steel target.

This behavior is resembled in the Mössbauer spec-

tra of the targets as shown in Fig. 5.2.

The Mössbauer spectrum of the original ARMCO

Figure 5.2: (a) Transmission Mössbauer spectrum of the original ARMCO-Iron sputter target; (b) CEM spectrum of the original AISI 316 sputter target. The corresponding distributions of the hyperfine fields $p(B)$ are given on the right.

target shows, as mentioned in the theory section, a split Zeeman sextet (Fig. 5.2 a) due to the magnetic splitting of the nuclear energy levels. From the fitting, a mean hyperfine field of $\langle B \rangle = 32.9$ T with a width of $\sigma = 0.7$ T is obtained from the $p(B)$ distribution. In contrast, the original AISI 316 target in Fig. 5.2b) shows the typical non-magnetic central line of austenite with an isomer shift of $\delta = -0.10(1)$ mm/s [94].

MOKE measurements as presented in Fig. 5.3 clearly demonstrate the ferromagnetic behavior of the ARMCO sputter target. A coercive field of $H_C \approx 75$ Oe is found. The observed magnetic in-plane anisotropy is less than 1 %.

The angular dependence of the magnetic anisotropy as shown in Fig. 5.3 were deduced by

Figure 5.3: Angular scans of ARMCO-iron sputter target: (top) coercive field H_C ; (middle) relative remanence M_r/M_s ; (bottom) magnetization energy density E_s/M_s .

fitting the magnetization energy density E_s/M_s required for saturation. The quantity of E_s/M_s can be determined by numerically integrating the anhysteretic magnetization loops averaged over both branches of the magnetization curves measured by MOKE [95], and was parameterized by the expression [96]:

$$\begin{aligned} \frac{E_s}{M_s} = & \frac{K_u}{M_s} \sin^2(\varphi - \varphi_0) \\ & + \frac{K_1}{4M_s} \sin^2 2(\varphi - \varphi_1) + \frac{E_0}{M_s} \end{aligned} \quad (5.1)$$

where E_0/M_s accounts for an isotropic contribution due to the random distribution of domains in the polycrystals. The parameters K_u/M_s and K_1/M_s indicate the contributions of uniaxial and fourfold magnetic anisotropies with φ_u and φ_1 being the respective symmetry angles.

The results of the fitting procedure can be obtained in Table 5.1.

Targets for Magnetron-sputtering possessed a diameter of 76 mm and 2 mm in thickness, targets for

Table 5.1: Fitting results of the MOKE analysis. χ^2 and χ_{red}^2 represent the values of the statistical significance tests.

χ^2	0.640
χ_{red}^2	0.172
K_u/M_s	0.860(372)
$K_1/4M_s$	1.616(1498)
φ_0	19.596(12444)
φ_1	75.500(13142)
E_0/M_s	56.986(288)

PLD possessed a dimension of 25×25 mm and also 2 mm in thickness.

In the next chapters, the results of this work are presented and discussed. As a consequence of the facility of inspection, first, the results of the Magnetron-sputtered films are shown, which are followed by the results of pulsed laser deposited films and by the results of FEL surface treated films.

Chapter 6

Results for magnetron-sputtered films

6.1 Results for magnetron-sputtered FeC films

The films were sputter-deposited with an rf magnetron onto amorphous SiO_2 substrates (oxidized Si(100) wafer of 0.5 mm thickness, pre-cleaned with acetone and oxidized in air, no further treatment) utilizing a pre-combined target consisting of graphite and commercial ARMCO-Iron (purity: 99.96 %). To achieve a stoichiometric FeC phase, the sputter yield of Fe and C was calculated using SRIM [97] in dependence to the incoming Ar^+ ion energy, which is illustrated in Fig. 6.1.

As obtained from Fig. 6.1, the sputter yield of

Figure 6.1: Sputtering-yield Y of Fe, C and the sum of both elements in dependence of the Ar^+ ion energy.

Fe is 10 times greater than that of C at an Ar^+ of approximately 80 eV. As a consequence, the target was made in that way, that the area fraction of graphite was 10 times greater than that of ARMCO-Iron. The form of the target can be readily seen in Fig. 6.2.

The target-substrate distance was set to 2 cm to

Figure 6.2: The $\text{Fe}_{50}\text{C}_{50}$ Magnetron sputter target.

achieve valuable sputter rates. The processing parameters were always 100 W magnetron power. The gas flow was increased from 14.5 to 140 sccm (sccm = standard cubic centimeter, i.e. flow volume of gas at normal conditions, 273.15 K and 1013 hPa) during deposition. The sputter rate was always in the range of 0.01-0.03 nm/s, and was depending on the processing parameters. The magnetron chamber was evacuated to a base pressure of 10^{-4} Pa before deposition. The target was always pre-sputtered for half an hour with the desired parameters before starting the deposition onto the substrate. The target was water cooled and the substrate temperature was controlled between room temperature (water cooling) and 673 K (electrical heating). The thickness of the deposited films was controlled by a quartz microbalance (with a film density set to 4.15 kg/m^3 , which is the density corresponding to the Fe and C ratio derived from the SRIM calculation). The samples were deposited with similar thicknesses as given by the quartz microbalance. As a result, deposition time and real film thickness varied. The deposition parameters and the resulting thicknesses and growth rates are summarized in

Table 6.1.

From these data it is derived that the growth rate

Table 6.1: Gas flow j , deposition time t , real film thickness d (as measured by Rutherford Backscattering Spectrometry (RBS) after deposition) and derived growth rate $g = \frac{d}{t}$ for the deposited films. All samples were deposited at 298 K with a magnetron power of 100 W and a target-substrate distance of 2 cm.

sample	j_{Ar} [sccm]	t [min]	d [nm]	g [nm/min]
A145	14.5	145:41	64(10)	0.44(7)
A300	30.0	102:03	119(10)	1.17(10)
A400	40.0	233:57	45(10)	0.19(4)

A800	80.0	80:55	107(10)	1.32(13)
A1000	100.0	106:43	109(10)	1.02(9)
A1400	140.0	107:23	102(10)	0.95(9)

Figure 6.3: Growth rate g as a function of the Ar gas flow j_{Ar} for the room temperature deposition.

is divided into two regions: the first region starts from 0 to 50 sccm Ar gas flow, wherein the growth rate is oscillating (hatched area in Fig 6.3). This behavior could already be seen during deposition, where the formation of the plasma was hindered and where the processing had to be adjusted instantaneously. This behavior could be due to an enhanced plasma interaction caused by oxygen in the chamber. The second region follows the first up to 140 sccm, wherein the growth rate is constant at about 1.0 nm/min. It seems that, in this region, the energy of the Ar^+ atoms do not linearly correlate with the increase of the gas flow, but it is rather constant. As a consequence, no more target ions can be sputtered, which leads to a constant sputter rate. The evolution of the growth rate as a function of the Ar gas flow can be seen in Fig 6.3.

6.1.1 Deposition at room temperature and influence of the Ar gas flow

Figure 6.4: GIXRD (2°) spectra of the inert sputtered samples. The Ar gas flows are given in the graphs.

Figure 6.5: Peak position and peak width of the first broad peak in the XRD spectra of the reactive sputtered stainless steel films.

The Argon gas flow was systematically increased from 14.5 to 140.0 sccm. For all these deposited films, the inert magnetron deposited samples show the typical broad XRD appearance of amorphous materials. For the sake of clearness only the spectra of the samples sputtered with 14.5 and 50.0 sccm Ar gas flow are shown in Fig. 6.4. These diffractograms show a clear amorphous signature, but due to the high carbon content reflections of graphite are de-

Figure 6.6: Mössbauer spectra of the inert sputtered FeC films.

Table 6.2: Mössbauer fitting results of the sputtered FeC samples, deposited at room temperature with a magnetron power of 100 W (f - area fraction (error), mean values of $\langle\delta\rangle$ - isomer shift, $\langle\Delta\rangle$ - the quadrupole splitting for the paramagnetic subspectra, $\langle\epsilon\rangle$ the quadrupole splitting for the magnetic subspectra, B - hyperfine field).

noted.

Fig. 6.5 shows the position and the width of the first broad peak for the spectra shown in Fig. 6.4.

There is the same clear tendency for peak position and peak width as obtained for the growth rate. For high Ar gas flows, peak position and peak width are nearly constant, indicating that no phase transition takes place.

Fig. 6.6 summarizes the CEMS measurements of the samples with increasing gas flow. They show the typical Mössbauer spectra of amorphous materials and are magnetically split. They also include distributions, which can be attributed to oxides. Especially, the samples sputtered between 14.5 and 70 sccm Ar gas flow contain high hyperfine fields which can be identified as α -Fe₂O₃ oxides. The results of the fitting procedures are presented in Table 6.2.

The spectra were fitted by hyperfine field distributions, and with quadrupole splitting distributions in the paramagnetic state, respectively.

For the FeC films sputtered between 70 and 140 sccm Ar gas flow, these distributions could be attributed to an amorphous iron carbon-alloy, possibly rich in carbon as indicated by ferro-l. Another possibility could be that the low fields in ferro-l are an artifact of the fitting procedure and correspond to paramagnetic doublets. In contrast to the low hyperfine fields, hyperfine fields as labeled as ferro-h could be attributed to Fe carbides.

These Mössbauer results were confirmed by MOKE measurements. Due to the fact, that all samples show the same behavior in MOKE, exemplary the result of the FeC sample sputtered at 50 sccm Ar gas flow is shown in Fig. 6.7. The coercive field H_C of all samples is approximately 10 Oe.

Figure 6.7: Hysteresis curve of the inert deposited FeC film sputtered at 50 sccm Ar gas flow.

As seen in Fig. 6.7 the saturation is not reached. From the MOKE pattern it is estimated that a maximum external field of 0.30 T is needed to reach saturation. As a consequence, no angular dependencies could be determined. However, the coercive field H_C is not constant for different φ .

To characterize the surface of the samples, STM measurements were performed, as shown for the FeC sample deposited with an Ar gas flow of 140 sccm in Fig. 6.8.

For all films, a roughness of about 4 nm was

Figure 6.8: STM pattern for the FeC sample sputtered at 140 sccm Ar gas flow.

found. To characterize the structure of the surface, an autocorrelation of the image was compiled and a power-spectral density (PSD) diagram derived which are illustrated in Fig. 6.9 and 6.10.

The structure obtained by the autocorrelation is not strongly minted, but a characteristic wavelength of 25 nm is derived by the PSD.

To determine the composition of the films, RBS measurements were carried out. As a consequence

Figure 6.9: Autocorrelation of the STM image as shown in Fig. 6.8

Figure 6.10: Power-spectral density diagram derived from the line scan, which is shown in Fig. 6.9. The parameters of the Gauss multi-peak fit are given in the graph.

of the low space between target and substrates, the films are very inhomogeneous, which is illustrates in Fig. 6.11.

Thus, more than 25 measurements were carried

Figure 6.11: FeC film after deposition. The numbers indicate the positions of the RBS measurements.

out. For clarity, only the summarized results were

presented in Fig. 6.12.

As obtained from the fitting, the FeC films also

Figure 6.12: Mean concentrations as derived from the RBS fitting routine.

contain oxygen ($\approx 10\%$). As a result, the desired stoichiometric FeC film is not obtained. A closer look to the Richardson-Ellingham diagram reveals, that at those deposition pressures - such as used in this work - lead to the formation of iron oxides.

Another problem could be the poisoning of the target by reflected C ions or ions which are bombarding the target due to the selected target-geometry.

Fig. 6.13 illustrates the poisoning of the target as a function of the sputter yields of Fe and C at an fixed Ar ions energy of 400 eV. Thus, for any stoichiometries $\text{Fe}_{100-c}\text{C}_c$, the poisoning of the target can be deduced.

From this SRIM calculation a poisoning of nearly

Figure 6.13: Poisoning of the target as a function of the sputter yields of Fe and C at fixed $E_{Ar^+} = 400$ eV. The black dashed line corresponds to the $\text{Fe}_{50}\text{C}_{50}$ stoichiometry.

70 % is predicted.

According to the RBS analysis, a large graphite

Figure 6.14: RBS spectra of the target before (black) and after (red dashed) sputtering.

layer on the surface of the target can be observed. This amount of graphite could lead to hysteresis effects, which hardly influence the stoichiometry of the deposited films.

As a consequence of this, the Magnetron sputtering technique seems not to be suitable to synthesize the stoichiometric FeC phase. Geometric effects of the target configuration, hysteresis effects (as indicated by RBS) and re-sputtering constitute severe problems to the deposition process. Even the small addition of H_2 could not enhance the deposition process. Otherwise, Magnetron sputtering revealed the formation of films with amorphous character. These films exhibit carbon contents, which exceed the maximum solubility limits in known carbides. As a result of this, reactive sputtering of stainless steel - by using methane, nitrogen and oxygen as reactive gas - was performed to synthesize amorphous films or quasi metallic glasses based on conventional steels. The results will be discussed in the next sections.

6.2 Results for carburized stainless steel films

The films were sputter-deposited with an rf magnetron onto amorphous SiO₂ substrates (oxidized Si(100) wafer of 0.5 mm thickness, pre-cleaned with acetone and oxidized in air, no further treatment) utilizing a commercial AISI 316 (X5CrNiMo17-12-2, 1.4401) target. The target-substrate distance was set to 10 cm. The processing parameters were always 100 W magnetron power at a constant total gas flow of 12 sccm (sccm = standard cubic centimeter, i.e. flow volume of gas at normal conditions, 273.15 K and 1013 hPa) during deposition. Several sample series were deposited at different CH₄ flows (0.00-1.25 sccm). The sputter rate was always in the range of 0.1-0.2 nm/s, and was depending on the processing parameters. The magnetron chamber was evacuated to a base pressure of 10⁻⁴ Pa before deposition. The target was always pre-sputtered for half an hour with the desired parameters before starting the deposition onto the substrate. The target was water cooled and the substrate temperature was controlled between room temperature (water cooling) and 673 K (electrical heating). The thickness of the deposited films was controlled by a quartz microbalance (with a film density set to 7.89 kg/m³, which is the density of AISI 316). The samples were deposited with similar thicknesses as given by the quartz microbalance. As a result, deposition time and real film thickness varied. The deposition parameters and the resulting thicknesses and growth rates are summarized in Table 6.3. From these data it is derived that

Table 6.3: Gas flow j , deposition time t , real film thickness d (as measured by Rutherford Backscattering Spectrometry (RBS) after deposition) and derived growth rate $g = \frac{d}{t}$ for the deposited carburized films. All samples were deposited at 298 K with a magnetron power of 100 W and a target-substrate distance of 10 cm.

sample	j_{CH_4} [sccm]	j_{Ar} [sccm]	t [min]	d [nm]	g [nm/min]
M0	0.00	12.00	17:00	205(10)	12.06(92)

the growth rate is decreasing with increasing CH₄ flow what is visualized in Fig. 6.15. The growth rate drops more or less exponentially from about 12 nm/min for the inert sputtering to half of this value for higher methane flows. This might be due

to the varying sputtering rates induced by the carbon uptake into the surface of the sputtering target.

Figure 6.15: Growth rate g as a function of the CH₄ gas flow j_{CH_4} for the room temperature deposition.

The methane gas flow was systematically increased from 0.01 sccm to 1.25 sccm. For all these deposited films, the reactive magnetron deposited and carburized samples show the typical broad XRD appearance of amorphous materials, as seen in Fig. 6.16. These diffractograms show a clear amorphous signature.

Fig. 6.17 shows the position and the width of the first broad peak for the spectra shown in Fig. 6.16. There is a clear tendency for peak position and peak width, where the peak position is decreasing and the peak width is increasing with increasing CH₄ flow. Fig. 6.19 summarizes the CEMS measurements of

Figure 6.17: Peak position and peak width of the first broad peak in the XRD spectra of the reactive sputtered stainless steel films.

the samples with increasing gas flow. They show the typical Mössbauer spectra of amorphous materials. Spectra in a-c are magnetically split, those in e)-g)

are non-magnetic, where the spectrum in d) shows both parts. This observation is consistent with the XRD results in Fig. 6.16. The results of the fitting procedures are presented in Table 6.4. The spectra were fitted by hyperfine field distributions, and with quadrupole splitting distributions in the paramagnetic state, respectively. These distributions are attributed to an amorphous stainless steel carbon-alloy, possibly rich in carbon. The quadrupole splittings are broad and close to the values of the usual carbides. Not much information can therefore be taken from them. Summarizing, all samples appear as an amorphous material which shows magnetic behavior below a gas flow of 0.75 sccm.

Figure 6.18: Angular scans of (left) 0.01 sccm CH₄ and (right) 0.10 sccm CH₄ gas flow. The coercive field H_C (top) and the relative remanence M_R/M_S (bottom) are shown.

Figure 6.19: Mössbauer spectra of the reactive sputtered AISI 316 films. The numbers in the graphs represent the methane gas flow.

These Mössbauer results were confirmed by MOKE measurements. Figure 6.18 shows the result of the MOKE measurement of the 0.01 sccm CH_4 sample. The sample carburized with a gas flow of 0.05 sccm CH_4 shows an identical MOKE appearance.

A uniaxial anisotropy of about 70% can be seen with the maximum of the remanence around 150° . This behavior could be due to magnetostriction effects by stresses in the film. The coercive field H_C of both samples is approximately 4 Oe. Figure 6.18 b) shows the MOKE result of the as-carburized sample sputtered with 0.1 sccm CH_4 gas flow. It exhibits only a weak (fourfold) anisotropy, which is normally observed for an fcc phase [89,98]. The coercive field was derived as 30 Oe. The samples with CEMS spectra shown in Fig. 6.19 d-g) do not show any magnetic behavior (e.g. no hysteresis loops in MOKE), which is in good agreement. These observations have now to be correlated to the carbon content of the film.

The EDX analyses of the deposited films revealed the original composition of the sputtering targets within the experimental limits. Unfortunately, the EDX did not allow to accurately determine elements lighter than oxygen. Therefore, in order to evaluate the amount of incorporated carbon, RBS measurements were carried out, whose results are shown in Fig. 6.20.

The thickness of the films as obtained from the RBS analysis was already given in Table 6.3. The carbon concentration of the films as obtained from the RBS analysis is given in Fig. 6.21 and can reach almost 70 at.%. There seems to be a clear correlation (parabolic-like) of the carbon content with the CH_4 gas flow, with a minimum close to 25% carbon for 0.5 sccm CH_4 flow. Unfortunately, RBS cannot distinguish between free carbon and carbon dissolved in the film. The C-content as achieved

Figure 6.20: RBS spectra of the reactively sputtered films. The CH_4 flow is given in the graph.

Figure 6.21: Carbon content in the reactively sputtered films as derived from the RBS analysis versus the CH_4 gas flow.

by the RBS analyses exceeds the limit of 25 at.% for Fe_3C . Therefore, excessive carbon could eventually form graphite distributed in the film or on the surface of the film, but no signs of graphite could be detected in XRD. On the other hand, amorphous carbon would be difficult to see. To clarify this, AFM measurement were performed which is shown in Fig. 6.22 for the sample sputtered with a CH_4 gas flow of 0.01 sccm. Nanoscaled surface struc-

Figure 6.22: AFM measurement (left) and cross section analysis (right) of the sample sputtered with a CH_4 gas flow of 0.01 sccm. The cross section analysis (right bottom) shows the line from which the roughness and the cluster-size were derived.

tures with the shape of half eggs can be observed. This shape is typical for carbon nanoclusters [99]. The clusters have a size between 10 and 80 nm in diameter and the roughness of the film is $R_a = 3$ nm. This method is not able to show the type of chemical bonding of the carbon clusters. Thus, the carburized samples were examined by means of Raman spectroscopy, which is displayed in Fig. 6.23. The Raman results show a narrow weak peak at a Raman shift of 1550 cm^{-1} for the soft ferromag-

Figure 6.23: Raman results for the amorphous soft ferromagnetic carburized AISI 310 and AISI 316 films.

netic phase found in carburized thin AISI 316 (at 0.01 sccm CH_4 gas flow) and AISI 310 (at 0.05 sccm CH_4 gas flow) films. In literature [100], this shift has been attributed to the carbon g-band (sp^2 hybridized C). No d-band is observed around 1300–1350 cm^{-1} . The low intensity and the narrow peak form is typical for nanoparticles. This is a hint that at least some carbon forms graphite nanoparticles at the surface. One can compare the overall carbon ratios of the different films. These are in good agreement with the RBS results. According to the method described in [101], the stress in the film could be derived on the basis of the Raman peak positions, which add up to 2.5 - 3.3 GPa. Note, no clear dependencies can be seen between the stress in the film and composition of the target material.

6.2.2 Vacuum annealing of films carburized at room temperature

In order to analyze the thermal stability of the amorphous soft ferromagnetic phase, we performed annealing at a temperature of 973 K. The exposition times were set to 1, 10 and 120 h. The Mössbauer results of this isothermal series are shown in Fig. 6.24.

The Mössbauer spectra show various subspectra which can be attributed to carbides. The observed carbides and their fractions support the carbide formation upon annealing and hint to the carbide transformation $\text{M}_3\text{C}/\text{M}_7\text{C}_3 \rightarrow \text{M}_{23}\text{C}_6 \rightarrow \text{M}_6\text{C}$ with increasing exposition time [102]. The Mössbauer results are summarized in Table 6.5. The hyperfine parameters after annealing for 1 h are well-defined and the quadrupole doublets can be identified as $\text{M}_3\text{C}/\text{M}_7\text{C}_3$ carbides [103, 104]. The observed α -Fe

Figure 6.24: Mössbauer spectra of vacuum annealed AISI 316 film sputtered with a magnetron power of 100 W and 0.01 sccm methane. Exposition time and temperature are given.

sextet can be interpreted as bcc Fe probably containing some Ni, but almost no Cr and Mo [105]. After 10 h annealing, the doublets were identified as M_{23}C_6 according to Refs. [103, 106] and an α -Fe sextet as before. After 120 h vacuum annealing, the doublets can be identified as M_6C [107]. The corresponding XRD patterns are shown in Fig. 6.25.

The XRD patterns are in good agreement with the Mössbauer results. The mixed carbides $\text{M}_7\text{C}_3/\text{M}_{23}\text{C}_6/\text{M}_6\text{C}$ are observed. In consideration of these data, the transformations during annealing can be understood as follows [103, 104, 108, 109]: carbon diffuses out of the amorphous matrix and forms Cr-rich carbides, which further enriches in Cr and further transforms with increasing exposition time. The remaining matrix is more and more enriched in Ni and then transforms to γ . The α -Fe(110) peak and the M_7C_3 -peak are overlapping, first this peak consists mostly of α -Fe which is then more and more transformed into M_7C_3 . In the bottom-most XRD pattern it is only M_7C_3 . Any supersaturated dissolved carbon tries to segregate and is used for carbide formation. A closer look to the stoichiometry shows an decrease of the C-content in the car-

bides with annealing time, from M_7C_3 over $M_{23}C_6$ to M_6C .

SEM pictures show that the excessive C diffuses also towards the surface and there forms nanowires, as seen in Fig. 6.26. In addition, Raman spectroscopy was used to examine the bond behavior of the carbon after annealing. The spectra are shown in Fig. 6.27.

Both sp^2 - and sp^3 -hybridized carbon is observed. According to the three stage model of Ferrari et

Figure 6.26: SEM pictures of the post-vacuum annealed samples: a) 1 h at 973 K, b) 10 h at 973 K and c) 120 h at 973 K.

Figure 6.27: Raman measurements of the post-vacuum annealed samples.

al. [110]

$$I_D/I_G = C'(\lambda) \cdot L^2_a \quad (6.1)$$

where I_D and I_G are the intensities of the D and G peak, C the Raman coupling coefficient ($C'(514.5 \text{ nm}) = 0.0055$) and L_a the cluster size, the sp^2/sp^3 ratio can be derived and thus the cluster size, which is in good agreement to AFM measurements. The results are given in Table 6.6. Finally,

Table 6.6: Raman results of the vacuum-annealed samples

Annealing time at 973 K [h]	I_D/I_G	L_a [nm]
1	0.53(3)	10(1)
10	0.85(2)	12(2)
120	0.75(1)	12(1)

the samples can be embedded in the ternary phase diagram of amorphous carbon, which can be attributed to sputtered a-C. The weak and narrow peak at 1550 cm^{-1} again implies nanoclustering of graphite on the surface of the samples.

6.2.3 The influence of deposition temperature

In Fig. 6.28 the CEM spectra of carburized AISI 316 films deposited at increasing substrate temperatures are shown. The deposition temperature clearly changes the nature of the deposited films, as seen by the changes in the spectra. It seems that at higher temperatures, the low B region has transformed in a non-magnetic quadrupole distribution. RBS show a decrease of carbon content from 60(2) % to 30(2) %, which affects the XRD pattern, in which a more clearer formation of the γ -phase is observed. The decrease of the carbon content originates in the formation of carbon-oxides or -hydroxides, which shade again into the vapor phase. The Mössbauer results are given in Table 6.7.

Consequently, the long-range diffusion process and thus the suppression of nucleation are less severe at higher deposition temperatures. In Fig. 6.29 the XRD diffraction patterns are shown, the bars indicate the Bragg positions of the different reflexes as indicated.

At 298 K the amorphous phase dominates. At 673 K, a partial recrystallization process can be observed by the formation of carbides, but the amorphous character of the sample is maintained. Discrepancies in the peak positions imply the presence of stress in the films.

The results for the deposition temperature of 473 K were not reproducible, especially the Mössbauer spectra showed different grades of oxidation. This could be due to an enhanced plasma interaction between CH_4 -radicals and oxygen. As a consequence of this, these results were not shown. Fig. 6.30

Figure 6.29: GIXRD (2° incidence angle) spectra of the as-carburized samples sputtered with a magnetron power of 100 W and 0.01 sccm methane. The substrate temperatures are given.

Figure 6.30: Angular scans of the film sputtered at 673 K with 0.1 sccm CH_4 gas flow. The polar diagrams of the coercive field H_C (left) and the relative remanence M_R/M_S (right) are shown.

shows the MOKE measurement of the sample sputtered at 673 K. A weak fourfold anisotropy can be observed, which is typical for fcc phases [111]. The coercive field is about 6 Oe. This is in good agreement with the CEMS and GIXRD results. Deposition temperature is not as critical in phase formation as shown in inert sputtered AISI 316 stainless-steel films. The amorphous soft ferromagnetic phase mostly remains.

Figure 6.28: CEM spectra of carburized AISI 316 films sputtered with a magnetron power of 100 W and 0.01 sccm methane at two temperatures: $T = 298$ K (top), $T = 673$ K (bottom). On the right hand side, the hyperfine field distribution $p(B)$ and the quadrupole splitting distribution $p(\Delta)$ are shown.

Table 6.7: CEM results of AISI 316 films, deposited at 673 K with a magnetron power of 100 W and 0.01 sccm CH_4 flow (f - area fraction (error), mean values of δ - isomer shift, $\langle \Delta \rangle$ - the quadrupole splitting for the paramagnetic subpectra, $\langle \epsilon \rangle$ the quadrupole splitting for the magnetic subpectra, B - hyperfine field).

6.2.4 Corrosion tests of carburized stainless steel films

In order to investigate the influence of the carburization on corrosion resistance, corrosion tests were performed on carburized stainless steel films, whose results are presented in Fig. 6.31. A comparison of the two graphs provides the following differences between AISI 310 and AISI 316: the first peak at -1.3 V can be attributed to surface-diffused Cr. Note, the intensities in both steels are different due to the frequency of occurrence of the alloying elements. AISI 316 shows a better corrosion resistance in the passive area. In the range of -1 to -0.25 V it achieves negative current densities. Negative current densities are useful for the formation of oxides at the surface which increases the corrosion resistance. AISI 310 holds more Cr than AISI 316, but its current density rises again at -0.6 V. This can be attributed to the Ni surface-diffusion. The Richardson-Ellingham diagram clearly shows that

Ni has a bad oxide formation ability which could result in a worse corrosion resistance. Indeed, a certain Ni-Cr ratio is needed for an ideal corrosion resistance. This is given for AISI 316 [112]. The rising current density before the transpassive area is attributed to Mn surface-diffusion for AISI 310, and Mo surface-diffusion for AISI 316. The break-out potential for sputtered films is dominated by the Fe potential. The carburized AISI 316 sample sputtered at 298 K cannot be shown due to metallic disbandment, but its characteristics should be similar to those of the sample carburized at 673 K.

As a general observation, the corrosion resistance improves after carburization. More and more Cr (as well as Ni) diffuses to the surface and is used to form a thin oxide layer. This effect is less severe in the case of carburized AISI 316 films. The dimension of the corrosion resistance is given by the metallic disbandment. For inert sputtered AISI 316, we obtained a metallic disbandment at 3.5 V; 7 V for inert sputtered AISI 316 films sputtered at 673 K

Figure 6.31: Corrosion tests of AISI 310 (a) and AISI 316 (b) sputtered films. All samples were sputtered at a magnetron power of 100 W, inert-sputtered sample with 12 sccm Ar gas flow, carburized samples with 0.01 sccm CH_4 gas flow. Temperatures are given in the graphs.

and 8 V for as-carburized AISI 316 films. Thus, carburization improves corrosion resistance by a factor of 2 in the case of AISI 316 films. As-sputtered AISI 310 films already have a high metallic disbandment (~ 8 V). This can be attributed to the high Cr- and Ni-content. For similar carburizing conditions a metallic disbandment at 11 V for carburized AISI 310 films was obtained. This is an improvement by a factor of nearly 1.5, which is attributed to the disadvantageous Cr-Ni ratio in AISI 310. The substrate temperature during carburizing has a bigger influence on the corrosion resistance, but it has a marginal influence on the metallic disbandment. Finally, carburizing significantly improves the corrosion resistance.

6.2.5 Microhardness of carburized stainless steel films

Nanoindentation was performed to achieve an understanding of the influence of carburization on the microhardness and the mechanical properties. The results are presented in Table 6.8 and ??, where also the carbon content derived from RBS is included.

Different dependencies were observed for the differ-

Table 6.8: Hardness, Young modulus and C-content of carburized AISI 310 films, where E is the elastic modulus and ν the poisson ratio

CH_4 Gas flow	Hardness	Young modulus	C-content
[sccm]	[GPa]	$E/(1-\nu^2)$	[at.%]
0.10	6.1(5)	129(2)	39.75
0.50	3.4(2)	98(1)	29.90
0.75	4.3(3)	101(1)	52.10
1.00	7.3(2)	166(3)	52.90
1.25	5.8(3)	120(2)	65.80

Table 6.9: Hardness, Young modulus and C-content of carburized AISI 316 films, where E is the elastic modulus and ν the poisson ratio

CH_4 Gas flow	Hardness	Young modulus	C-content
[sccm]	[GPa]	$E/(1-\nu^2)$	[at.%]
0.01	5.2(4)	113(1)	60.0
0.05	4.8(1)	105(1)	14.9
0.10	5.1(3)	108(1)	55.0
0.50	4.1(5)	98(1)	29.9
0.75	5.1(2)	108(1)	44.9
1.00	4.4(9)	97(1)	59.8
1.25	4.0(1)	88(1)	65.1

ent steel types. While the C-content rises quite linearly in carburized AISI 310 films with the methane gas flow, no clear dependencies are obtained for AISI 316 films. Both phenomena can be explained with the model of Lux and Haubner [113] mentioned in the discussion area. In the case of carburized AISI 310 films, all carbon is used to form carbides and graphite from the vapor phase. For carburized AISI 316 films we assume a higher and faster plasma interaction between CH_x radicals and sputter-adsorbates which can deplete already existing carbides or graphite. The hardness values for the amorphous soft ferromagnetic phases are conspicuous. For AISI 310, this phase exhibits the lowest hardness. Amorphous carburized AISI 316 is the hardest sample.

6.2.6 Discussion on a nucleation model for carburized stainless steel films

Now three questions arise: how can the formation of the amorphous soft ferromagnetic phase be explained and how much carbon is incorporated in the

films, which finally leads to the question of the carbide formation. According to Lu et al. [13] the first question can be answered as follows: the present Fe-based alloy is associated with the deep eutectic point of the Fe-C system. It is well known that compositions around the deep eutectic point are ideal for glass formation in many systems. As a result, glass formation is greatly favored thermodynamically. Further, the minor addition of Mo could promote glass formation in the Fe-C system by suppressing the formation of the primary phase (i.e. Fe carbides). Because of their limited solubility in Fe carbides, the molybdenum atoms must redistribute and long-range diffusion is required upon solidification. Thus, the minor addition of Mo could retard the nucleation process.

Another approach is the so-called Carbide Formation Ability (CFA) [114], which evaluates the effect of the composition elements. CFA is based on physicochemical analysis [114] of the carbide formation processes accompanying the primary and secondary crystallization of a weld metal with reliance on quantum-chemical theories that depict the structure of transition metals and carbides. CFA is defined as

$$\Theta_i = \frac{R_i}{d_i}, \quad (6.2)$$

where R_i is the radius of the alloy elements and d_i the number of the electrons in d-orbital. The CFAs of common steel elements are given in Table 6.10. The growth mechanism of the fabricated stainless steel films is assumed as a combination of the pre-mentioned models. Whereas the first model prescribes that molybdenum aids a diffusion process which suppresses carbide formation, the CFA model predicts the highest CFA value for molybdenum. The fact that the present carburized steel system consists of five elements, the probability of each atom to interact only with one sort of element is not given. Thus, the CFA model can only be used auxiliary. A clear evidence of this hypothesis could be a topic of further investigations, wherein the ion-distribution functions of carburization processes could be investigated.

In contrast to inert gas sputtered AISI 316 films, the role of Ni is insignificant. Even the method of instantaneous recording of the electromotive force (MIE) [93, 115] was inconclusive. The chemical potential of the films changed from Fe-potential at room temperature to Fe_2O_3 -potential at 673 K. Thus, the Gibbs-Thomson effect cannot be used to explain the formation of carbides. This backs the thesis of long-range diffusion during nucleation. It can be assumed that - due to the relative abundances of the steel elements - these carbides are $(\text{Fe,Cr})_3\text{C}$ carbides.

In consideration to the present results, an entire

conception of the nucleation process which is referred by Lux and Haubner [113] can be stated as follows: during the nucleation process carbonaceous species were adsorbed on the surface. Via vapor phase interaction, e.g. hydrogen recombination and formation of CH_x radicals, free C atoms were formed. Diffusion processes already inserted by Mo atoms solve the C atoms in the metal matrix. The carburization initially takes up all available C out of the vapor phase, until a closed carbide film is formed. With increasing thickness of the carbide film, the C transport in the metal matrix is slowed down. This leads to an increasing C-content on the surface which induces metastable clustering. The differing carbon content in the carburized stainless steel films is originated in the inserted diffusion process (and thus in the differing carbon take up in the metal matrix) which depends on the processing parameters. If the grain sizes exceeds a critical value, even diamond-like carbon films can be built [113]. This model explains the variety of the observed phases and the different carbon contents in the carburized films. It is reasonable to assume that the solubility limit of C in Fe_3C is reached. Excessive C-content exists in form of graphite nanoclusters on top of the film. This is confirmed by Fig. 6.32 which shows the dependence between peak width and carbon content.

A clear tendency can be seen: with higher carbon

Figure 6.32: Peak width of the first amorphous peak in dependence of the carbon content of reactive sputtered stainless steel films.

concentration, higher peak widths can be reached. Only the sample sputtered at 0.10 sccm CH_4 gas flow deviates. The first reflex in the XRD pattern of this sample had to be fitted with two peaks: one attributed to an amorphous phase and one attributed to a crystalline phase. It is reasonable to assume that all XRD pattern could be fitted by two peaks, but there are no clear hints (peak asymmetry etc.)

Table 6.10: Carbide Formation Ability (CFA) of AISI steels. The lattice constants a are also given.

Element	Electron Configuration	Atom radius [Å]	Crystallographic structure	a [Å]	CFA
Fe	$3d^6 4s^2$	1.260	BCC(α)	2.861	0.210
			FCC(γ)	3.564	
Cr	$3d^5 4s^2$	1.270	BCC	2.885	0.256
Ni	$3d^8 s^2$	1.250	FCC	3.520	0.156
Mn	$3d^5 4s^2$	1.270	SC(α)	8.894	0.254
			SC(γ)	6.300	
			FCC(γ)	3.774	
			BCC(δ)	3.720	
Mo	$4d^5 4s^1$	1.390	BCC	2.885	0.278

as seen for the 0.10 sccm sample. Even here, no quantitative conclusion can be given how many carbon is solved in the metallic matrix as graphite or as carbide.

6.2.7 Microstructure of the amorphous and soft ferromagnetic phase

The structural nature of the amorphous soft ferromagnetic phase is still unknown, but due to the previous mentioned results, it is reasonable to assume that Mo triggers a diffusion processes which suppresses the formation of carbides and should thus lead to a loss of distal-order and to a dramatic change in the liquidus temperature. With respect to this, TEM, FIM, DSC and EXAFS were carried out to reach a full understanding of the microstructure of amorphous steels.

TEM and FIM analysis As a first attempt to explain the microstructure of the amorphous and soft ferromagnetic phase, TEM patterns were taken, which are shown in Fig. 6.33.

Fig. 6.33 a) and b) show the dark field patterns of the amorphous and soft ferromagnetic phase. They show nano-crystallites with a diameter of 5-10 nm at the film/SiO₂ interface and the surface of the film. The mostly amorphous structure of the film is confirmed by the selected area diffraction (SAD) pattern, which is depicted in Fig. 6.33 c) and shows the typical behavior of amorphous films. Furthermore, Fig. 6.33 d) shows the high-resolution pattern of the film. Inhomogeneities in metal concentration can be observed. Considering the high carbon concentration ($\approx 60\%$ derived by RBS), this decomposition of stainless steel and carbon could be due to diffusion during deposition. This corresponds to our model, that Mo suppresses the primary phase formation and induces long-range diffusion, which finally leads to metastable clustering of graphite as observed in Raman spectroscopy [22].

In order to confirm the TEM results and to get

more information on the observed inhomogeneities, a FIM analysis was performed. The result can be readily seen in Fig. 6.34.

The observed FIM pattern predominantly shows

Figure 6.34: FIM pattern of the amorphous and soft ferromagnetic film (sputtered at 298 K at 0.01 sccm CH₄).

the behavior of an amorphous alloy, but there are also appendages of crystallization: in the bottom of Fig. 6.34, the formation of about 10 nm ring-like atom strings can be observed. According to the literature [116], these characteristics are typical for an initiating crystallization and can be observed for complex intermetallic compounds. Thus, it is reasonable to assume that some of the observed inhomogeneities are nano-crystallites. Summarizing, the amorphous and soft ferromagnetic phase appears as a quasi-metallic glass.

DSC measurement The thermal properties of the amorphous and soft ferromagnetic phase obtained by DSC are shown in Fig. 6.35.

The scan exhibits a glass transition (at 598.8 K) and two crystallization events (at 622.05 and 683.45 K), indicating that this stainless steel has

Figure 6.33: TEM pattern of the amorphous and soft ferromagnetic film (sputtered at 298 K at 0.01 sccm CH_4). a) and b) dark field pattern, c) SAD pattern and d) HR-TEM of the film.

a mostly amorphous structure. For AISI 316 stainless steel films we obtained recrystallization at the temperature range 923-1073 K [93], thus the metallic glass behavior is confirmed. The obtained glass transition temperature T_g is significant lower than those given in the literature [12-14], which indicates the potential of the amorphization of conventional steels.

EXAFS analysis of the amorphous and soft ferromagnetic phase To investigate the short-range order of the amorphous and soft ferromagnetic phase EXAFS experiments were carried out at the ESRF beamline BM29. The investigated depth area was estimated to be ~ 80 nm for the Fe k-edge region and ~ 105 nm for the Ni k-edge region, respectively, according to the formula reported by Elam et al. [117]. For comparison, EXAFS spectra of α -Fe, bulk AISI 316, and Fe_3C were taken. Data analysis was performed using the HORAE package [65-67] according to following procedure: the origin of the kinetic energy was chosen as the maximum of the first derivative of the absorption edge; the fine-structure oscillations were isolated in the energy space to simulate the continuous atomic cross section; the $\chi(E)$ was converted to k space and the $k^2\chi(k)$ data were Fouriertransformed in the region $2 < k < 12 \text{ \AA}^{-1}$. Figure 6.36 shows the fine-structure oscillations (weighted with factor k^2) of the standards α -Fe, γ -(Fe,Cr,Ni) (bulk AISI 316), Fe_3C and the reactive magnetron-sputtered sample deposited with 0.01 sccm CH_4 gas flow.

In order to have a quantitative information, the spectra were analyzed by superimposition of theoretical models of different crystal structures calculated by ATOMS and FEFF [65,67] (using a multi-

Figure 6.36: Fine-structure oscillations weighted with k^2 factor of: a) γ -(Fe,Cr,Ni) (bulk AISI 316), b) α -Fe, c) Fe_3C and the reactive magnetron-sputtered sample deposited with 0.01 sccm CH_4 .

Figure 6.37: BFT moduli of bulk AISI 316 (solid) and the amorphous and soft ferromagnetic film (sputtered at 298 K at 0.01 sccm CH_4) (dashed line) measured at the Fe K-edge (top) and at the Ni K-edge (bottom).

shell model). To minimize the number of variables, σ^2 and ΔR were set equal for every path of each structure. The back Fourier transform (BFT) was calculated in the region $1.0 < R < 2.8$ Å, which can be seen in Fig. 6.37 recorded at the Fe- and Ni k-edge.

Whereas the BFT modulus of the bulk mate-

rial can simply be fitted by a face-centered cubic structure, drastic changes in the Fe and Ni environment can be observed for the reactive magnetron-sputtered sample. At the Fe k-edge an immense decrease of long-range order can be observed, but the local Fe-environment is dominated by a superimposition of γ -(Fe,Cr,Ni), martensite and a carbon-rich (Fe,Cr,Ni) environment.

At the Ni k-edge the loss of long-range order is not as severe as observed at the Fe k-edge and the BFT can be fitted by a superimposition of γ -(Fe,Cr,Ni), α -(Fe,Cr,Ni) and a trigonal-Ni₃C phase. The results of the fitting routine can be obtained from Table 6.11 and Table 6.12 (for clarity only the paths in the fitting range are listed).

The reported disorder parameters σ^2 show the poor quality of the crystallinity of the obtained phases, which is in good agreement to TEM, FIM, DSC and as well as to the results mentioned in [22]. According to this analysis, the XRD pattern was revalued, which is presented in Fig. 6.38. Note, all significant reflexes were reproduced by the phases obtained by the EXAFS analysis.

Figure 6.38: XRD pattern of the reactive magnetron-sputtered film deposited at 0.01 sccm CH₄ gas flow.

The origin of magnetism In order to explain the origin of ferromagnetism in the reactive magnetron sputtered sample, as shown by CEMS and MOKE, the EXAFS data have to be interpreted. From this analysis two phases are known, which show harder magnetism: martensite and the α -(Fe,Cr,Ni) phase.

A combination of both phases would result in higher coercitive fields as observed by MOKE. Even in consideration of the high disorder parameter of martensite ($\sigma^2 = 0.109$) and of α -(Fe,Cr,Ni) ($\sigma^2 = 0.021$) obtained by the EXAFS analysis, a resulting coercive field of about 4 Oe would be improbable by

a superimposition of these magnetic phases. This leads to the assumption that the carbon diffuses into both structures (as indicated by the high disorder parameters and as indicated by the high-carbon containing (Fe,cr,Ni)-environment) and decreases the hyperfine field. Indeed, this behavior is derived from Mössbauer analysis for reactive magnetron-sputtered stainless steel films [22], which can be seen in Fig. 6.39.

Due to the high carbon concentration and its de-

Figure 6.39: Median hyperfine field B_{hf} in dependence of the carbon content of reactive sputtered stainless steel films.

magnetizing effect, the contribution of both phases to magnetism is adopted as negligible.

Recent studies report on the ferromagnetic behavior of Ni₃C [118, 119], which crystal structure is shown in Fig. 6.40 and was drawn by the crystal visualization software DIAMOND [120].

A linear-muffin-tin-orbital (LMTO) method showed that for ordered Ni₃C carbon has a s-state character in its lowest valence band, which is populated by strongly hybridized Ni p-, d- and C p-states at its bottom [119]. Thus, ordered Ni₃C is theoretically expected to be non-magnetic.

The origin of the observed magnetism has been ascribed to the presence of crystal defects. According to a LMTO band structure calculation, the C vacancies which generate locally Ni-rich regions (by removing the hybridization between Ni and C states) are believed to sustain the magnetic moments exhibiting spin glassy (SP), paramagnetic (P) and ferromagnetic (FM) properties. The order of magnetism can not be explained by this method, but it additionally predicts the presence of paramagnetic and spin glass phases.

Monte Carlo simulations on the ferromagnetic behavior of amorphous Co-Ni-B and Fe-Ni-B nanoparticles were reported by De Biasi et al. [121, 122]. Simulations based on a core-shell model, describ-

Figure 6.40: Crystal structure of trigonal Ni_3C phase: space group $R\bar{3}c$ (167), $a = 4.5530 \text{ \AA}$, $c = 12.9200 \text{ \AA}$.

ing the nanoparticles as consisting of a ferromagnetic core and a disordered surface shell, reproduce satisfactorily the different orders of magnetism by randomly oriented spins of the SP surface shell. These spin moments would then contribute to demagnetize the core ferromagnetism via the SP-FM exchange coupling as H approaches zero. Hence, a severely reduced coercivity is observed around $H = 0$. He et al. [118] applied this core-shell model to disordered Ni_3C nanoparticles and were able to explain coercive fields which have the same order as obtained in this work.

Summarizing, ferromagnetism in this amorphous phase can be reduced to a disordered Ni_3C phase, which is indicated by the disorder parameter (note: good crystallinity is represented for $\sigma < 10^{-4}$) and is surrounded by a spin glassy surface shell, which demagnetize the ferromagnetic Ni_3C -core.

The influence of the chemical composition

To focus on how the differences in chemical composition of conventional steels and steels as described in the literature affect the amorphization, two categories of explanations have to be reconsidered: thermodynamics and kinetics.

As described in [12, 13], from a thermodynamical point of view, the superior GFA in BMGs can be associated with a stabilization (through kinetics) outside the equilibrium - the (Fe-C)-system as deep eutectic. This means that the liquid state is energetically favored over the ordered solid state in a large temperature range above the eutectic tem-

perature via stabilization of the liquid or through destabilization of distal-order [32, 123]. Below the eutectic temperature, the force of crystal growth is relatively small. As a consequence, the amorphous state can be reached easier for liquid quenched materials as described in the literature.

For amorphous materials or films which are fabricated by vapor phase techniques as described here, kinetics have to be considered. Also here, we assume that the given system is around the deep eutectic. Atomic-size mismatches induce simultaneous rearrangement of different species of atoms, which suppresses the formation of competing ordered phases and significantly limits the kinetics. As a consequence, glass formation is favored.

Indeed, the enhancement of GFA by atomic-size mismatches and efficient atomic packing is shown by computer simulations [124], topological studies [125] and experimental results [126].

In [125] the local efficiency packing factor P is derived from the ratio (R) of the solute atom radius to the solvent atom radius. Table 6.13 present this ratio of the elements used in this work compared to those mentioned in [12, 13].

Smaller values for $R_{i/j}$ and R_N^* can be ob-

Table 6.13: A list of used alloying elements and selected properties: r is the atomic radius; $R_{i/j}$ is the the ratio (R) of the solute atom radius to the solvent atom radius; R_N^* is the radius ratio, where the subscript N specifies the particular coordination number; σ^{e^-} is the electronic configuration and CFA the Carbide Formation Ability.

tained for this present work compared to those of the literature, which is originated in the similarity of radii of the alloying elements used in this

study. According to [125], an efficiency packing factor $P \approx 0.76 - 0.77$ is derived by taking the ratio of the sum of all atomic volumes to the total volume concerned, which is slightly higher than that derived in [12]. This is even larger than the 0.74 of fcc-crystals, which confirms that our used system is highly efficiently packed after carburization. As a first summary we can stress out, that the amorphization of conventional steels is more complicated than the amorphization of Zr-based steels. This is confirmed by the low coordination number N , which indicates a lower atomic-mismatch interaction and thus, a shorter solidification time.

This is confirmed by the negative heat of mixing ΔH^{mix} , which is also reported to benefit GFA. According to [127], ΔH^{mix} for Fe-Cr, Cr-Ni and Fe-Ni are -4, -4 and -5 kJ·mol⁻¹, and -1 kJ·mol⁻¹ for the ternary Fe-Cr-Ni system. According to [12], an improvement of local packing efficiency and repression of long-range diffusion of atoms can be obtained by negative ΔH^{mix} by enhancing interactions among components, which promote chemical short-range order. The ΔH^{mix} for the steel used in [12] is 4-6 times higher, which is consistent with the observed coordination numbers.

Now the question arise, in which way conventional AISI 316 can be driven to the amorphous state.

Already during inert sputtering we assume a non-insignificant part of kinetic participation, wherein the Ni content is decreased under the critical γ -stabilizing content and finally leads to ferromagnetic stainless steel films [93]. Also here, the Mo triggers a long-range diffusion, which then could lead to a modification of the sticking coefficient, which is inversely proportional to the exponential of the temperature and also inversely proportional to the square of the distance between atomic steps (and thus indirectly proportional to the atomic radius) on the surface [128]. The diminution of Ni content can be observed in several types of steels [93, 129].

The introduction of C during carburization additionally disturbs the nucleation process by establishing higher probabilities of coordination as represented by R_{23}^* . This leads to simultaneous rearrangement of different species of atoms, which suppresses the formation of competing ordered phases. As a consequence, phases outside the equilibrium can be formed like the disordered trigonal Ni₃C phase. This is confirmed by the Carbide Formation Ability (CFA) [22, 114], which were derived from the electronic configuration σ^{e^-} and were given in Table 6.13.

Ni has the lowest CFA of all elements, nevertheless, the observed Ni₃C carbide is formed instead of the established carbides (i.e. Fe₃C etc.).

The main difference between the steel used in this study and that used in [13] is the number of alloying elements. Here, a quintuple system is used, whereas Lu et al. chose a octuple system to enhance the coordination number and thus the interatomic interaction (which is supported by the borocarburation of that system).

The next step should be the amorphization of conventional steels via liquid quenching. However, first experiments showed severe problems due to the formation of Cr-oxides. Upcoming experiments should deal with the introduction of various carrier gases which should prevent the oxide formation in such a way that thermodynamics and kinetics were not hardly dominated by competing processes.

6.3 Results for nitrated stainless steel films

The films were sputter-deposited with an rf magnetron onto amorphous SiO₂ substrates (oxidized Si(100) wafer of 0.5 mm thickness, pre-cleaned with acetone and oxidized in air, no further treatment) utilizing a commercial AISI 316 (X5CrNiMo17-12-2, 1.4401) sputter-target. The target-substrate distance was set to 10 cm. The processing parameters were always 100 W magnetron power at a constant total gas flow of 12 sccm during deposition. Several sample series were deposited at different N₂ flows (0.00-1.00 sccm). The sputter rate was always in the range of 0.1-0.2 nm/s and was depending on the gas flow parameters. The deposition procedure were carried out in the same way as for as-carburized stainless steel films. The deposition parameters and the resulting thicknesses and growth rates are summarized in Table 6.14. From

Table 6.14: Gas flow j , deposition time t , real film thickness d (as measured by Rutherford Backscattering Spectrometry (RBS) after deposition) and derived growth rate $g = \frac{d}{t}$ for the deposited nitrated films. All samples were deposited at 298 K with a magnetron power of 100 W and a target-substrate distance of 10 cm.

sample	j_{N_2} [sccm]	j_{Ar} [sccm]	t [min]	d [nm]	g [nm/min]

Figure 6.41: Growth rate g as a function of the N₂ gas flow j_{N_2} for the room temperature deposition (line is only to guide the eye).

these data it is derived that the growth rate has a

sinusoidal form (Fig. 6.41) with its first maximum at 0.03 sccm and its second maximum at 0.80 sccm N₂ gas flow, which is contrary to carburized samples, where growth rate drops more or less exponentially from about 12 nm/min for the inert sputtering to half of this value for higher methane flows [22]. As be seen below, these parameters represent two metastable phases: an amorphous and soft ferromagnetic phase rich in nitrogen (@ 0.03 sccm N₂ gas flow) and the cubic (Fe,Cr, Ni)N phase (@ 0.80 sccm N₂ gas flow).

6.3.1 Deposition at room temperature and influence of the nitrogen gas flow

Figure 6.42: GIXRD (2°) spectra of the nitrated films. The N₂ gas flows are given in the graph; the peaks of the ZnS-type (Fe,Cr,Ni)N phase are indexed.

The nitrogen gas flow was systematically increased from 0.01 sccm to 1.00 sccm. For the most deposited films, the reactive magnetron deposited and nitrated samples show the typical broad XRD appearance of amorphous materials, as seen in Fig. 6.42. Only exceptions are the nitrated samples deposited with an nitrogen gas flow of 0.75 and 1.00 sccm. According to [130], these reflections can be attributed to the ZnS-type

Table 6.15: Mössbauer fitting results of the nitrated AISI 316 samples, deposited at room temperature with a magnetron power of 100 W (f - area fraction (error), mean values of $\langle\delta\rangle$ - isomer shift, $\langle\Delta\rangle$ - the quadrupole splitting for the paramagnetic subspectra, $\langle\epsilon\rangle$ the quadrupole splitting for the magnetic subspectra, B - hyperfine field).

γ'' -(Fe,Cr,Ni)N phase, which exhibits a lattice constant of $a = 0.392(22)$ nm.

Fig. 6.43 shows the position and the width of the first broad peak for the spectra shown in Fig. 6.42. There is a clear tendency for peak position and peak width, which both decrease with increasing N_2 flow, having its minimum at 0.75 sccm N_2 gas flow, before the peak width and especially the peak position rises again.

As a first conclusion a phase transition from the

Figure 6.43: Peak position and peak width of the first broad peak in the XRD spectra of the reactive sputtered stainless steel films.

formation of an amorphous to a cubic (Fe,Cr,Ni)N phase can stress out. The earlier phase is formed at a N_2 gas flow of 0.75 sccm (with a lattice parameter of $a = 0.392(22)$ nm). Further increasing of the N_2 gas flow to 1.00 sccm N_2 gas flow, the XRD pattern of the nitrated sample ($a = 0.394(33)$ nm) shows a decrease of the grain size. This implies, that with higher gas flow the peak width decreases and thus the grain size rises. This tendency is also confirmed by Fig. 6.41 and Fig. 6.43. The discrepancy between the lattice parameters found in this study

and in the literature [130] ($a = 0.389$ nm) may be caused by the presence of Chromium, Nickel and Molybdenum which is known to enlarge the lattice. Fig. 6.44 summarizes the CEMS measurements of the samples with increasing gas flow. They show the typical Mössbauer spectra of amorphous materials. Spectra in a-c are magnetically split, those in d-f) are non-magnetic. This observation is consistent with the XRD results in Fig. 6.42. The fitted hyperfine parameters are presented in Table 6.15.

For these spectra, hyperfine field and quadrupole splitting distributions were assumed, respectively. These distributions are attributed to an amorphous stainless steel nitrogen-alloy, possibly rich in nitrogen (as also seen for carburized samples). The quadrupole splitting distributions are broad and close to the values of the cubic nitride. Indeed a single line analysis shows that the observed spectra can be identified as the γ'' -FeN phase. The results of the single line analysis are given in Table 6.16. Summarizing, all samples below 0.50 sccm N_2 gas flow appear as an amorphous material which shows magnetic behavior.

These Mössbauer results were confirmed by MOKE measurements. Figure 6.45 shows the result of the MOKE measurements for two samples: nitrated with 0.01 sccm N_2 or 0.10 sccm N_2 gas flow. Both result in identical MOKE spectra.

Figure 6.44: Mössbauer spectra of the reactive sputtered AISI 316 films. The numbers in the graphs represent the nitrogen gas flow.

Table 6.16: Hyperfine interaction parameters of the single line analysis of the as-sputtered samples shown in Fig. 6.44 e) and f). Hyperfine parameters: δ is the isomer shift, QS the quadrupole splitting, Γ the line width (HWHM), and RA the relative area.

N_2 [sccm]	δ [mm/s]	QS [mm/s]	Γ [mm/s]	RA [%]
0.75	0.10(3)		0.20	16.6(13)

	0.45(1)	0.46(2)	0.20	77.1(21)
1.00	0.09(5)		0.20	18.2(47)
	0.48(9)		0.20	4.6(56)
	0.39(2)	0.48(2)	0.20	77.2(45)

Figure 6.45: Angular scans of the reactive sputtered films with: (top) 0.01 sccm N_2 and b) (bottom) 0.05 sccm N_2 gas flow. The polar diagrams of the coercive field H_C are shown left and the relative remanence M_R/M_S at the right.

A uniaxial anisotropy of about 75% can be seen with the maximum of the remanence around 180° . This behavior could be due to magnetostriction effects and stresses in the film. The coercive field H_C of both samples is approximately 4 Oe. Figure 6.45 b) shows the MOKE result of the as-nitrided sample sputtered with 0.05 sccm N_2 gas flow. It does not exhibit any anisotropy. The coercive field was derived as 30 Oe. The samples with CEMS spectra shown in Fig. 6.44d-f) do not show any magnetic behavior (e.g. no hysteresis loops in MOKE), which is in good agreement. These observations have now to be correlated to the nitrogen content of the films.

The EDX analyses of the deposited films revealed the original composition of the sputtering targets within the experimental limits. Unfortunately, the EDX did not allow to accurately determine elements lighter than oxygen. Therefore, in order

to evaluate the amount of incorporated nitrogen, RBS measurements were carried out, whose results are shown in Fig. 6.46.

The thickness of the films as obtained from the RBS analysis was already given in Table 6.14. The nitrogen concentration of the films as obtained from the RBS analysis is given in Fig. 6.47 and can reach almost 55(2) at.%. This seems to be a clear increasing correlation of the nitrogen content with the N_2 gas flow, with a minimum at 17% nitrogen for 0.05 sccm N_2 flow. At 1.00 sccm N_2 flow the nitrogen content decreases again; this is in good agreement with all previously mentioned results.

Figure 6.46: RBS spectra of the reactively sputtered films. The N_2 flow is given in the graph.

Figure 6.47: Nitrogen content in the reactively sputtered films as derived from the RBS analysis versus the N_2 gas flow.

To confirm the observed nitrogen contents, RNRA depth-profiling measurements were performed, which are shown in Fig. 6.48. The RNRA analysis shows the same tendency as the RBS measurements, but the nitrogen contents derived from

Figure 6.48: RNRA depth-profiling results of the as-nitrided samples. The N_2 gas flow are given in the graph.

RNRA are slightly smaller than the RBS results (normally 3 at.%). Thus, the maximum nitrogen content derived from this data is 52(2) at.%. We then can conclude, that the (Fe,Cr,Ni)N phase is formed at 0.75 sccm N_2 gas flow.

6.3.2 PAC characterization of the vacuum annealed soft ferromagnetic phase

To study the influence of vacuum annealing of the amorphous and soft ferromagnetic phase found at 0.05 sccm N_2 , ^{111}In atoms were implanted at an energy of 400 keV at the 530 kV IONAS accelerator facility in Göttingen and then carefully analyzed by PAC at 10 and 298 K. After analyzing the as-nitrided sample, it was vacuum annealed ($p_a = 10^{-3}$ Pa) at 973 K for 2 hours. The results of the PAC measurement are shown in Fig. 6.49. The spectra measured at 10 K did not show any changes in comparison to the as-nitrided sample recorded at 298 K. Therefore, only the spectra recorded at 298 K for the as-nitrided and vacuum annealed sample are shown in Fig. 6.49. As the PAC spectra give no indication of a magnetic hyperfine field, they have been fitted assuming an EFG-distribution. Fig. 6.49 a) shows the typical behavior of amorphous materials, where the PAC probe has no defined position in the matrix due to the absence of crystalline order. As a consequence, the quadrupole interaction frequency ν_Q shows a broad frequency distribution caused by randomly excited EFGs (note: this system consists of five elements and thus, there are 14 combinations of pair interactions). No further information can be taken from

Table 6.17: PAC interaction parameters of the annealed amorphous and soft ferromagnetic phase at 973 K for 2 hours shown in Fig. 6.49 b). Hyperfine parameters: ν_Q is the quadrupole interaction frequency, δ the damping of ν_Q , η the asymmetry parameter, and RA the relative area.

ν_Q [MHz]	δ [MHz]	η	RA [%]
169(13)	26(13)	0.57(11)	51(1)
228(10)	21(10)	0.28(8)	46(1)
4(10)	0(1)	0.01(12)	3(1)

them.

In contrast to Fig. 6.49 a), Fig. 6.49 b) shows clearer oscillations in the perturbation function $R(t)$ and thus in its Fourier transform. The values derived from the analysis are given in Table 6.17. According to the literature [131], these parameters are similar to $\alpha\text{-Cr}_2\text{O}_3$. The high damping frequencies and thus the high asymmetry parameter η are typical for amorphous materials or for materials with broad distributions in their EFGs. For a damping of $\delta \approx 20$ %, the asymmetry parameter η should be greater than 0. If δ exceeds 35 %, η can reach values greater than 0.5. Thus, the observed η -values are consistent. Summarizing, it is shown that this new phase crystallizes and is sensitive to oxidation during even vacuum-annealing.

6.3.3 Microhardness of nitrided stainless steel films

Nanoindentation was performed by using a Fischerscope HV100 [92] with a Vickers diamond in order to investigate the influence of nitriding on the microhardness and the mechanical properties. The maximum indentation force was set to 2 mN. Four positions were measured for each sample. The mean values are reported in Table 6.18, where also the mean nitrogen content derived from RNRA is included.

By including data from [132], [133], a clear

Table 6.18: Hardness, Young modulus and N-content of nitrided AISI 316 films, where E is the elastic modulus and ν the poisson ratio

N_2 Gas flow [sccm]	Hardness [GPa]	Young modulus [GPa]	N-content [at.%]

parabolic tendency between hardness and nitrogen

Figure 6.49: ^{111}In PAC perturbation spectra along with their Fourier transforms for measurements of the as-nitrided samples: a) (top) PAC measurement of the as-nitrided sample sputtered at 0.05 sccm N_2 gas flow and b) (bottom) PAC measurement after 2 hours of post vacuum annealing treatment performed at $T_a = 973 \text{ K}$. All presented spectra are recorded at 298 K.

content can be seen, which is depicted in Fig. 6.50. The values obtained in this study are in good

Figure 6.50: Dependency between Martens hardness and nitrogen content including data from [132], [133]. The N values are obtained from the RNRA analysis.

agreement to those reported in the literature. Nitrogen is known to occupy interstitial sites in AISI 316 which results in hardening [8]. Additional strengthening mechanisms are associated with the formation of nitrides. With involvement of the alloying elements in AISI 316, the reported values can be explained by $\text{CrN}/\text{Cr}_2\text{N}$ nitrides (which are difficult to identify in XRD) accompanied with the formation of $\epsilon\text{-Fe}_2\text{N}\text{-Fe}_3\text{N}$ nitrides.

The hardness value for the amorphous soft ferromagnetic phase is surprisingly high. For AISI 316, this phase exhibits a relative high hardness value.

6.3.4 Discussion on a nucleation model for nitrided stainless steel films

Similar to carburized samples, the experiments described above pose the following questions 1): how can the formation of the amorphous and soft ferromagnetic phase be explained. No. 2): How does the incorporation of nitrogen influence the phase formation, which leads to the question of the ruling phenomenon of nitride formation.

Also here, a combined model which refers to Lu et al. [13] and Lux and Haubner [113], so that the first question can be answered as follows: the present Fe-based alloy is associated with the deep eutectic point of the Fe-N system. It is well known that compositions around the deep eutectic point are ideal for glass formation in many systems. As a result, glass formation is greatly favored thermodynamically. Further, the minor addition of Mo could promote glass formation in the Fe-N system by suppressing the formation of the primary phase (i.e. Fe nitrides) and hindering grain growth. Because of their limited solubility in Fe nitrides, the molybdenum atoms must redistribute and long-range diffusion is required upon solidification. This is confirmed by RNRA, where the samples nitrided at 0.01-0.10 sccm N_2 gas flow show a dramatic variation in nitrogen content. Thus, the minor addition of Mo could retard the nucleation process. Indeed, the given parameter range show amorphous XRD

patterns.

The emerged phases above 0.10 sccm N_2 gas flow can be explained by combining the mentioned model from Lu et al. with that of Lux and Haubner [113]: during the nucleation process nitronaceous species were adsorbed on the surface. Via vapor phase interaction, free N atoms were formed. Diffusion processes already inserted by Mo atoms solve the N atoms in the metal matrix, until nitrides like ϵ -(Fe,Cr) $_2$ N and (Fe,Cr) $_3$ N nitrides were formed. These phases were needed to form a closed nitride film, which then favors the formation of the FeN phase. This seems to be proven by RNRA, where the N-content at the beginning of the nucleation process start to increase until N values around 50 at.% were reached. Also this is confirmed by XRD. The long range diffusion in the range of 0.50-1.00 sccm N_2 gas flow appears to be less severe. According to Fig. 6.41, the growth rate reaches here higher values, which could retard the diffusion process. This leads then to the formation of nitride phases as seen by CEMS and XRD.

These two combined models explain the variety of the observed phases and the different nitrogen contents in the nitrided films and is further confirmed by Fig. 6.51, which shows similar to Fig. 6.50 a clear parabolic tendency: for nitrogen concentrations up

obtained for the reactive gas flow, any given phase - from amorphous to crystalline - can be reached for magnetron-nitrided stainless steel films.

The similarity of the amorphous states observed in carburized and nitrided samples lead to conclusion, that in both cases the underlying mechanism is the same. Thus, the magnetism in the amorphous and soft ferromagnetic phase (sputtered at 0.05 sccm N_2 gas flow) is due to nano-crystalline grains consisting of a disordered Ni_3N phase surrounded by a spin glassy surface shell.

To investigate, if the found similarity of the observed amorphous states are based on a generalized model, which is independent of the used reactive gas, experiments with oxygen were carried out. The results were presented in the next section.

Figure 6.51: Peak width of the first amorphous peak and reactive gas flow in dependence of the nitrogen content of reactive sputtered stainless steel films.

to 25 %, the peak width increases. At 25 % N-content, the stoichiometry of Fe_3N , Fig. 6.51 has its maximum and starts then to decrease, until it reaches the parameter of the FeN phase. Simultaneously, the gas flow increases exponential from 0.01 to 1.00 sccm N_2 gas flow. Both Figures, Fig. 6.50 and Fig. 6.51, have the form of a Gibbs plot, wherein the parameter range exhibits the Fe_3N as minimum, and thus, as thermodynamically favored phase. Combined with the shown tendency

6.4 Results for oxidized stainless steel films

The films were sputter-deposited with an rf magnetron onto amorphous SiO₂ substrates (oxidized Si(100) wafer of 0.5 mm thickness, pre-cleaned with acetone and oxidized in air, no further treatment) utilizing a commercial AISI 316 (X5CrNiMo17-12-2, 1.4401) sputter-target. The target-substrate distance was set to 10 cm. The processing parameters were always 100 W magnetron power at a constant total gas flow of 12 sccm during deposition. Several sample series were deposited at different O₂ flows (0.00-1.00 sccm). The sputter rate was always in the range of 0.10-0.25 nm/s and was depending on the gas flow parameters. The deposition procedure were carried out in the same way as for carburized and nitrated stainless steel films. The deposition parameters and the resulting thicknesses and growth rates are summarized in Table 6.19.

From these data it is derived that the growth

Table 6.19: Gas flow j , deposition time t , real film thickness d (as measured by Rutherford Backscattering Spectrometry (RBS) after deposition) and derived growth rate $g = \frac{d}{t}$ for the deposited oxidized films. All samples were deposited at 298 K with a magnetron power of 100 W and a target-substrate distance of 10 cm.

sample	j_{O_2} [sccm]	j_{Ar} [sccm]	t [min]	d [nm]	g [nm/min]
O0	0.00	12.00	17:00	205(10)	12.06(92)
O1	0.01	11.99	16:55	260(10)	15.37(118)
O5	0.05	11.95	15:42	269(10)	17.13(135)
O10	0.10	11.90	17:09	362(10)	21.11(138)
O50	0.50	11.50	20:57	92(10)	4.39(53)
O75	0.75	11.25	25:13	65(10)	2.58(41)
O100	1.00	11.00	26:44	469(10)	17.54(79)

rate has a sinusoidal form (Fig. 6.52), which was also seen for nitrated samples [134]. The first maximum of the growth rate characteristic can be found at 0.10 sccm, its second maximum at 1.00 sccm O₂ gas flow. As be seen below, these parameters represent two metastable phases: a nano-crystallized cubic FeO phase (@ 0.10 sccm O₂ gas flow) and an amorphous and soft ferromagnetic phase rich in oxygen (@ 1.00 sccm O₂ gas flow).

6.4.1 Deposition at room temperature and influence of the oxygen gas flow

The oxygen gas flow was systematically increased from 0.01 sccm to 1.00 sccm. For all these deposited films, the reactive magnetron deposited

Figure 6.52: Growth rate g as a function of the O₂ gas flow j_{O_2} for the room temperature deposition (line is only to guide the eye).

Figure 6.53: GIXRD (2°) spectra of the oxidized films. The O₂ gas flows are given in the graph.

and oxidized samples show the typical broad XRD appearance of amorphous materials, as seen in Fig. 6.53. These diffractograms show a clear amorphous signature.

Fig. 6.55 shows the position and the width of the first broad peak for the spectra shown in Fig. 6.53. There is a clear tendency for peak position and peak width; both, peak position and peak width, have a parabolic form with its minimum at 0.75 O₂ gas flow.

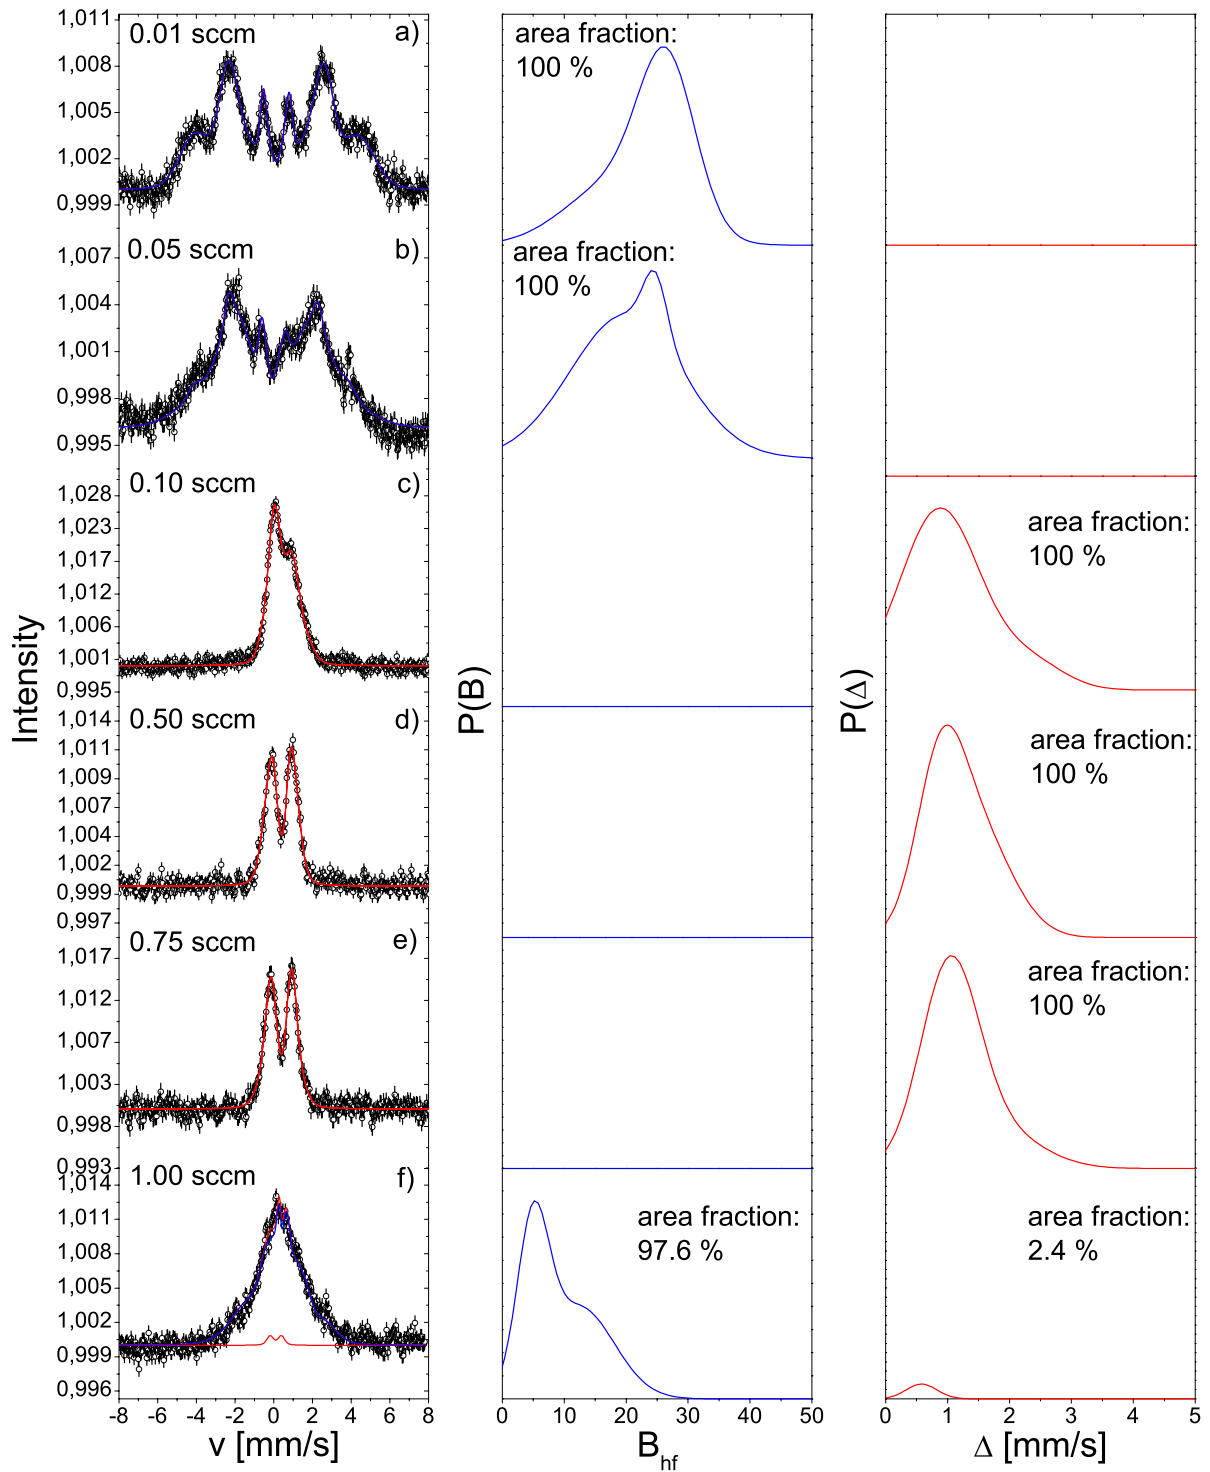

Figure 6.54: Mössbauer spectra of the reactive sputtered AISI 316 films. The numbers in the graphs represent the oxygen gas flow.

Figure 6.55: Peak position and peak width of the first broad peak in the XRD spectra of the reactive sputtered stainless steel films.

Fig. 6.54 summarizes the CEMS measurements of the samples with increasing gas flow. They show the typical Mössbauer spectra of amorphous materials. Spectra in a) and b) are magnetically split, the spectrum in c) reveals the (Fe,Cr,Ni)O phase, whereas d) and e) represent spectra for γ -(Fe,Cr,Ni) $_2$ O $_3$. Finally, spectrum f) exhibits the quasi-metallic glass phase, which was also observed for carburized and nitrided samples. The difference between the quasi-metallic phase sputtered with an oxygen atmosphere and those sputtered with methane and nitrogen is the relative high isomer shift. Whereas the carburized and nitrided quasi-metallic glass sample have a relative insignificant isomer shift, the oxidized sample reveals an isomer shift of $\delta \sim 0.30$ mm/s. This indicates a participation of iron atoms with a high oxidation state (i.e. Fe oxides). The fitted hyperfine parameters are presented in Table 6.20.

To confirm the magnetic properties obtained by Mössbauer Spectroscopy, MOKE measurements were carried out. While the Fig. 6.54 a) and b) show a magnetically split sextet, no MOKE-signal is obtained for these samples. Due to the information depth of MOKE (5-10 nm), two explanation are possible: 1) there could be non-magnetic Fe-oxides on the surface and 2) the whole sample is antiferromagnetic. Since there is no noticeable amount of additional doublets in the spectra, the second explanation is more probable. As a consequence, only the quasi-metallic phase sputtered at 1.00 sccm O $_2$ gas flow exhibits a MOKE signal. The results are illustrated in Fig. 6.56.

A clear fourfold anisotropy can be observed, which could be due to magnetostriction effects, stresses or by a phase transition to a γ phase [88,89,111]. The coercive field H_C is approximately 6 Oe.

The EDX analyses of the deposited films revealed

Figure 6.56: Angular scans of the deposited film sputtered at 1.00 sccm O $_2$ gas flow. The polar diagrams of the coercive field H_C (top) and the relative remanence M_R/M_S (bottom) are shown.

Figure 6.57: RBS spectra of the reactively sputtered films. The O $_2$ flow is given in the graph.

the original composition of the sputtering targets within the experimental limits. Therefore, in order to evaluate the amount of incorporated nitrogen, RBS measurements were carried out, whose results are shown in Fig. 6.57 and can reach almost 72(2) at.%.

In Fig. 6.58 the oxygen content derived from the RBS analysis can be seen. Also here a clear parabolic tendency can be seen with increasing O $_2$ gas flow. The maximum regions for the samples sputtered with 0.50 and 0.75 sccm correspond, with respect to their oxygen content, to Fe $_2$ O $_3$ oxides. Since no magnetism can be observed in Mössbauer Spectroscopy and MOKE, these oxides can be iden-

tified as γ -Fe₂O₃ oxides.

6.4.2 PAC characterization of the vacuum annealed soft ferromagnetic phase

To study the influence of vacuum annealing of the amorphous and soft ferromagnetic phase found at 1.00 sccm O₂, ¹¹¹In atoms were implanted at an energy of 400 keV at the 530 kV IONAS accelerator facility in Göttingen and then carefully analyzed by PAC at 10 and 298 K. After analyzing the as-oxidized sample, it was vacuum annealed ($p_a = 10^{-3}$ Pa) at 973 K for 2 hours. The results of the PAC measurement are shown in Fig. 6.59. The spectra measured at 10 K did not show any changes in comparison to those which were recorded at 298 K. Therefore, only the spectra recorded at

Table 6.21: PAC interaction parameters of the annealed amorphous and soft ferromagnetic phase at 973 K for 2 hours shown in Fig. 6.59 b). Hyperfine parameters: ν_Q is the quadrupole interaction frequency, δ the damping of ν_Q , η the asymmetry parameter, and RA the relative area.

ν_Q [MHz]	δ [MHz]	η	RA [%]
296(13)	4(1)	0.00	6(2)
210(17)	0	0.26(11)	7(6)
177(13)	55(5)	0.56(21)	84(12)

298 K for the as-oxidized and vacuum annealed sample are shown in Fig. 6.59. As the PAC spectra give no indication of a magnetic hyperfine field, they have been fitted assuming an EFG-distribution.

Fig. 6.59 a) shows the typical behavior of amorphous materials, where the PAC probe has no defined position in the matrix due to the absence of crystalline order. As a consequence, the quadrupole interaction frequency ν_Q shows a broad frequency distribution caused by randomly excited EFGs (note: this system consists of five elements and thus, there are 14 combinations of pair interactions). No further information can be taken from them.

In contrast to Fig. 6.59 a), Fig. 6.59 b) shows clearer oscillations in the perturbation function $R(t)$ and thus in its Fourier transform. The values derived from the analysis are given in Table 6.21.

According to the literature [131], these parameters are similar to α -Cr₂O₃. In contrast to the PAC results of the nitrated samples, the damping frequencies are very small, except of that for the 177 MHz frequency, however, the high asymmetry parameter η are typical for amorphous materials or for materials with broad distributions in their EFGs. For a damping of $\delta \approx 20$ %, the asymmetry parameter η should be greater than 0. If δ exceeds 35 %, η can

Figure 6.59: ^{111}In PAC perturbation spectra along with their Fourier transforms for measurements: a) (top) PAC measurement of the as-oxidized sample sputtered at 1.00 sccm O_2 gas flow and b) (bottom) PAC measurement after 2 hours of post vacuum annealing treatment performed at $T_a = 973\text{ K}$. All presented spectra are recorded at 298 K.

reach values greater than 0.5. Thus, the observed η -values are consistent. Summarizing, it is shown that this new phase crystallizes and is sensitive to oxidation during even vacuum-annealing and is in its annealing behavior verisimilar to the quasi-metallic glass phase obtained after nitriding.

6.4.3 Microhardness of oxidized stainless steel films

Nanoindentation was performed by using a Fischerscope HV100 [92] with a Vickers diamond in order to investigate the influence of nitriding on the microhardness and the mechanical properties. The maximum indentation force was set to 2 mN. Four positions were measured for each sample. The mean values are reported in Table 6.22.

Fig. 6.60 shows the hardness as a function of oxy-

Figure 6.60: Dependency between Martens hardness and oxygen content. The Oxygen values are obtained from the RBS analysis.

Table 6.22: Hardness, Young modulus and O-content of oxidized AISI 316 films, where E is the elastic modulus and ν the poisson ratio

O_2 Gas flow	Hardness	Young modulus	O-content
[sccm]	[GPa]	$E/(1-\nu^2)$ [GPa]	[at.%]
0.01	5.8(1)	92(4)	20(2)
0.05	5.7(1)	92(5)	25(2)
0.10	6.0(2)	94(3)	59(2)
0.50	6.8(1)	119(18)	72(2)
0.75	6.5(3)	73(2)	66(2)
1.00	6.9(2)	128(12)	50(2)

gen content. A clear tendency can be seen, where the hardness of the films increase linearly with increasing oxygen content and follows the law:

$$y = 0.02(1)x + 5.42(22)\text{ GPa} \quad (6.3)$$

It seems, that the hardness of the films is only influenced by the incorporation of oxygen independently of the formed phase.

The highest oxygen contents are observed for the samples sputtered at 0.50, 0.7 sccm O_2 gas flow - i.e. samples containing Fe_2O_3 oxides - and the amorphous and soft ferromagnetic phase sputtered

at 1.00 sccm O_2 gas flow. Besides Mössbauer Spectroscopy, this is another hint that the formation of the amorphous and soft ferromagnetic phase is influenced by the formation of oxides.

6.4.4 Discussion on a nucleation model for oxidized stainless steel films

Similar to carburized and nitrided samples, following questions arise: 1) how can the formation of the amorphous and soft ferromagnetic phase be explained and 2): how does the incorporation of oxygen influence the phase formation and what is the ruling phenomenon of oxide formation.

Also here, a combined model which refers to Lu et al. [13] and Lux and Haubner [113], so that the first question can be answered as follows: the present Fe-based alloy is associated with the deep eutectic point of the Fe-O system. It is well known that compositions around the deep eutectic point are ideal for glass formation in many systems. As a result, glass formation is greatly favored thermodynamically. Further, the minor addition of Mo could promote glass formation in the Fe-O system by suppressing the formation of the primary phase (i.e. Fe oxides) and hindering grain growth. Because of their limited solubility in Fe oxides, the molybdenum atoms must redistribute and long-range diffusion is required upon solidification. Thus, the minor addition of Mo could retard the nucleation process. Indeed, all XRD patterns show the behavior of amorphous materials.

The incorporation of oxygen can be explained by

Figure 6.61: Peak width of the amorphous peak and reactive gas flow in dependence of the oxygen content of reactive sputtered stainless steel films.

combining the mentioned model from Lu et al. with that of Lux and Haubner [113]: during the nucleation process oxynaceous species were adsorbed on the surface. Via vapor phase interaction, free O

atoms were formed. Diffusion processes already inserted by Mo atoms solve the O atoms in the metal matrix. This explains the relative low O content in the parameter range up to 0.05 sccm O_2 gas flow, wherein stoichiometric oxides were formed only locally. With increasing growth rate, the oxygen take up is enough to form oxides globally in the films. At 1.00 sccm O_2 gas flow, the growth rate achieves its maximum (and a similar value as for samples sputtered at low O_2 gas flow), the parameter for the amorphous and soft ferromagnetic phase.

For small and for high O_2 gas flows, the samples appear amorphous (which can be seen for the developing FWHM in Fig. 6.61), whereas samples sputtered in the range of 0.1-0.75 sccm O_2 gas flow begin to crystallize. If the O_2 gas flow and the FWHM is arranged according to ascending oxygen content, Fig. 6.61 can be understood as a Gibbs plot of a multi-phase system, in which the transition from the amorphous state (domain I) to the crystalline phases (domain II - the formation of FeO, Fe_2O_3 oxides) is depicted. Therefore, the growth rate in Fig. 6.52 is confirming this hypothesis, in which the growth rate of crystalline and amorphous samples are verisimilar. The minima of the systems are the quasi metallic glass and the FeO/ Fe_2O_3 phase.

Due to the similarity of the amorphous states, carburized and nitrided samples were described by a core-shell model, describing the nanoparticles as consisting of a ferromagnetically Ni_3C core and a disordered surface shell. By contrast, Mössbauer Spectroscopy and RBS indicate the participation of Fe-oxides. As a consequence, the model for the amorphous state for carburized and nitrided samples can not be applied in the same form for oxidized samples.

According to He et al. [118] and Kodama et al. [135], the previous model is also applicable to different ferromagnetically cores, e.g. also for $NiFe_2O_4$. Since Ni is a crucial for phase formation in stainless steels [7,91,129], it is reasonable to assume that the amorphous state observed for the sample sputtered at 1.00 sccm O_2 gas flow can be described by a multi-shell model consisting of a ferromagnetically $NiFe_2O_4$ core surrounded by a spin-glassy surface layer. This would be in good agreement to RBS and especially Mössbauer, where the isomer shift $\delta \approx 0.3$ mm/s indicate a Fe-oxide participation in phase formation.

Finally, EXAFS investigations on oxidized samples are required to resolve the microstructure of oxidized Magnetron-sputtered samples.

6.4.5 Summary of the amorphization process and nucleation model of Magnetron-sputtered stainless steel films

Various aspects of the carbide, nitride and oxides formation and their stability in reactive magnetron-sputtered austenitic stainless-steel films were studied.

Intrigued by the predictions of Lee et al. [9], inert sputtering from a pre-combined $\text{Fe}_{50}\text{C}_{50}$ was used to synthesize the stoichiometric NaCl-type FeC phase. Unfortunately, geometric effects of the target configuration, hysteresis effects and re-sputtering constitute severe problems to the deposition process. As a consequence of this, the Magnetron sputtering technique seems not to be suitable to synthesize the stoichiometric FeC phase, but the films exhibit carbon contents, which exceed the maximum solubility limits in known carbides. As a result, reactive sputtering of stainless steel - by using methane, nitrogen and oxygen as reactive gas - was performed to synthesize amorphous films or quasi metallic glasses based on conventional steels.

All carburized stainless steel films revealed amorphous character and the magnetic properties investigated by means of Mössbauer Spectroscopy and MOKE showed the formation of various phases and carbides at a sputtering temperature of 298 K. In addition, a new amorphous soft ferromagnetic phase was observed. Vacuum annealing of this phase showed the carbide reaction $\text{M}_7\text{C}_3 \rightarrow \text{M}_{23}\text{C}_6 \rightarrow \text{M}_6\text{C}$ and confirmed the existence of a stable Fe-graphite and the metastable Fe-cementite system [136–138].

By using low gas fluxes, nitrided samples also showed the formation of films with typical amorphous behaviors and also the new amorphous soft ferromagnetic phase was observed. For this samples, RNRA showed extremely differing N-depth profiles. In contrast, high fluxes revealed the formation of a cubic ZnS-type γ'' -(Fe,Cr,Ni)N phase and their depth profiles were, as expected, constant. Noticeable is that the investigated Fe/stainless steel-N system behaves like a perfect Gibbs-system with the Fe_3N phase as minimum.

Oxidized samples showed amorphous character over the whole range of the processing parameters, also including the new amorphous soft ferromagnetic phase, but showed appendages of crystallization as indicated by Mössbauer and XRD. These crystallites could be identified as Fe_2O_3 oxides. A PAC study, which was also performed on nitrided samples, revealed, that this new phase crystallizes and is even sensitive to oxidation during vacuum-annealing. Noticeable is that the Fe/stainless steel-

O system can be understood as a Gibbs multi-phase system, in which the transition from the amorphous state to the crystalline phases can be observed.

Fig. 6.62 shows the dependence of the normalized gas flow, which is needed to form the new amorphous soft ferromagnetic phase, as a function of the radius of the reactive gas atoms. A clear tendency can be seen, where the normalized flow decreases exponentially with increasing reactive gas radius.

The most important parameters to obtain this new

Figure 6.62: Normalized gas flow in dependence of the radius of the reactive gas atoms. The parameters for the exponential decay fitting routine are given in the graph.

amorphous and soft ferromagnetic phase are given in Table 6.23.

To characterize the microstructure of the new amorphous and soft ferromagnetic phase, DSC, FIM, TEM and EXAFS experiments were carried out for carburized samples.

DSC, FIM and TEM showed the quasi metallic glass behavior of these phase, but the microstructure could only be explained by the EXAFS analysis, which revealed a disordered Ni_3C phase. The magnetism of this phase could be predicted by a LMTO model [119], the order of magnetism could be explained by a core-shell model, describing the nano-particles as consisting of a ferromagnetically core and a disordered surface shell [121, 122].

These experiments confirmed a pre-suggested model, which is based on thermodynamical and kinetic remarks of Lu et al. [13] and of Lux and Haubner [113]: the present Fe-based alloy is associated with the deep eutectic point of the Fe-X system. It is well known that compositions around the deep eutectic point are ideal for glass formation in many systems. As a result, glass formation is greatly favored thermodynamically. Further, the minor addition of Mo could promote glass formation in the Fe-X system by suppressing the formation of the primary phase and hindering grain growth. Be-

Table 6.23: Summary of the synthesization parameters of the new amorphous and soft ferromagnetic phase: R is the theoretical calculated radius, R_I the ionic or van-der-Waals radius, R_C the covalent radius, $\sigma_{50:50}$ the structure of stoichiometric FeX phase (where X represent the reactive gas atom), $T_{\sigma_{50:50}}$ the temperature at which the stoichiometric phase can be formed and Λ the amorphization parameter.

cause of their limited solubility in iron bases anions, the molybdenum atoms must redistribute and long-range diffusion is required upon solidification. The introduction of a reactive sputtering gas additionally disturbs the nucleation process by establishing higher probabilities of coordination. This leads to simultaneous rearrangement of different species of atoms, which suppresses the formation of competing ordered phases. As a consequence, phases outside the equilibrium can be formed like the disordered trigonal Ni₃C phase.

The incorporation of the reactive sputter gas atoms can be described as follows: during the nucleation process the dissociated reactive sputter gas molecules were adsorbed on the surface. Via vapor phase interaction, free atoms were formed. Diffusion processes already inserted by Mo atoms solve the sputter atoms in the metal matrix depending on the processing parameters.

Due to the presence of isomorphic phases in nitrated samples and the fact, that the new phase almost has the same hyperfine parameters, it is assumed that the origin of magnetism in this phase succumbs the same phenomenon - a disordered Ni₃C phase surrounded by a spin-glassy surface shell.

In contrast to the carburized and nitrated quasi metallic phase, Mössbauer Spectroscopy and RBS of the oxidized phase indicated the participation of Fe-oxides. As a consequence, the model for the amorphous state for carburized and nitrated samples can not be applied in the same form for oxidized samples.

According to He et al. [118] and Kodama et al. [135], NiFe₂O₄ cores surrounded by spin-glassy surface shells satisfy the observed results. In contrast to the nitrated quasi metallic phase, for the oxidized phase a more exact investigation (e.g. EXAFS) is required to resolve the microstructure.

Magnetron sputtering is suitable to form amorphous and quasi metallic glasses, but the stoichiometric FeC phase was not obtained. As a consequence, iron/carbon and for comparison stainless steel/carbon films were deposited by PLD. The re-

sults were presented in the next sections.

Chapter 7

Results for pulsed laser deposited films

Results using the Siemens XP2020 excimer laser

7.1 Results for FeC films prepared by STPLD

Figure 7.1: Different stainless steel STPLD targets in comparison to a conventional stainless steel PLD target (right). The red lines indicate the laser scan area. As indicated in SS/BN 50:50 STPLD target, for ultra-thin films a scan area of 4 mm (4 mm stainless steel/4 mm C) and 8 mm (8 mm stainless steel/8 mm C) for thin-films were used.

Ultra-thin high-carbon iron films (ARMCO, 99.96 %; maximal thickness 20 nm) were deposited by Sequential Target Pulsed Laser Deposition (STPLD) with a commercial Siemens XP2020 excimer laser ($\lambda = 308$ nm, pulse duration 55 ns, repetition rate 8 Hz) on TEM grids in order to directly examine the structure of the STPLD films. The STPLD process relies on the pre-combination of the target to a desired stoichiometry (assuming the same ablation rate for all elements) as shown

in Fig. 7.1 and is determined by the inlay thickness and the laser scan area.

For comparison films with higher thicknesses were deposited onto amorphous SiO_2 substrates (oxidized Si(100) wafer of 0.5 mm thickness, pre-cleaned with acetone and oxidized in air, no further treatment) and the influence of substrate temperature was investigated. The deposition parameters and the resulting thicknesses and growth rates are summarized in Table 7.1.

Table 7.1: Deposition temperature T_{dep} , laser energy, number of pulses $\#$, real film thickness d (as measured by Rutherford Backscattering Spectrometry (RBS) after deposition) and derived growth rate $g = \frac{d}{t}$ for the deposited STPLD films.

sample	T_{dep} [K]	energy [mJ/cm ²]	$\#$	d [nm]	g [nm/min]
FeC4mm	298	1.30	933	20(5) ¹	10.26(87)
FeC8mm	298	0.96	36000	77(10)	1.03(9)
FeC8mm	823	1.00	43000	258(10)	2.88(30)

¹ this thickness was derived from a quartz microbalance during deposition

Synthesis of NaCl-type FeC The directly TEM-prepared STPLD showed different phases, inter alia many face-centered cubic structures as seen in Fig 7.2.

By taking the diffraction pattern of one of the grains, it could be identified as γ -Fe.

One characteristic was found in all the samples: all the grains were embedded in an amorphous Fe matrix. Another astonishing feature can be seen in Fig. 7.3. Some grains were surrounded by Fe and C multilayers with a thickness of 0.238(4) nm which merge fluently into the grains. This could be a hint that stress is a crucial factor for phase formation in these thin films. On the right corner of Fig. 7.3, the FFT can be seen. It shows the appearance of a metallic glass which indicates a high-carbon concentration.

This grain has a diameter of about 10 nm. All

Figure 7.4: TEM pattern of the NaCl-type FeC grain and its FFT on the right hand.

Figure 7.2: (top) HR-TEM pattern of a grain. (bottom) diffraction pattern of this grain. The orientation of the reflexes are given in the graph.

attempts to obtain an SAD pattern from these grains were futile, because the grains disappeared after focussing the electron beam. These grains seem to be thermally unstable. In order to get information on the structure a FFT was taken, which is depicted on the right side of Fig. 7.4. Fig. 7.4 shows one of the various nano-scale grains

Figure 7.3: Fine Fe and C multilayer system surrounding a metallic glassy grain observed by TEM and its FFT of that area (right).

which could be observed over the whole film. Lee et al. [9] predicted in the NaCl-type FeC phase a bond length of 0.236 nm, the value obtained here is 0.229(3) nm. As a consequence, the obtained lattice constant $a_0 = 0.458(6)$ nm is verisimilar to the predicted NaCl-type lattice constant $a_0 = 0.473$ nm. EDX does not show any hints of other element impurities, only Fe and C are observed. As known from the Fe-C system so far, no simple cubic structure Fe-C exists, but the observed structure seems to prove the predicted NaCl-type Fe-C.

As next step, films with higher thicknesses were deposit to investigate the macroscopical properties of this phase.

Fig. 7.5 shows the XRD pattern of the STPLD sample sputtered at 298 and 823 K.

Figure 7.5: GIXRD (2°) spectra of the STPLD films deposited at 298 (top) and 823 K (bottom). The temperatures and reflexes are given in the graph.

Deposition of NaCl-type FeC films The spectrum for the STPLD films sputtered at 298 K show the typical broad XRD appearance of amorphous materials. A mean grain size of 3(2) nm can be calculated with the Scherrer formula [139]:

$$\Delta\beta = \frac{0.89\lambda}{d \cdot \cos\theta} \quad (7.1)$$

In contrast, the STPLD film deposited at 823 K exhibit clear reflexes, which can be attributed to the Fe_7C_3 -phase [130]. It is well crystallized and a mean grain size of 50(5) nm is derived by eq. 7.1 [139].

Fig. 7.6 summarizes the CEMS measurements of the samples deposited at 298 K and 823 K. For these spectra, hyperfine field and quadrupole splitting distributions were assumed, respectively. The quadrupole splitting distributions are broad and close to the values of $\text{Fe}_3\text{C}/\text{Fe}_7\text{C}_3$ carbides (which is confirmed by a Lorentzian single line analysis). This is in good agreement with the XRD pattern for the STPLD sample deposited at 823 K, which clearly exhibit the Fe_7C_3 -phase. The distribution for the sample deposited at 298 K is broader than that deposited at 823 K. Taking the XRD pattern into account, the CEM spectrum could be attributed to an amorphous FeC alloy. Both samples show magnetic split sextets, however, the hyperfine fields of both films are diminished. This can be attributed to carbon which should be in the next-nearest neighborhood. By using the

Table 7.3: Hyperfine interaction parameters of the single line analysis of the STPLD FeC film deposited at 823 K. Hyperfine parameters: δ is the isomer shift, QS the quadrupole splitting, Γ the line width (HWHM), and RA the relative area.

δ	QS	Γ	RA
[mm/s]	[mm/s]	[mm/s]	[%]
0.15(7)	0.49(22)	0.25	47.9(30)
0.17(11)	0.71(37)	0.25	52.1(21)

dependency between median hyperfine field and carbon content for carburized stainless steel films as found in 6.2.7 and by inserting the hyperfine field of ARMCO-iron, a linear correlation between hyperfine field and carbon content is found (Fig. 7.7):

$$y = -0.38(3)x + 30.32(164) \text{ T} \quad (7.2)$$

Note: due to the fact, that Ni and Cr have a crucial

Figure 7.7: Median hyperfine field B_{hf} in dependence of the carbon content.

influence on the hyperfine field, the slope for FeC films should be smaller; thus the carbon content in FeC films should be greater than predicted by this correlation.

Consequently, a carbon content of about 9.0(12) % and 36.8(22) % is predicted for the samples deposited at 298 K and 823 K, respectively.

The fitted hyperfine parameters are presented in Table 7.2, the results of the single line analysis in Table 7.3.

While Mössbauer Spectroscopy revealed hyperfine fields, MOKE did not exhibit any signal, which can be attributed to the different information depths of both methods (MOKE is surface sensitive).

To investigate the carbon content in the films, RBS measurements were carried out, which can be seen in Fig. 7.8.

The results of the RBS analysis are summarized in Table 7.4.

Figure 7.6: Mössbauer spectra of the STPLD deposited FeC films at 298 K (top) and 823 K (bottom).

sample	Fe at. %	C at. %	O at. %
298 K	80(5)	10(5)	10(5)
823 K	10(5)	40(5)	50(5)

and Magnetron-sputtered FeC films have the additional oxygen content in common. According to Huczowski [140], the small addition of Si in Fe-based alloys enhances the oxide formation. Thus, the inter-diffusion between Fe and the substrate SiO_2 (as obtained by the RBS depth-profile) favours the formation of oxides in the film. Conspicuous is, that neither Mössbauer Spectroscopy nor XRD show any hints of oxide formation. This yields a conclusion that only parts of the oxygen content participate on oxide formation. The remaining part is arranging at the grain boundaries.

Comparing the properties of high-carbon films,

which were directly deposited on TEM grids, with thicker ones deposited on SiO_2 substrates, the assumption arises that the observed γ - and NaCl-type structure could be due to a thickness effect.

Indeed, thickness effects are observed in thin Fe and stainless steel films, wherein the formation of thin γ -layers (5-10 nm) are thermodynamically favored [141].

Summarizing, the synthetization of NaCl-type FeC succeeded in ultra-thin films (~ 20 nm). More investigations have to be done to synthesize thin NaCl-type FeC films (e.g. choose different substrates, applying biases at the substrates etc.).

As well as for Magnetron-sputtered FeC films, the STPLD film deposit at 298 K exhibit an amorphous signature. Therefore, stainless steel films prepared by Reactive Pulsed Laser Deposition (RPLD) were deposited to compare those with Magnetron sputtered films and to possible obtain the new amorphous and soft ferromagnetic disordered Ni_3C phase.

7.2 Results for carburized stainless steel films prepared by RPLD

The film was reactive sputter-deposited by pulsed laser deposition (RPLD) with a Siemens XP2020 excimer laser ($\lambda = 308$ nm, pulse duration 55 ns, repetition rate 8 Hz) onto amorphous SiO_2 substrates (oxidized Si(100) wafer of 0.5 mm thickness, pre-cleaned with acetone and oxidized in air, no further treatment) utilizing a commercial AISI 316 (X5CrNiMo17-12-2, 1.4401) target. Before deposition, the PLD-chamber was evacuated to a base pressure of 10^{-6} Pa to prevent hysteresis effects. The laser energy was set to 2 mJ/cm^2 . The CH_4 gas was tuned by the vacuum penning and set to a total chamber pressure of 10^{-5} Pa. The growth rate $g = \frac{d}{t}$ was derived to $0.96(4) \text{ nm/min}$ by using the thickness $d = 80$ nm as measured by RBS after deposition.

7.2.1 Deposition at room temperature and influence of the methane gas flow

In contrast to the original AISI 316 target as illustrated in Fig. 5.1), which shows the typical γ -structure ($a = 0.3592(1) \text{ nm}$), the RPLD sample (illustrated in Fig. 7.9) shows both γ -(Fe,Cr,Ni) and α -(Fe,Cr,Ni) structures, but a small broad signature is observed as well indicating an amorphous phase.

Figure 7.9: GIXRD (2°) spectra of the RPLD film. The reflexes are given in the graph.

The lattice constant were derived to.

In contrast to the XRD pattern, the CEM spectrum is depicted in Fig. 7.10.

It reveals the typical Mössbauer spectrum of an amorphous material and is magnetically split. The results of the fitting procedure are presented in Table 7.5.

As well as carburized stainless steel films prepared Magnetron sputtering, the Mössbauer spectra were fitted by hyperfine field distributions, and with quadrupole splitting distributions in the paramagnetic state, respectively. The distributions are attributed to an amorphous stainless steel carbon-alloy, possibly rich in carbon. In contrast to carburized stainless steel films, the ratio between high-field and low-field amorphous state are different. Here, the high field distribution dominates. From the fitting, a hyperfine field of $B = 15.6 \text{ T}$ with a width of $\sigma = 8.5 \text{ T}$ is obtained from the $p(B)$ distribution. The high σ is indicating a participation of other hyperfine fields, which could possibly correspond to an α -phase, but there is no clear indicator for this (in contrast to the XRD pattern). Now following question arise: where does the CEM spectrum differ from the XRD pattern?

The answer can be seen in Fig. 6.33: the dark field image (TEM) of the disordered Ni_3C phase shows many crystallites at the interface between film and SiO_2 substrate (the first 50 nm) embedded in an amorphous matrix. Since the overall thickness of the layer is derived to 80 nm as measured by RBS, the differing observations from Mössbauer and XRD can be explained by the differing information depth of both methods.

CEMS is sensitive to the first 150 nm, whereas the GIXRD with $\omega = 2^\circ$ corresponds to an information depth of 350 nm. Additionally, only the reflexes are shown in GIXRD, which have the correct orientation. As a consequence, the fraction of the

Figure 7.10: CEM spectrum of the RPLD sample. The CH_4 /chamber pressure is given in the graph.

Table 7.5: Mössbauer fitting results of the RPLD film, deposited at room temperature: (f - area fraction (error), mean values of $\langle\delta\rangle$ - isomer shift, $\langle\Delta\rangle$ - the quadrupole splitting for the paramagnetic subspectra, $\langle\epsilon\rangle$ the quadrupole splitting for the magnetic subspectra, B - hyperfine field).

CH ₄ pressure [Pa]	part	f [%]	$\langle\delta\rangle$ [mm/s]	$\langle\Delta\rangle, \langle\epsilon\rangle$ [mm/s]	σ_Δ [mm/s]	$\langle B\rangle$ [T]	σ_B [T]
10^{-6}	ferro-l	4.1(58)	-0.04	0.02		5.0(12)	0.3(12)
	ferro-h	93.4(74)	-0.04	0.02		15.6(12)	8.5(15)
	para	2.5(45)	-0.10	0.10	0.05		

amorphous phase could be very small in comparison to the crystallites. In contrast, CEMS is sensitive to the whole film and thus the volume fraction of amorphous phase and crystallites are different as observed in GIXRD. As a consequence, the CEM spectrum is dominated by the spectrum of the amorphous phase.

Carbon content was derived by RBS measure-

Figure 7.11: RBS spectra of the RPLD films. The CH_4 /chamber pressure is given in the graph.

ments, which are depicted in Fig. 7.11.

A carbon content of 14(2) % is found, which is about 45 % less than in carburized stainless steel films prepared by Magnetron-sputtering [7,91]. Another fea-

ture is the decrease of the Mo content (under 1 %), whereas the Ni content is simultaneously increasing.

7.2.2 Modification of the nucleation model

This could be another confirmation of the nucleation model presented in 6.2.6: as mentioned above, this sample shows the beginning of the formation of the disordered Ni_3C phase. During deposition the Mo atoms insert long range diffusion and are hindering phase, but not completely. Inhomogeneities in the inserted long range diffusion allow the formation of nano-crystallites, while the carbon is solving into the matrix. In this stage of nucleation, the Mo atoms were re-sputtered, which leads to a diminution of Mo in the film of under 1 % and Ni content increases.

At a critical carbon content of 10-15 %, the metastable - but disordered - Ni_3C phase is formed and the carbon diffusion is fully established (inserted by the Mo atoms at the beginning of the deposition process and which are additionally hindering the nucleation process by establishing higher atomic mismatches through higher probabilities of coordination). As a consequence, the Mo content rises again to the target stoichiometry. For films with thicknesses above 250 nm (like those deposited in 6.2), the Mo decrease in the first 30-50 nm is not

commensurable by EDX.

In the course of deposition, more and more carbon is adsorbed, which leads to the formation of graphite and spin-glassy phases. Thus, for films with higher thicknesses excessive C contents are observed, but the critical carbon content seems to be between 10 and 15 %, which is also seen for nitrated samples (see 6.3 and [134]).

Excessive carbon content can be prevented by higher laser densities. As a consequence, a Quantel Brilliant Nd:YAG laser is used for further experiments (its laser density is 4 times higher than that of the used excimer laser). The results are shown in the following sections.

Results using the Quantel Brilliant Nd:YAG laser

7.3 Results for carburized stainless steel films prepared by RPLD

The films were reactive sputter-deposited by pulsed laser deposition (RPLD) with a Brilliant Nd:YAG laser ($\lambda = 1064$ nm, pulse duration 5–6 ns, repetition rate 20 Hz) onto amorphous SiO₂ substrates (oxidized Si(100) wafer of 0.5 mm thickness, pre-cleaned with acetone and oxidized in air, no further treatment) utilizing a commercial AISI 316 (X5CrNiMo17-12-2, 1.4401) target. Before deposition, the PLD-chamber was evacuated to a base pressure of 10^{-6} Pa to prevent hysteresis effects. The laser energy was set to 5 mJ/cm². The CH₄ gas was tuned by the vacuum penning. Thus, total chamber pressures of $5 \cdot 10^{-5} - 1 \cdot 10^{-1}$ Pa were generated. The thickness of the deposited films was controlled by a quartz microbalance (with a film density set to 7.89 kg/m³, which is the density of AISI 316). The deposition parameters and the resulting thicknesses and growth rates are summarized in Table 7.6.

From these data it is derived that the growth rate has a parabolic form with increasing CH₄/chamber pressure, which is visualized in Fig. 7.12.

As demonstrated by Mössbauer Spectroscopy, the maximum of this curve indicates the transition to the amorphous and soft ferromagnetic disordered Ni₃C phase.

Table 7.6: Total chamber pressure j , deposition time t , real film thickness d (as measured by RBS after deposition) and derived growth rate $g = \frac{d}{t}$ for the carburized RPLD films. All samples were deposited at 298 K with a laser energy of 5 mJ/cm² and a target-substrate distance of 7.5 cm.

Figure 7.12: Growth rate g as a function of the CH₄/chamber pressure for the room temperature deposition.

7.3.1 Deposition at room temperature and influence of the methane gas flow

The methane/chamber pressure was systematically increased from $5 \cdot 10^{-5} - 1 \cdot 10^{-1}$ Pa. For all these deposited films, the reactive pulsed laser deposited samples show the typical broad XRD appearance of amorphous materials; additionally Fig. 7.13 c), e) and f) show appendages of crystallization. The GIXRD patterns are shown in Fig. 7.13.

Fig. 7.14 shows the position and the width of the first broad peak for the spectra shown in Fig. 7.13. There is a clear tendency for peak position and peak width, where the peak position is decreasing with increasing CH₄/chamber pressure, except the RPLD sample deposited at 10^{-3} Pa.

Fig. 6.19 summarizes the CEMS measurements of the samples with CH₄/chamber pressure.

They show the typical Mössbauer spectra of amorphous materials. All spectra are magnetically split, even if the hyperfine field in spectrum b) is small. It seems, that the disordered phase is also here formed,

Figure 7.15: Mössbauer spectra of the reactive sputtered AISI 316 films. The numbers in the graphs represent the methane gas flow.

but the screw thread of the gas inlet was not fine enough to observe the full transition. The results of the fitting procedures are presented in Table 7.7. The Mössbauer results were confirmed by MOKE measurements. They show the same behavior as for the spectra presented in 6.2.1.

The EDX analyses of the deposited films revealed the original composition of the sputtering targets

within the experimental limits. Unfortunately, the EDX did not allow to accurately determine elements lighter than oxygen. Therefore, in order to evaluate the amount of incorporated carbon, RBS measurements were carried out, whose results are shown in Fig. 7.16.

The thickness of the films as obtained from the

Figure 7.16: RBS spectra of the RPLD films. The CH₄/chamber pressure is given in the graph.

RBS analysis was already given in Table 7.6. The carbon concentration of the films as obtained from the RBS analysis is given in Fig. 7.17.

A clear tendency can be seen, where the C content increases with e^{x^2} with increasing CH₄/chamber pressure. Furthermore, all samples show moderate carbon contents and the incipient disordered Ni₃C phase has a C content of 20(5) %. This is in good agreement with the previous mentioned results (RPLD film prepared by excimer laser, nitrated samples prepared by Magnetron sputtering) and confirms the modified model.

Figure 7.17: Carbon content in the RPLD films (as derived from the RBS analysis) versus the CH₄/chamber pressure.

7.3.2 Microhardness of the RPLD films

Nanoindentation was performed by using a Fischerscope HV100 [92] with a Vickers diamond in order to investigate the influence of nitriding on the microhardness and the mechanical properties. The maximum indentation force was set to 2 mN. Four positions were measured for each sample. The mean values are reported in Table 7.8.

Fig. 7.18 shows the hardness as a function of carbon content. A clear tendency can be seen, where the hardness of the RPLD films increase logarithmical with increasing carbon content and follows the law:

$$y = 2.58(19) \text{ GPa} + 0.58(9) \cdot \ln(x) \quad (7.3)$$

This function approaches asymptotically to the (Fe,Cr,Ni)₃C phase.

All experiments of this section confirm the modified nucleation model and indicate that the properties of carburized RPLD films strongly depend on

Table 7.8: Hardness, Young modulus and C-content of RPLD AISI 316 films, where j is the CH_4 /chamber pressure, E the elastic modulus and ν the poisson ratio.

the laser density and on the resulting crystallinity of the films.

In the next section, the STPLD technique will be applied on the formation of amorphous stainless steel films.

7.4 Self-organized structures in carbon-stainless steel multilayer films

The films were deposited by Sequential Target Pulsed Laser Deposition (STPLD) with a Brilliant Nd:YAG laser ($\lambda = 1064$ nm, pulse duration 5–6 ns, repetition rate 20 Hz) onto amorphous SiO_2 substrates (oxidized Si(100) wafer of 0.5 mm thickness, pre-cleaned with acetone and oxidized in air, no further treatment) utilizing a commercial AISI 316 (X5CrNiMo17-12-2, 1.4401) target. Before deposition, the PLD-chamber was evacuated to a base pressure of 10^{-6} Pa. The laser energy was set to 5 mJ/cm^2 . The targets were pre-combined in that way, that area ratios (of stainless steel to carbon) of

90:10, 80:20, 60:40 and 50:50 were obtained (laser scan area 20×2 mm on a 25×25 mm STPLD target - except the 80:20 sample: here the 90:10 STPLD target was used, the desired area ratio was obtained by reducing the laser scan area to 10×2 mm). The thickness of the deposited films was controlled by a quartz microbalance (with a film density set to 7.89 kg/m^3 , which is the density of AISI 316). The deposition parameters and the resulting thicknesses and growth rates are summarized in Table 7.9.

From these data it is derived that the growth rate

Table 7.9: Deposition time t , real film thickness d (as measured by TEM after deposition) and derived growth rate $g = \frac{d}{t}$ for the STPLD films. All samples were deposited at 298 K with a laser energy of 5 mJ/cm^2 and a target-substrate distance of 7.5 cm.

sample	t	d	g

has a Gaussian form with increasing carbon area fraction, which is visualized in Fig. 7.19.

Figure 7.19: Growth rate g as a function of the carbon area fraction for the room temperature STPLD deposition.

7.4.1 Deposition at room temperature and influence of the carbon area fraction

The inlay area, and thus the carbon concentration, was systematically increased from 10 to 50 %. For all these deposited films, the STPLD samples show

Figure 7.22: Mössbauer spectra of the STPLD stainless steel films. The numbers in the graphs represent the stainless steel/carbon area fraction of the STPLD targets.

the typical broad XRD appearance of amorphous materials, as seen in Fig. 7.20. These diffractograms show a clear amorphous signature.

Fig. 7.21 shows the position and the width of the first broad peak for the spectra shown in Fig. 7.20. There is a clear tendency for peak position and peak width, where the peak position is decreasing (until to SS/C 60:40) and is then increasing rapidly. In contrast, the peak width increases exponentially.

Fig. 7.22 summarizes the CEMS measurements of the samples with increasing gas flow. They show the typical Mössbauer spectra of amorphous materials.

All spectra are - except the 80:20 STPLD sample - magnetically split and are consistent with

the XRD results in Fig. 7.20. The results of the single line fitting procedures are presented in Table 7.10. The spectra were fitted by hyperfine field distributions, and with quadrupole splitting distributions in the paramagnetic state, respectively. These distributions are attributed to an amorphous stainless steel carbon-alloy, possibly rich in carbon. The quadrupole splittings are broad and close to the values of the usual carbides and austenite. Not much information can therefore be taken from them. Summarizing, predominantly all samples appear as an amorphous material and show magnetic behavior.

The paramagnetic behavior of the 80:20 STPLD sample is assumed to be originated in the reduced

Table 7.10: Mössbauer fitting results of the STPLD stainless steel samples, deposited at room temperature with a laser energy of 5 J/cm^2 (f - area fraction (error), mean values of $\langle\delta\rangle$ - isomer shift, $\langle\Delta\rangle, \langle\epsilon\rangle$ - the quadrupole splitting for the paramagnetic subspectra, $\langle\epsilon\rangle$ the quadrupole splitting for the magnetic subspectra, B - hyperfine field).

Figure 7.23: Polar diagrams of the coercive field H_C and the relative remanence M_R/M_S for the STPLD 90:10 (left), the 60:40 (middle) and the 50:50 sample (right).

scan area and, thus, an increase of laser scan speed, which could be an important parameter (this will be investigated in the next section).

Mössbauer results were confirmed by MOKE results, which are presented in Fig. 7.23.

While the samples with 90:10, 60:40 and 50:50 exhibit a MOKE signal, the sample 80:20 does not appear magnetic in MOKE. The 90:10 sample exhibits a uniaxial anisotropy at 20° and additionally a six-fold anisotropy. According to Ref. [88, 89], this can be attributed to epitaxial growth. In contrast to the 90:10 sample, the 60:40 and 50:50 specimens exhibit fourfold anisotropy. The coercive fields (H_C) differ: the specimen 90:10 and 50:50 show soft ferromagnetic behaviour ($H_C \approx 10 \text{ Oe}$), in contrast to the 60:40 specimen, which show harder ferromagnetism ($H_C \approx 35 \text{ Oe}$). These observations have now to be correlated to the carbon content of the film.

The EDX analyses of the deposited films revealed the original composition of the sputtering targets

within the experimental limits. Unfortunately, the EDX did not allow to accurately determine elements lighter than oxygen. Therefore, in order to evaluate the amount of incorporated carbon, RBS measurements were carried out, whose results are shown in Fig. 7.24.

The thickness of the films as obtained from the RBS analysis are in good agreement of those derived by TEM, which were given in Table 7.9. However, the RBS spectra show an exceptionally oscillating behavior.

The oscillating characteristics in the spectra indicate that the films consist of a multilayer system. A first RBS fitting tool developed for high-resolution RBS spectra was used to get a concentration depth profile [142]. As an example, the fitting result for the 90:10 specimen is illustrated in Fig.7.25.

A periodic sequence of alternating stainless-steel and C layers can be observed. The thickness of the steel layer is about 25 nm and that of the carbon

Figure 7.26: TEM pattern of the STPLD 9010 sample. Left: overview of the sample; middle: HR-TEM image of film/interface region; right: HR-TEM image of the surface region.

Figure 7.20: GIXRD (2°) spectra of the STPLD films. The stainless steel/carbon area fractions are given in the graph.

layer 15 nm. It can be also seen that the layer thickness of the 80:20 sample is smaller than in the other samples and that the laser scanning frequency could be a crucial factor for the multilayer formation, as already mentioned by Mössbauer Spectroscopy. Thus, a dependency between film properties such as magnetism/microstructure and layer growth is assumed. Another problem is presented by the number of multilayer: by knowing the complete deposition time and the time for one laser scan cycle, the number of the multilayer can be estimated. In all samples this number does not correspond to the observed numbers of multilayer. This phenomenon will be discussed later, wherein an induced self-organizing effect will be revealed.

Figure 7.21: Peak position and peak width of the first broad peak in the XRD spectra of the STPLD stainless steel films.

Figure 7.24: RBS spectra of the STPLD films. The stainless steel/carbon area ratios are given in the graph.

To achieve a higher resolution, high-resolution Rutherford backscattering spectrometry (HR-RBS)

Figure 7.25: RBS depth profile of the STPLD 90:10 sample.

measurements were carried out, but no difference between conventional RBS and HR-RBS was found. Thus, TEM patterns were taken, which are depicted in Fig. 7.26.

The TEM patterns of all STPLD samples confirm the RBS results, but one characteristic can be taken from them: all samples show a gradually decrease of the multilayer thickness during deposition and it seems to be a constant decreasing factor of about $1/3$. Also, the quality of the multilayer near the surface is decreasing. The observed characteristics are originated in the cavation of the target by the laser beam, which induces a shift of the laser plasma plume. For this, experiments using a target-wobbler system were performed, but as next step a dependency between scan frequency and multilayer thickness is investigated.

7.4.2 Influence of the scan frequency on the multilayer thickness

To investigate the dependency between scan frequency and multilayer thickness of high-carbon stainless steel films, STPLD 60:40 and 50:50 targets were combined in the way as displayed in Fig. 7.1 and labeled as 60:40mod and 50:50mod, respectively.

Drastic changes can be seen in the CEM spectra: whereas the 60:40 spectrum show both - magnetic and paramagnetic - sites, the 60:40mod spectrum exhibit only a broad paramagnetic site indicating a high carbon concentration. The quadrupole splittings are very close to the values of the usual carbides, but no further information can therefore be taken from them. The absence of magnetism is also observed in MOKE measurements which exhibit no MOKE signal. The results of the fitting procedures are presented in Table 7.11.

Also the TEM patterns show significant changes in the multilayer structure: whereas the 60:40 STPLD sample show 50 nm thick stainless steel layers and 30 nm C layers, the 60:40mod STPLD sample consists of very thin layers ($\sim 4-8$ nm), which form a superstructure of about 25 nm. The TEM pattern for the 60:40mod STPLD sample exhibit a high amount of diffusion. As a consequence, no clear and well defined multilayer structure can be seen. Furthermore, no crystallites were seen in the 60:40mod STPLD sample as seen in TEM patterns of the 60:40 STPLD sample.

TEM results were partially confirmed by RBS. Only the superstructure can be observed, which has a layer thickness of about 25 nm. Noticeable is the carbon content of 60:40mod STPLD sample, which was derived by an advanced and enhanced fitting tool [143]: about 50 % carbon content are observed - 10 % more than in conventional 60:40 STPLD films. Also here the number of multilayers do not correspond to scan process of the laser beam, but the discrepancy is not as high as observed in the 90:10 STPLD sample.

As a first conclusion it can be stressed out, that the modification of STPLD targets lead to the formation of nano-scaled multilayers.

Fig. 7.28 shows a comparison between the results of conventional and modified 50:50 STPLD films, which exhibit similar properties. The CEM spectrum of the modified 50:50 STPLD film do not reveal magnetic properties (as also observed for the 60:40mod STPLD film). The paramagnetic site is broad; even broader than the site in the 60:40mod STPLD film and also indicating a higher carbon content. The CEMS results were confirmed by MOKE, which exhibit no MOKE signal. The results of the fitting procedures are presented in Table 7.11.

As seen in the TEM patterns of the 60:40mod STPLD film, the 50:50mod STPLD film exhibit a similar multilayer structure, whereas the 50:50 STPLD sample show an alternating multilayer system consisting of 30-50 nm stainless steel and 20-30 nm carbon layers. The layers in the 50:50mod sample can be better distinguished than the 60:40mod STPLD film, but carbon diffusion can also be observed. The thin layer thickness can be derived to $\sim 3-6$ nm.

RBS results for the 50:50 and 50:50mod STPLS films are depicted in the bottom of Fig. 7.28 and exhibit the same superstructure as seen for the 60:40mod film. The superstructure exhibit a layer thickness of about 20 nm. The median carbon content of 50 % as shown in the depth profile, was also observed in the 60:40mod film. The difference between the 60:40mod and 50:50mod films is the solved carbon in the steel matrix. Whereas in the

Table 7.11: Mössbauer fitting results of the 60:40, 60:40mod, 50:50 and 50:50mod STPLD samples, deposited at room temperature with a laser energy of 5 J/cm² (f - area fraction (error), mean values of $\langle\delta\rangle$ - isomer shift, $\langle\Delta\rangle$ - the quadrupole splitting for the paramagnetic subspectra, $\langle\epsilon\rangle$ the quadrupole splitting for the magnetic subspectra, B - hyperfine field).

sample	part	f [%]	$\langle\delta\rangle$ [mm/s]	$\langle\Delta\rangle, \langle\epsilon\rangle$ [mm/s]	σ_{Δ} [mm/s]	$\langle B\rangle$ [T]	σ_B [T]

	para	48.8(1)	0.11	0.67	0.32		
50:50mod	para-1	7.6(13)	0.22	0.58	0.20		
	para-2	92.5(74)	0.22	0.85	0.49		

60:40mod film are only solved 20-25 % carbon in the metal matrix, 30-35 % are solved in 50:50mod films, which results in a lower RBS-yield for the 50:50mod spectrum.

Fig. 7.27 shows a comparison between the results of conventional and modified 60:40 STPLD films.

Finally it could be shown, that the laser scan frequency has a crucial influence on the formation of carbon-stainless steel multilayer and that it is an important parameter to control the multilayer thickness.

Figure 7.27: Comparison between conventional and modified 60:40 STPLD films: Mössbauer spectra (top); TEM pattern (middle) and RBS spectra with calculated depth profile (bottom).

Figure 7.28: Comparison between conventional and modified 50:50 STPLD films: Mössbauer spectra (top); TEM pattern (middle) and RBS spectra with calculated depth profile (bottom).

7.4.3 Thermal stability of carbon-stainless steel multilayer films

Vacuum annealing of carbon-stainless steel multilayer films In order to analyze the thermal stability of carbon - stainless steel multilayers, vacuum annealing at a temperature of 973 K for 1 hour was performed for the 90:10 STPLD film.

Fig. 7.29 shows the XRD pattern of the vacuum annealed 90:10 film.

The GIXRD pattern exhibit two crystallized

Figure 7.29: GIXRD (2° incidence angle) spectrum of the post-vacuum annealed STPLD film. Phase, annealing temperature and time are given in the graph.

phases: the γ -(Fe,Cr,Ni) phase ($a = 0.359(2)$ nm) and the BCC σ -(Fe,Cr,Ni) ($a = 0.892(3)$ nm), which corresponds to the $\text{Fe}_{32}\text{Cr}_{10}\text{Ni}_7\text{Mo}_7$ steel. As a consequence, magnetic subspectra are expected in the CEM spectrum, which is depicted in Fig. 7.30 [144].

The CEM spectrum reveals, that the post-vacuum

Figure 7.30: CEM spectrum of the post-vacuum annealed 90:10 STPLD film.

Figure 7.31: TEM patterns of the post-vacuum annealed 90:10 STPLD film.

annealed 90:10 film is in the paramagnetic state in contrast to the as-deposited 90:10 sample, which exhibit both magnetic and paramagnetic subspectra. The hyperfine parameters after annealing for 1 h are well-defined, correspond to austenite and are presented in Table 7.12.

The differences in CEMS and XRD can be explained by the unequal information depths of both methods (CEMS: ~ 150 nm; 2° GIXRD: ~ 350 nm). As a result, the magnetic σ -(Fe,Cr,Ni) phase can only be observed in deeper regions, as detected by GIXRD.

This is confirmed by TEM which is illustrated in Fig. 7.31 and which show, in contrast to the as-deposited 90:10 film, that the multilayer structure pry open (and thus no clear multilayer system is observed) due to carbon diffusion during annealing. Furthermore, a segregation of the metal atoms to the film/substrate interface can be seen. An EDX analysis showed that the composition of the film has changed dramatically. In addition, the composition is not homogenous in the film; every dark area in the TEM pattern has another composition, but

Figure 7.32: RBS spectra of the post-vacuum annealed and as-deposited 90:10 STPLD film. the depth profile of the post-vacuum annealed can be found at the bottom

as indicated by GIXRD, the Mo concentration is higher than in the initial target. This could be due to different diffusion constants of the metal atoms. RBS measurements were carried out to derive the carbon content. The results - spectra and depth profile - can be seen in Fig. 7.32.

RBS confirms the TEM results. A broad multi-layer structure can be seen in the spectrum for the post-vacuum annealed film with varying layer thicknesses, which can be also observed in the calculated depth profile. The carbon content approximates the content as seen in the as-deposited 90:10 film. Summarizing, post-vacuum annealing is not an ap-

propriate technique to improve the properties of carbon - stainless steel multilayers. As a consequence, the influence of substrate temperature during deposition has to be investigated. The results of those experiments are presented in the next section.

Influence of the substrate temperature on the properties of carbon - stainless steel multilayers To investigate the influence of substrate temperature on the properties of carbon - stainless steel multilayer, a 90:10 film with a substrate temperature of 673 K was deposited.

The GIXRD pattern, as shown in Fig. 7.33, exhibit

Figure 7.33: GIXRD (2° incidence angle) spectrum of the 90:10 STPLD film deposited with a substrate temperature of 673 K.

the typical shape of amorphous materials. Whereas the peak position has not changed (in comparison to the 90:10 film deposited at room temperature), the peak width has decreased indicating appendages of crystallization. This can also be seen for higher 2θ -values, where small peaks protrude from the amorphous underground (and could possibly be attributed to an α - and a γ -phase. As a consequence, the film could be nano-crystalline.

The CEM spectrum is depicted in Fig. 7.34.

Some significant changes can be observed for the 90:10 film deposited with a substrate temperature

Figure 7.34: CEM spectrum of the 90:10 STPLD film deposited with an substrate temperature of 673 K.

Table 7.13: Mössbauer fitting results of the 90:10 STPLD stainless steel samples, deposited at room temperature and at 673 K (f - area fraction (error), mean values of $\langle\delta\rangle$ - isomer shift, $\langle\Delta\rangle$ - the quadrupole splitting for the paramagnetic subspectra, $\langle\epsilon\rangle$ the quadrupole splitting for the magnetic subspectra, B - hyperfine field).

of 673 K. Although, the film exhibit a magnetic split sextet, but its area fraction is decreased in comparison to the 90:10 film deposited at room temperature. Furthermore, changes in the hyperfine distribution can be seen: whereas in the room temperature film the probability for bigger fields is higher, the film deposited at 673 K exhibits a higher probability for small fields, which could be attributed to an amorphous stainless steel carbon-alloy, possibly rich in carbon. The amount of the quadrupole splitting is here increased indicating a transformation to austenite or carbides. due to the broadness of the quadrupole splitting, no more information can be taken from them. The results of the fitting procedures are presented in Table 7.13.

Although the CEM spectrum exhibit magnetically split sextets, no MOKE signal is detected. Since MOKE is sensitive to the first 5-10 nm, it is reasonable to assume, that the magnetic grains are found in deeper regions.

Again RBS measurements were carried out to investigate the carbon content and to get a first estimation about the multilayer structure. The results are presented in Fig. 7.35.

The carbon content in the sample deposited at 673 K is verisimilar to that film deposited at room

Figure 7.35: RBS spectra of the 90:10 STPLD film deposited at 298 and 673 K. The depth profile of the film deposited at 673 K can be found at the bottom.

Figure 7.36: TEM patterns of the 90:10 STPLD sample deposited at 673 K. Left: overview of the sample; right: HR-TEM pattern.

temperature. The depth profile show well defined multilayer, which are verisimilar in thickness. Also the decrease of the multilayer thickness seems to be less severe than in room temperature depositions. The beat in the oscillation at a depth of 300-500 nm is not a result of diffusion processes in deposition, but can be rather attributed to straggling effects during the RBS measurement.

RBS results were confirmed by TEM patterns, which are shown in Fig. 7.36.

Except for small waves between the layer interfaces of carbon and stainless steel, the multilayer structure is well defined; even better than in room temperature deposition. Small crystallites can be observed in the HR-TEM image, but no SAD patterns could be taken indicating the poor thermal stability of the grains, which is in good agreement to the results for post-vacuum annealed samples (an electron beam, focussed between 5-30 keV, induces structure modifications in a mostly amorphous metal matrix up to 20 nm; as a consequence the grains can disappear). As indicated by RBS, the decrease of the layer thickness to the surface is less severe than for room temperature depositions.

Summarizing, the deposition at higher substrate temperatures leads to an improvement of the layer thickness and homogeneity. Future experiments should find the ideal substrate temperature to deposit clear and well defined carbon - stainless steel multilayer.

7.4.4 The quality of the carbon-stainless steel multilayer

As mentioned in the previous section, substrate temperature has a non insignificant influence on the multilayer structure. Thus, it is necessary to char-

acterize the morphology of the multilayer systems and to find methods to improve their properties.

From an industrial point of view, multilayer systems at the nano-scale would be interesting. As derived from the TEM analysis, the 50:50mod STPLD film seems to answer this purpose. As a consequence, X-ray reflectivity (XRR) experiments were performed and analyzed with the IMD extension pack of the XOP X-ray optics software toolkit [145, 146]. The result is depicted in Fig. 7.37.

The analysis exhibits a superstructure, which is

Figure 7.37: X-ray reflectivity pattern of the 50:50mod STPLD film.

corresponding to the RBS results. The superstructure has a thickness of 28 nm and consists of 10 layers (alternating carbon and stainless steel). The roughness σ_R of each layer was fitted using a diffusion profile with $\sigma_R \approx 2$ nm. The repetition rate of the superstructure is $N = 12$. As a consequence of this, the quality of the multilayer derived by XRR is very poor, but a tendency can be found regarding the RBS and TEM results.

The 60:40mod sample showed a verisimilar multilayer structure compared to the 50:50mod sample, but the diffusion of carbon and stainless steel was even higher. The RBS pattern of the 80:20 sample (which was fabricated with the 90:10 target with a reduced laser scan area and, thus, an increased scan frequency) showed a superstructure with similar measures, as well. As a consequence it is reasonable to assume, that the increase of the scan frequency induces a self-organizing effect, which leads to this superstructures. This is investigated more exactly in the next section.

As mentioned above, all samples show a decrease of the layer thickness during preceding deposition. As a result, a wobbler system of the target holder was developed. This system allows a controlled wobble of the target to prevent the cavation of the target. Here a wobble-angle of $\omega_{wob} = 3^\circ$ from the rest position was chosen. Under this conditions, the 50:50mod film was deposited, which is labeled in the following as 50:50modwob.

Fig. 7.38 shows the RBS result of the 50:50modwob film.

In contrast to the other 50:50 films, the 50:50mod-

Figure 7.38: RBS spectra of the 50:50, 50:50mod and 50:50modwob STPLD film deposited at 298 K. The depth profile of the 50:50modwob STPLD film can be found at the bottom.

wob film exhibit a broad oscillation in the RBS

spectrum. On closer inspection, more small oscillations can be seen on the broad ones. In fact, the depth profile of the 50:50modwob film exhibits two superstructures: a small one, which was already seen in modified samples with a thickness of 25 nm, and a new one with a thickness of 120-130 nm denoted by the semicircle in the depth profile. Since the 50:50modwob depth profile has the form of the depth profile of the post vacuum annealed 90:10 sample, a pry opened multilayer structure is expected. Unfortunately, the TEM patterns of this sample were not available until completion of this work and, thus, no further remarks can be done.

The properly aim to synthesize uniform multilayer structures has failed. Thus, the cavation of the target and the resulting shift of the laser plasma plume should be prevented by reducing the energy density of the laser (reducing via Q-switch or by increasing the target-substrate distance).

7.4.5 Self-organization and nucleation model of carbon-stainless steel multilayer films

The RBS spectra of all multilayer structured STPLD films indicated a self-organization of the films given that the number of multilayer as derived by TEM did not correspond to the laser scan process of the target.

Therefore, an EDX line scan of the 90:10 and 50:50mod STPLD films were carried out. The curve progression was the corrected by the Cliff-Lorimer equation [73]:

$$I_A = C_A \cdot k_A \quad (7.4)$$

where I_A is the number of X-rays generated for, C_A the concentrations and k_A the Cliff-Lorimer sensitivity k-factor for element A.

Note: as a consequence of the insufficient sensitivity of the EDX detector to elements lighter than oxygen, no relative frequency could be derived (caused by the inappropriate carbon k-factor).

Thereafter, the result was correlated with a time to space diagram of the scan process convoluted with the laser spot diameter ($\varnothing = 2$ mm). Fig. 7.39 illustrates this for the 90:10 STPLD film.

At first glance, no correspondence between layer thickness and locality of the laser beam can be made. Although, the maximum of the carbon layers correspond to the moment when the laser spot hits the graphite inlay of the target, but the thickness does not comply.

As recently as the convolution of the laser beam on the time to space correlation (TTSC) is taken into account, a weak signal of a superstructure can be

Figure 7.39: EDX-time to space correlation diagram of the 90:10 STPLD film. The dashed line corresponds to the situation, in which the laser spot hits the graphite layer of the target.

seen (as indicated by the red semicircles). This superstructure corresponds very well to the observed TEM multilayer structure. As a first summary, it is reasonable to assume, that the phenomenon observed in carbon - stainless steel multilayers is an induced self-organization: the alternating scan process of the target induces long range diffusion, which leads to segregation of carbon and the metal atoms, instead of forming carbides. As for inert sputtered stainless steel films, also here the Mo atoms can redistribute and induce long-range diffusion.

Note: if the observed phenomenon is based on a target scan effect, the multilayer structure should correspond to the distance/time between two dashed lines in the EDX TTSC diagram and

Figure 7.40: EDX-time to space correlation diagram of the 50:50 STPLD film. The dashed line corresponds to the situation, in which the laser spot hits the graphite layer of the target.

the carbon layer should be very small (a few nanometers). This is not the case.

Fig. 7.40 shows the EDX TTSC diagram for the 50:50mod film.

Just as seen for the 90:10 EDX TTSC, a superstructure due to the convolution of laser beam and TTSC can be seen. Its thickness corresponds very well to the XRR, RBS and TEM results and is about 25 nm. The number of dashed lines is significant higher than the number of multilayers caused by an exclusive scanning effect. As a consequence, the self-organization is also induced by the scanning of the target.

Nucleation model of carbon-stainless steel multilayer films Now the question arise, on which nucleation model are the observed multilayer structures based on?

As indicated by the TTSC diagrams, the self-organization in carbon - stainless steel multilayer is induced. First, the nucleation of the 90:10 film is discussed. Therefore, an estimation of the plasma ion energies is needed: by mapping the target voltage during deposition, an estimation of the plasma ion energies of the ablated target atoms can be obtained by taking the first derivative of the curve, which is shown for the 90:10 target in Fig. 7.41.

As a consequence, the adatoms have barely suf-

Figure 7.41: Ion distribution of the plasma ions of the 90:10 target.

ficient energy to adsorbate. By the reduction of energy, the influence of the Mo atoms seems to be more severe than in reactive sputtered films. No solidification occurs and benefits the carbon diffusion in the metal matrix. Local carbon inhomogeneities were induced via the target scan process. This induces local diffusion gradients which leads to a self-organizing effect and which promotes the decomposition of carbon and stainless steel and assists multilayer formation.

Fig. 7.42 illustrates the plasma ion distribution of the 50:50mod target.

In contrast to the plasma ions of the 90:10 target,

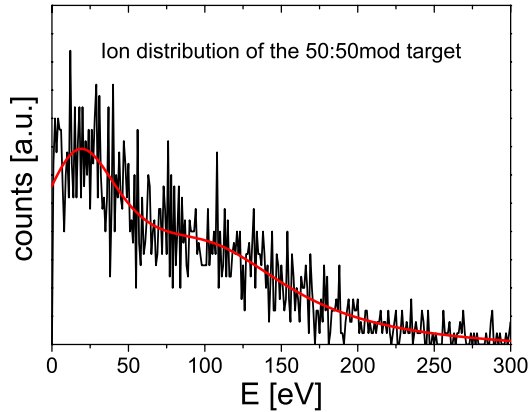

Figure 7.42: Ion distribution of the plasma ions of the 50:50 target.

the plasma ions of the 50:50mod target show considerably higher energies. As a result the nucleation gets more complicated given that ion implantation has to be taken into account.

In this case, the beginning of the nucleation is quite the same: Mo triggers a long-range diffusion and allows a carbon diffusion through the metal matrix. Via a SRIM simulation [95] an implantation depth of carbon into stainless steel (and vice versa) of about 3 nm is found. This implantation leads to a locally rearrangement which hinders the overall carbon diffusion in the matrix, but not complete. As a consequence the size of the superstructure is reduced. The ion implantation could lead to opposing diffusion gradients in the nano-scale regime, which could lead again to a self-organization and the formation of multilayer by decomposing carbon and stainless steel.

As mentioned above, all films show a decrease of the multilayer thickness during deposition process, which is caused by the cavation of the target. As a consequence, the laser plasma plume shifts and the deposition rate drops during deposition. Thus, no linear deposition rate can be assumed as done in the beginning. In fact, the deposition rate is higher than the calculated value and drops exponentially. The calculated value only constitutes a median value.

Finally, the formation of carbon - stainless steel multilayer with high-carbon concentrations were synthesized and crucial parameters, such as graphite-inlay thickness and, thus, the scan speed and substrate temperature determined. Now the question arise, if this procedure can be transferred to other elements and in which way the multilayer

thickness is influenced for different elements.

For this, experiments with pre-combined Al and Ti STPLD targets were performed.

The RBS results for the Al/C 60:40mod film is depicted in Fig. 7.43.

Also here, a multilayer structure can be seen. How-

Figure 7.43: RBS spectra of the Aluminum bulk material and the Al/C 60:40mod STPLD film deposited at 298 K. The depth profile of the Al/C 60:40mod STPLD film can be found at the bottom.

ever, the depth profile exhibit pry opened multilayer structure, which is very surprising. Since it is known that carbon is not very solvable in Al, a well defined structure was expected. On the other hand, the depth profile is not very reliable given that for film thicknesses, as observed here, marginal energies were achieved, in which the resolution is influenced by effects like straggling etc.

Nevertheless, a layer thickness of Al could be derived to about 15 nm, whereas the carbon layer are only 5 nm in thickness. In comparison to carbon - stainless steel multilayer, the thickness has decreased. This is another hint for self-organization. If the formation is only based on a scan effect, for all elements the same multilayer structure would be expected given that the multilayer structure would only depend on the preparation of the target (and all targets were pre-combined in the same way).

Fig. 7.44 shows the RBS results for Ti multilayer.

In comparison to all multilayer films prepared from

Figure 7.44: RBS spectra of the Titanium bulk material, the Ti/C 90:10 and the Ti/C 60:40mod STPLD films deposited at 298 K. The depth profile of the Ti/C 90:10 and of the Ti/C 60:40mod STPLD film can be found at the middle/bottom.

STPLD targets, Ti/C multilayer exhibit the clearest RBS oscillations indicating a well defined multilayer structure for films deposited at room temperature. In deed, this is confirmed by the depth profiles. A layer thickness of Ti could be derived to about 20 nm, whereas the carbon layer are only 10 nm in thickness - still being smaller than in carbon - stainless steel multilayer.

Fig. 7.45 shows the dependence between multilayer thickness and atomic number at constant carbon content. For this, all films, which were prepared by the same STPLD target configuration were summarized, viz. SS/C-, Al/C- and Ti/C 60:40mod films. A clear tendency can be seen, where the layer thick-

Figure 7.45: Dependence between multilayer thickness and atomic number at constant carbon content. Here, the thicknesses of SS/C, Al/C and Ti/C 60:40mod samples are summarized.

ness - both metal and carbon - is increasing exponentially with increasing atomic number. Even these would not be expected, if the multilayer formation were only based on a target scanning effect (it should be constant). This indicates again a self-organizing effect.

By the introduction of the STPLD technique, a new induced self-organizing effect was found. First experiments showed crucial processing parameters, but more experiments have to be done, to understand the complete process and to achieve films, which can be used for industrial application. Therefore, experiments with varying laser energy should be carried out to synthesize multilayer films, which layer interfaces are sharper (e.g. to use those films in the electronic industry as conducting paths or for X-ray mirrors by achieving sufficient crystallinity). Furthermore, a wide range of elements should be used to fabricate STPLD films to investigate the evolution of multilayer thickness to obtain an empirical formula for this phenomenon.

As next step, the STPLD method is applied to other inlays, e.g. boron-nitride, to investigate, if multilayer systems can be formed with other materials and if amorphous films can be obtained. The next section will discuss those results.

7.5 Results for boron - implanted and boro - nitrated stainless steel films

The films were prepared by different methods: (1) conventional stainless steel samples (X5CrNiMo17-12-2, 1.4401; size 10×10 mm) containing 1, 3 and

6 at.% boron were prepared by ion implantation at the IONAS accelerator facility in Göttingen. Using SRIM [95], fluences for different energies were calculated, to form implantation profiles with the desired B contents. The parameters are summarized in Table 7.14. The implantation profiles are

Table 7.14: Implantation fluences for stainless steel samples containing 1, 3 and 6 at.% for different implantation energies. The samples are labeled as 1P, 3P and 6P.

E [keV]	sample		
	1P	3P	6P
200	$1.2 \cdot 10^{16}$	$4.0 \cdot 10^{16}$	$8.0 \cdot 10^{16}$
130	$7.5 \cdot 10^{15}$	$2.0 \cdot 10^{16}$	$3.8 \cdot 10^{16}$
65	$6.5 \cdot 10^{15}$	$2.0 \cdot 10^{16}$	$4.0 \cdot 10^{16}$
30	$3.2 \cdot 10^{15}$	$8.5 \cdot 10^{15}$	$1.5 \cdot 10^{16}$
15	$8.5 \cdot 10^{14}$	$4.0 \cdot 10^{15}$	$8.5 \cdot 10^{15}$

Figure 7.46: Implantation profiles calculated by SRIM for stainless steel samples containing 1, 3 and 6 at.% boron.

shown in Fig. 7.46.

Figure 7.47: Growth rate g as a function of the boron-nitride area fraction for the room temperature STPLD deposition.

(2) Films were deposited by Sequential Target Pulsed Laser Deposition (STPLD) with a Brilliant Nd:YAG laser ($\lambda = 1064$ nm, pulse duration 5–6 ns, repetition rate 20 Hz) onto amorphous SiO_2 substrates (oxidized Si(100) wafer of 0.5 mm thickness, pre-cleaned with acetone and oxidized in air, no further treatment) utilizing a commercial AISI 316 (X5CrNiMo17-12-2, 1.4401) target. Before deposition, the PLD-chamber was evacuated to a base pressure of 10^{-6} Pa. The laser energy was set to 5 mJ/cm^2 . The targets were pre-combined in that way, that area ratios (of stainless steel to boron nitride) of 90:10, 85:15, 80:20, 60:40mod and 50:50mod were obtained (laser scan area 20×2 mm on a 25×25 mm STPLD target - except the 80:20 sample: here the 90:10 STPLD target was used, the desired area ratio was obtained by reducing the laser scan area to 10×2 mm). The thickness of the deposited films was controlled by a quartz microbalance (with a film density set to 7.89 kg/m^3 , which is the density of AISI 316). The deposition parameters and the resulting thicknesses and growth rates are summarized in Table 7.15.

From these data it is derived that the growth

Table 7.15: Deposition time t , real film thickness d (as measured by RBS after deposition) and derived growth rate $g = \frac{d}{t}$ for the STPLD films. All samples were deposited at 298 K with a laser energy of 5 mJ/cm^2 and a target-substrate distance of 6.5 cm.

sample	t [min]	d [nm]	g [nm/min]

rate has a Gaussian form with increasing carbon area fraction, which seems to be characteristic for STPLD processes. The correlation between growth-rate g and inlay fraction is visualized in Fig. 7.19.

7.5.1 Results for the implanted steel samples

To confirm the calculated boron content, RBS measurements were performed on the implanted stainless steel samples. The results are shown in Fig. 7.49.

As expected, the RBS spectra show exactly the

Figure 7.48: RBS spectra of AISI 316 samples implanted with 1, 3 and 6 at.% boron.

calculated boron content.

XRD shows well defined reflexes. Three different phases can be seen in all samples: the γ -(Fe,Cr,Ni) phase - remnants from the original starting material, the α -(Fe,Cr,Ni) phase - typically observed after ion implantation as a result of ion mixing, and the $(\text{Fe,Cr,Ni})_3\text{B}$. To derive the $(\text{Fe,Cr,Ni})_3\text{B}$ content, a peak analysis was performed. For clarity, only the pattern and peak analysis of the 6P sample is shown.

Also here, the observed area fractions correspond to the implanted boron contents.

The CEM spectra are summarized in Fig. 7.51. The spectra reveal both magnetically split sextets and paramagnetic sites. The fitted distributions are in good agreement to the XRD measurements. The hyperfine field distribution consist of two components, one corresponding to α -Fe with a random neighborhood (consisting of Cr, Ni and Mo) and one component which could be attributed to $(\text{Fe,Cr,Ni})_2\text{B}$ or $(\text{Fe,Cr,Ni})_3\text{B}$ borides [147]. The quadrupole splittings also confirm the XRD results, which exhibit a component corresponding to the original target material, and one which corresponds to the formation of austenite. The results of the

Figure 7.49: GIXRD (2°) spectrum and peak analysis of the AISI 316 sample implanted with 6 at.% boron.

Figure 7.50: Polar diagrams of the coercive field H_C (top) and the relative remanence M_R/M_S (bottom) of AISI 316 sample implanted with 1 at.% boron.

fitting procedures are presented in Table 7.16. These Mössbauer results were confirmed by MOKE

Figure 7.51: Mössbauer spectra of the implanted AISI 316 films. The numbers in the graphs represent the implanted boron concentration.

measurements. Figure 7.50 shows the result of the MOKE measurement of the AISI 316 sample containing 1 at.% boron. The other samples show similar MOKE measurements.

No clear anisotropy can be identified, but it seems to be a mixture of a uniaxial and a four-fold anisotropy indicating phase transformations from α - to γ -phase and vice versa. The uniaxial anisotropy is usually seen after ion implantations. This behavior could also be due to magnetostriction effects by stresses in the film. The coercive field H_C of all samples is approximately 80 Oe.

Summarizing, no amorphization of the boron implanted stainless steel samples was obtained, but rather a crystallization of borides due to the implantation of boron and a phase transformation from γ - to α -phase due to mixing effects during implantation. As next step, higher boron contents will be incorporated by the STPLD technique. The results are presented in the next section.

7.5.2 Results for boro-nitrided stainless steel films

Deposition at room temperature and influence of the boron-nitride area fraction The inlay area, and thus the carbon concentration, was systematically increased from 10 to 50 %. For all

Figure 7.52: Peak position and peak width of the first broad peak in the XRD spectra of the STPLD films.

these deposited films, the STPLD samples show the mostly broad XRD appearance of amorphous materials, but also a reflex corresponding to boron-nitride can be seen indicating a crystallization of BN-grains. The XRD spectra are resembled in Fig. 7.53. Fig. 7.52 shows the position and the width of the first broad peak for the spectra shown in Fig. 7.53. There is a clear tendency for peak position and peak width, where the peak position

Figure 7.53: GIXRD (2°) spectra of the carburized films. The stainless steel - boron nitride area fractions are given in the graph.

is decreasing linear with increasing boron-nitride, whereas the peak width has a parabolic form indicating different phase transformations.

Fig. 7.54 illustrates the CEM spectra of the STPLD films, which show the transition from a phase and which is verisimilar to the amorphous and soft ferromagnetic phase observed in carburized, nitrided

and oxidized stainless steel films. The only difference seems to be the absence of a component with higher hyperfine fields. The remaining component with small hyperfine fields - and the only one observed in boro-nitrided stainless steel films - can be assigned to the FeB phase [147]. Noticeable is, that the formation of the FeB phase needs a minimum boron content of 50 %. However, the films which show this amorphous phase are deposited from STPLD targets, which should deposit a maximum B content of 20 %. As a consequence, a boron segregation took place during deposition or areas have been locally formed with boron content of nearly/over 50 %. The films deposited from the SS/BN 60:40mod and SS/BN 50:50mod targets exhibit a doublet structure in their spectra. This could be attributed to a incorporation of more nitrogen out of the boron-nitride inlay of the target. Another possibility could be, that the observed doublet structure could be attributed to a $\text{Fe}_x\text{B}_{100-x}$. As a fact, that the XRD patterns only exhibit a broad appearance (and thus, that of amorphous materials), no further remarks can be done and none of the two possibilities can be limited as more probable. The results of the fitting procedures can be found in Table 7.17.

Figure 7.55 shows the result of the MOKE measurement of the SS/BN 90:10 STPLD film. It exhibits only a fourfold anisotropy, which is normally observed after phase transformation from a bcc to fcc phase or vice versa [89, 98]. The coercive field was derived to 66 Oe. Actually, a soft ferromagnetic phase was expected. This indicates, that the missing high-hyperfine field component in the Mössbauer spectra is attributed a spin glassy phase containing Fe, which surrounds the found disordered Ni_3C phase. All other STPLD samples exhibit a verisimilar behavior like the 90:10 film.

Figure 7.54: Mössbauer spectra of the STPLD stainless steel films. The numbers in the graphs represent the stainless steel/boron-nitride fraction of the STPLD targets.

Figure 7.55: Polar diagrams of the coercive field H_C (top) and the relative remanence M_R/M_S (bottom) of SS/BN 90:10 STPLD sample.

To evaluate the amount of incorporated boron and nitrogen, RBS measurements were carried out, whose results are shown in Fig. 7.56.

Due to the limited mass resolution of RBS,

Figure 7.56: RBS spectra of the STPLD films. The stainless steel/boron-nitride area ratios are given in the graph.

elements lighter than oxygen can not be accurately determined. However, a trend can be pointed out. As seen in the CEM spectra, RBS exhibit a verisimilar boron and nitrogen content (20 %) in the 90:10, 85:15 and 80:20 STPLD films. The reduction of the yield of the STPLD films indicates a boron-nitride surface layer of a few nano-meters. Generally, more boron than nitrogen can be observed in all films and the hypothesis of locally enriched boron domains seems to be confirmed. However, more important is the fact, that no oscillations can be observed in

the RBS spectra. This indicates that the films exhibit no multilayer structure.

Fig. 7.57 illustrates the TEM pattern of the SS/BN 80:20 STPLD film.

Noticeable problems can be seen: 1) several BN

Figure 7.57: TEM pattern of the SS/BN 80:20 STPLD film. The two numbers in the pattern indicate the position, where the histograms were taken.

pieces are distributed through the film and 2) a weak multilayer structure can be observed. To confirm this, histograms were taken which are depicted in Fig. 7.58.

The histograms confirm a very weak multilayer structure, which is difficult to see in the TEM pattern due to the similarity of the compositions of the multilayer. The thickness of the "metal rich" layer is about 3 nm and 10 nm of the "metal poor" layer, respectively. Thus, the layer thickness can not be resolved by RBS.

Now the question arise, which mechanism hinders multilayer growth: possibly, there are two factors, which are hindering. The first factor could be the inlay material, the boron nitride. As described above, the STPLD process induces diffusion. Since the inlay material consists of two elements, competing diffusion processes could be induced, which are hindering multilayer growth. However, the more probable factor seems to be the BN droplets, which are distributed through the film. Droplet formation is due to hydrodynamic instabilities generated during laser-induced melting and ablation [45]. There are four different mechanisms, which lead to droplet formation: 1) the expansion velocity of the laser plasma plume induces surface capillary waves; 2) Rayleigh-Taylor instabilities, caused by multiple-pulse irradiation, which lead to the motion of the

target liquid from valleys of capillary waves. This leads to an increase of corrugation and centrifugal forces near the hills cause droplet formation. 3) Kelvin-Helmholtz (shear flow) instabilities and 4) Necking and formation of solid particulates [45]. Here, the second mechanism is more probable.

During multilayer growth, nucleation usually takes place on top of terraces where the geometry of the diffusion process is well defined [148]. Thus, droplet deposition prevents multilayer growth.

Summarizing, the boro-nitriding of stainless steel lead to a verisimilar amorphous phase, which was observed in carburized, nitrided and oxidized stainless steel films. The difference between these amorphous phases is found in magnetism. Whereas the amorphous phase in magnetron and RPLD deposited exhibits two magnetic components and is soft ferromagnetic, the boro-nitrided amorphous phase exhibits only one magnetic component, which could be identified as FeB phase and the coercive field is by a factor of 10 higher. This indicates, that the missing high-hyperfine field component in the Mössbauer spectra is attributed to a spin glassy phase containing Fe, which surrounds the by EX-AFS identified disordered Ni_3C phase. As a consequence, the low-field components in carburized, nitrided and oxidized stainless steel films can possibly attributed to stoichiometric FeX phases.

The STPLD process of multi-component inlays (in this case boron-nitride) showed the decrease of the Ability of Multilayer Formation (AMF) by inducing competing diffusion processes. These processes could possibly hinder the formation of grains with spin glassy properties. Hence, future STPLD experiments should be only performed with one-component inlays, until the STPLD process is completely understood.

7.6 Summary of the pulsed laser deposited films

In all respects, the pulsed laser deposition of Fe-based amorphous films exhibit new properties and a huge potential for technical applications. Future experiments should especially be focussed on films prepared by the STPLD technique. Their films show new properties, which can be controlled by the processing parameters: laser beam density, scan velocity, inlay composition and -thickness.

Whereas the magnetron sputtering technique failed, the in this work presented STPLD technique succeeded: by pre-combining an ARMCO target with an graphite inlay, the prediction of Lee et al. [9], that a NaCl-type FeC phase can be formed, could be confirmed. Films with 20 nm in thickness were directly deposited on TEM grids and immediately TEM analyzed. A Fe-C bond length of 0.229(3) nm and, thus, a lattice parameter of $a_0 = 0.458(6)$ nm was obtained. This is in good agreement with Lee's predictions (bond length 0.236 nm and $a_0 = 0.473$ nm). Unfortunately, the synthesization of stoichiometric FeC films failed, which could be originated in inter-diffusion with the α -SiO₂ substrate [140] or by a thickness effect [141].

The STPLD of stainless steel - graphite targets lead to the formation of self-organized multilayer films. Together with the solidification disturbance induced by Mo atoms, carbon diffuses through the metal matrix. Local carbon inhomogeneities were induced via the target scan process. This induces local diffusion gradients which leads to a self-organizing effect and which promotes the decomposition of carbon and stainless steel and assists multilayer formation plus the formation of superstructures. By increasing the ion energies by increasing the scan velocity, an additionally implantation of the target materials lead to a locally rearrangement which hinders the overall carbon diffusion in the matrix, but not complete. As a consequence, the size of the superstructure is reduced. The ion implantation could lead to opposing diffusion gradients in the nano-scale regime, which could lead again to a self-organization and the formation of multilayer by decomposing carbon and stainless steel.

The STPLD technique was also used, to synthesize Al/C and Ti/C multilayer. As a consequence, an exponential correlation between the layer thickness and the atomic number of the metallic component of the target was found.

Unfortunately, the growth mechanism is not fully understood and several experiments have to be carried out to find an empirical formula.

As next step, the inlay material was varied and

boron-nitride was used. The boro-nitrided stainless steel film exhibit a verisimilar amorphous phase, which was observed in carburized, nitrided and oxidized stainless steel films. The difference between these amorphous phases is found in magnetism. Whereas the amorphous phase in magnetron and RPLD deposited exhibits two magnetic components and is soft ferromagnetic, the boro-nitrided amorphous phase exhibits only one magnetic component, which could be identified as FeB phase and the coercive field is by a factor of 10 higher. This indicates, that the missing high-hyperfine field component in the Mössbauer spectra is attributed to a spin glassy phase containing Fe. As a result, harder magnetism is observed.

Surprisingly, the synthesization of SS/BN STPLD films only revealed a weak AMF, which could be due to the deposition of BN-droplets. These particulates offer potential wells, on which the adsorbents nucleate. As a consequence, multiayer growth is hindered.

Also RPLD films exhibit the amorphous and soft and ferromagnetic phase. With the aid of this process, the nucleation model was confirmed and further improved.

Laser deposition showed various aspects of carbide formation and exhibit many new properties of iron and stainless steel films. As a consequence, the PLD technique (and especially the STPLD) demonstrates high potential and should be pressed ahead to focus on the development on new materials.

Chapter 8

FEL surface processing

For technical applications, surface processing is sometimes more convenient (concerning layer thicknesses, machining time, time expenditure etc.) than thin film deposition. Furthermore, the STPLD process and the magnetron-sputtering technique exhibit solidification times and cooling rates as crucial factors for film and layer microstructure. For this, FEL surface processing experiments for AISI 310 and AISI 316 were performed at the Jefferson lab. The processing parameters can be found in Table 4.1. As reactive gas nitrogen was used ($p_{chamber} = 1 \cdot 10^5$ Pa).

Light microscope images of the AISI 310 and AISI 316 samples after FEL surface processing are depicted in Fig. 8.1.

The melt pool convection determined tracks can

Figure 8.1: Light microscope images of the FEL surface processed stainless steel samples. Top: AISI 310; bottom AISI 316.

be clearly seen. Detailed information about the nitrogen transport mechanism and flow behavior in the melt are available in [149].

Fig. 8.2 shows the XRD patterns of the surface processed samples.

Both samples exhibit the γ -(Fe,Cr,Ni) structure.

Figure 8.2: GIXRD (2°) spectra of the FEL nitrided films. The stainless steel - boron nitride area fractions are given in the graph.

The lattice parameters are derived to $a_{0,AISI310} = 0.3600(2)$ nm and $a_{0,AISI316} = 0.3595(1)$ nm.

By using the equation

$$a = 3.572 \text{ \AA} + 0.7 \text{ \AA} \times c_N^\gamma \quad (8.1)$$

where c_N^γ is the nitrogen concentration, the nitrogen solved in the γ -phase can be obtained from the XRD patterns [150]. The c_N^γ value found for the AISI 310 steel was derived to $c_N^\gamma = 4.0$ % and $c_N^\gamma = 3.3$ % for the AISI 316 sample, respectively.

The CEM spectra are illustrated in Fig. 8.3.

A single line analysis showed in both case three subspectra: two of them are corresponding to the original steel material and one subspectrum corresponds to the formation of a $Fe_{1-x}N_x$ phase. The results of the fitting procedures can be obtained in table 8.1.

The nitrogen concentration c_N^γ can also be derived from the doublet subspectra by calculating a binomial distribution with $n = 2$ [151]. The obtained c_N^γ

	γ +N		0.65(27)		0.13	5.0(80)
	$\text{Fe}_{1-x}\text{N}_x$		0.38(7)		0.13	40.0(13)
AISI 316	γ +N	-0.05(4)	0.12(2)		0.13	58.9(41)
	γ +N		0.68(6)		0.13	11.2(33)
	$\text{Fe}_{1-x}\text{N}_x$		0.35(4)		0.13	29.9(40)

Figure 8.3: Mössbauer spectra of FEL nitrated AISI 310 and AISI 316 samples.

values are $c_N^\gamma = 9.4\%$ for AISI 310 and $c_N^\gamma = 7.2\%$ for AISI 316. These values are by a factor of two greater than those derived from the XRD pattern. This might be due to the fact, that the equation 8.1 is only valid for nitrogen in Fe. Thus, 8.1 is only an approximation for nitrated stainless steel films. Unfortunately, no XRD patterns with well defined reflexes were obtained in this work to derive a new correlation.

As a consequence, RBS measurements were carried out, which are shown in Fig. 8.4.

Here, the nitrogen concentration is verisimilar than that derived by Mössbauer Spectroscopy. For AISI 310 a median value of $c_N^\gamma = 9.8\%$ and $c_N^\gamma = 8.1\%$ for AISI 316, respectively were found. Furthermore, an oxide surface layer was found in both samples, which should have influence on the hardness of the films.

Figure 8.4: RBS spectra of the FEL nitrated AISI 310 and AISI 316 samples.

Microhardness of FEL nitrated stainless steel samples Nanoindentation was performed by using a Fischerscope HV100 [92] with a Vickers diamond in order to investigate the influence of nitrating on the microhardness and the mechanical properties. The maximum indentation force was set to 1000 mN. Four positions were measured for each sample. The hardness-depth profiles are illustrated in Fig. 8.5.

The hardness distribution close to the surface in-

Figure 8.5: Hardness-depth profiles of the FEL nitrated AISI 310 and AISI 316 samples.

dicates for both steels hardness values, which can be attributed to hard oxide layers, which is in good agreement to RBS.

By using the equation of Jönsson and Hogmark the hardness and the layer thickness were derived [152]:

$$H_f = H_s + \left[2k \frac{t}{d} - \left(\frac{t}{d} \right)^2 \right] (H_f - H_s) \quad (8.2)$$

where t is the film thickness, H_f , H_C and H_S the film, the composite and the substrate hardness, d the indentation depth and k an apparatus constant due to the geometry of the Vickers diamond of the indenter (here it was set to 0.14).

For AISI 310, a film hardness of 2.64(3) GPa and a layer thickness of 4.85(5) μm was found. For AISI 316, the film hardness was derived to $H_f = 2.49(2)$ GPa; the layer thickness to 5.84(40) μm .

In comparison to the hardness values of the starting materials, the hardness values of the FEL nitrided stainless steel samples are slightly increased, but are drastically lower than those of Magnetron-sputtered stainless steel films. This could be due to the rapid coagulation of the melt in this process. As a consequence, the nitrogen has not enough time to diffuse through the metal matrix to enhance hardening.

Summarizing, FEL surface processing of stainless steel samples lead to the formation of a well-crystallized surface layers, which have better tribological properties. Unfortunately, not enough nitrogen was incorporated and as a consequence, further experiments have to be done to localize the parameter range (overlap-parameter, laser energy, scan speed, chamber pressure etc.) to obtain amorphous surface layers.

Chapter 9

Summary and Outlook

The synthesization and characterization of amorphous iron and stainless steel films have been the subject of this work. For this, various aspects of the carbide, nitride, oxide and boron-nitride formation and their stability were studied in detail to localize the parameter range of the metastable amorphous state in the given systems.

Intrigued by the predictions of Lee et al. [9], inert sputtering from a pre-combined $\text{Fe}_{50}\text{C}_{50}$ was used to synthesize the stoichiometric NaCl-type FeC phase via Magnetron-sputtering. Unfortunately, geometric effects of the target configuration, hysteresis effects and re-sputtering constitute severe problems to the deposition process. As a consequence of this, the Magnetron sputtering technique seems not to be suitable to synthesize the stoichiometric FeC phase, but the films exhibit carbon contents, which exceed the maximum solubility limits in known carbides. As a result, reactive sputtering of stainless steel - by using methane, nitrogen and oxygen as reactive gas - was performed to synthesize amorphous films or quasi metallic glasses based on conventional steels.

For carburized samples, following results were obtained. All carburized samples showed a broad appearance in the GIXRD patterns revealing the character of amorphous materials. The magnetic properties investigated by means of Mössbauer Spectroscopy and MOKE showed the formation of various phases and carbides at a sputtering temperature of 298 K. In addition a new amorphous and soft ferromagnetic phase was observed. For this phase, a median hyperfine field of $\langle B \rangle = 10.3$ T with a width of $\sigma = 6.1$ T was obtained from the $P(B)$ distribution of the Mössbauer analysis. The soft ferromagnetic character was derived by MOKE, which revealed a coercive field of approximately 4 Oe. Furthermore, vacuum annealing of this phase showed the carbide reaction $\text{M}_7\text{C}_3 \rightarrow \text{M}_{23}\text{C}_6 \rightarrow \text{M}_6\text{C}$.

To characterize the microstructure of the new amorphous and soft ferromagnetic phase, DSC, FIM, TEM and EXAFS experiments were carried

out for carburized samples.

DSC, FIM and TEM showed the quasi metallic glass behavior of these phase, but the microstructure could only be explained by the EXAFS analysis, which revealed a disordered Ni_3C phase. The magnetism of this phase could be predicted by a LMTO model [119], the order of magnetism could be explained by a core-shell model, describing the nano-particles as consisting of a ferromagnetically core and a disordered surface shell [121, 122].

These experiments confirmed a pre-suggested model, which is based on thermodynamical and kinetic remarks of Lu et al. [13] and of Lux and Haubner [113]: the present Fe-based alloy is associated with the deep eutectic point of the Fe-C system. It is well known that compositions around the deep eutectic point are ideal for glass formation in many systems. As a result, glass formation is greatly favored thermodynamically. Further, the minor addition of Mo could promote glass formation in the Fe-C system by suppressing the formation of the primary phase and hindering grain growth. Because of their limited solubility in Fe carbides, the molybdenum atoms must redistribute and long-range diffusion is required upon solidification. The introduction of a reactive sputtering gas - here the carbon from methane - additionally disturbs the nucleation process by establishing higher probabilities of coordination. This leads to simultaneous rearrangement of different species of atoms, which suppresses the formation of competing ordered phases. As a consequence, phases outside the equilibrium can be formed like the disordered trigonal Ni_3C phase. To proof the transferability of this model to the p-block elements N and O, the reactive Magnetron-sputtering technique was used to deposit nitrided and oxidized sample. Indeed, both systems revealed the same amorphous and soft ferromagnetic phase.

As shown in Fig. 6.51, the FeN system can be understood as a perfect Gibbs system in the given parameter range, wherein the Fe_3N phase

represents the minimum of that system. Combined with the shown tendency obtained for the reactive gas flow, any given phase - from amorphous to crystalline - can be reached for Magnetron-nitrided stainless steel films. In fact, amorphous and crystalline phases, such as the new amorphous and soft ferromagnetic and ZnS-type γ'' -(Fe,Cr,Ni)N phase, were observed.

In contrast, Fig. 6.61 exhibit the FeO system as a Gibbs plot of a multi-phase system, in which the transition from the amorphous state (domain I) to the crystalline phases (domain II - the formation of FeO, Fe₂O₃ oxides) is depicted. In contrast to the carburized and nitrided amorphous and soft ferromagnetic phase, Mössbauer Spectroscopy and RBS of the oxidized phase indicated the participation of Fe-oxides. As a consequence, the model for the amorphous state for carburized and nitrided samples can not be applied in the same form for oxidized samples.

According to He et al. [118] and Kodama et al. [135], NiFe₂O₄ cores surrounded by spin-glassy surface shells would satisfy the observed results. This hypothesis has to be proven in upcoming EXAFS experiments.

Reconsidering all experiments, it is reasonable to assume, that the model mentioned above is transferable to all p-block elements.

As next step, the verifiability of the model concerning the synthesization mode was investigated. Therefore, the PLD technique was chosen to synthesize high-carbon iron and stainless steel films. For this purpose, the STPLD technique was developed to enlarge the advantages of the PLD. Until the introduction of STPLD, either precasted PLD targets had to chosen or complex rotating target systems were in use. Now, the material and area fraction of the STPLD inlay extend the number of processing parameters.

Whereas the magnetron sputtering technique failed, the in this work presented STPLD technique succeeded: by pre-combining an ARMCO target with an graphite inlay, the prediction of Lee et al. [9], that a NaCl-type FeC phase can be formed, could be confirmed. Films with 20 nm in thickness were directly deposited on TEM grids and immediately TEM analyzed. A Fe-C bond length of 0.229(3) nm and, thus, a lattice parameter of $a_0 = 0.458(6)$ nm was obtained. This is in good agreement with Lee's predictions (bond length 0.236 nm and $a_0 = 0.473$ nm). Unfortunately, the synthesization of stoichiometric FeC films failed, which could be originated in inter-diffusion with the α -SiO₂ substrate [140] or by a thickness effect [141].

The STPLD of stainless steel - graphite targets lead to the formation of self-organized multilayer

films. Together with the solidification disturbance induced by Mo atoms, carbon diffuses through the metal matrix. Local carbon inhomogeneities were induced via the target scan process. This induces local diffusion gradients which leads to an self-organizing effect and which promotes the decomposition of carbon and stainless steel and assists multilayer formation plus the formation of superstructures. By increasing the ion energies by increasing the scan velocity, an additionally implantation of the target materials lead to a locally rearrangement which hinders the overall carbon diffusion in the matrix, but not complete. As a consequence, the size of the superstructure is reduced. The ion implantation could lead to opposing diffusion gradients in the nano-scale regime, which could lead again to a self-organization and the formation of multilayer by decomposing carbon and stainless steel.

The STPLD technique was also used, to synthesize Al/C and Ti/C multilayer. As a consequence, an exponential correlation between the layer thickness and the atomic number of the metallic component of the target was found.

Unfortunately, the growth mechanism is not fully understood and several experiments have to be carried out to find an empirical formula, which describes the multilayer thickness.

As next step, the inlay material was varied and boron-nitride was used. The boro-nitrided stainless steel film exhibit a verisimilar amorphous phase, which was observed in carburized, nitrided and oxidized stainless steel films. The difference between these amorphous phases is found in magnetism. Whereas the amorphous phase in magnetron and RPLD deposited exhibits two magnetic components and is soft ferromagnetic, the boro-nitrided amorphous phase exhibits only one magnetic component, which could be identified as FeB phase and the coercive field is by a factor of 10 higher. This indicates, that the missing high-hyperfine field component in the Mössbauer spectra is attributed to a spin glassy phase containing Fe. As a result, harder magnetism is observed.

Surprisingly, the synthesization of SS/BN STPLD films only revealed a weak AMF, which could be due to the deposition of BN-droplets. These particulates offer potentials, on which the adsorbents nucleate. As a consequence, multilayer growth is hindered.

Also RPLD films exhibit the amorphous and soft and ferromagnetic phase. With the aid of this process, the nucleation model was confirmed and further improved. Furthermore, STPLD and RPLD confirmed the independence of the nucleation model on the preparation mode of the films.

For comparison, the amorphization behavior of surface treated samples was investigated. Therefore, FEL experiments at the Jefferson lab were carried out, wherein the nitrogen incorporation was assisted by laser beam radiation.

FEL surface processing of stainless steel samples lead to the formation of a well-crystallized γ -(Fe,Cr,Ni) surface layer. FEL treatment of AISI 310 improved the hardness. A film thickness of $t = 4.85(5) \mu\text{m}$ and H_f was derived to 2.64(3) GPa. For AISI 316, the film hardness was derived to $H_f = 2.49(2)$ GPa; the layer thickness to 5.84(40) μm . Thus, the FEL revealed its most important advantage: an extremely fast treatment process which allows the formation of functional layers in the micron-scale. However, further experiments have to be done to localize the parameter range (overlap-parameter, laser energy, scan speed, chamber pressure etc.) to obtain amorphous surface layers.

Danksagung

Zum Gelingen und zur Durchführung dieser Arbeit haben viele Menschen beigetragen, die mich während der Jahre der Konzentration auf das Thema unterstützt haben und denen ich an dieser offiziellen Stelle danken möchte.

Besonderen Dank gilt meinem Doktorvater Herrn Prof. Dr. Peter Schaaf für die interessante Aufgabenstellung, die weit genug gefasst war, mir nicht die Freiheit bei der Aufgabenstellung der Arbeit zu nehmen und die vielfältige Unterstützung durch immerwährende Diskussionsbereitschaft und Anregungen. Danken möchte ich auch Herrn Prof. Dr. Reiner Kirchheim für die kurzfristige Übernahme des Zweitgutachtens.

Ebenso möchte ich mich auch bei den Institutsmitgliedern des II. Physikalischen Institutes für die stetige Unterstützung und Hilfe, der guten Stimmung und Zusammenarbeit bedanken. Besonders hervorheben möchte ich Daniel Höche für die FEL Bestrahlung meiner Proben und seiner Hilfe bei den Härtemessungen, Christian Lange aka LSL ("Laser Safety Locke") für die Instandhaltung unserer Laser, Hendrik - Henni - Schikora für das Polieren der ADI Proben, sowie Hayo Zutz für das FIB-Präparieren meiner Proben und für die ein oder andere Problemlösung am TEM. Nicht zu vergessen sind in dieser Aufzählung auch Daniel Jürgens und Dr. Michael Uhrmacher für die PAC Untersuchungen. Durch das umsichtige Verhalten aller Institutsmitglieder wurde eine recht familiäre Atmosphäre geschaffen, die das Arbeitsklima immer angenehm gestaltete.

Auch den Kollegen anderer Institute möchte ich an dieser Stelle meinen Dank aussprechen; besonders hervorheben möchte ich Priv-Doz. Michael Seibt für die Einführung in die Transmissionsmikroskopie, sowie Prof. Dr. Al-Kassab für die FIB Untersuchungen.

Nicht versäumen will ich, mich bei den Werkstätten des II. Physikalischen Instituts für die große Hilfsbereitschaft bei der Lösung all der vielen Probleme zu bedanken. Stellvertretend seien hier nur die beiden Werkstattleiter Klaus Arndt und Kurt Schemmerling genannt. In diesem Zusammenhang gilt Andreas König besonderen Dank, da meist er mit der Bearbeitung meiner Aufträge beauftragt wurde und er auch das literarische Quartett beim Mensaessen (Daniel - Ocken? -, Christian - sexistische Kackscheiße - Andreas als rote Socke und mir - Salat? Bin ich ne Raupe???) komplettierte.

Die Bewältigung all der kleinen und großen Alltagsprobleme wären ohne Christa Wohlfarth, Ina Watterott, Lucie Hamdi und Heike Ahrens wohl nicht zu meistern gewesen. Vielen Dank für all die Hilfe in den letzten Jahren.

Für aufmerksames Durchsehen meiner Arbeit, anregende Diskussionen bzw. Soforthilfe bei inhaltlichen, chemischen- oder auch Computerfragen möchte ich Andreas Schenk danken. Vor allem jedoch für die kleinen Dinge des Alltags, die uns seit 16 Jahren Freundschaft begleiten und sich auch in beruflicher Produktivität niedergechlagen haben und dies hoffentlich in Zukunft auch tun werden.

Last but not least möchte ich meiner Familie danken. Sie hat mir eine Universitätsausbildung als so selbstverständlich erscheinen lassen und mich von jeher an in

jedweder Hinsicht unterstützt und an mich geglaubt. Danke für Euren Rückhalt.

Curriculum vitae

Name: Salvatore Cusenza
Geburtstag: 18. Dezember 1979 in Wolfsburg/Niedersachsen
Adresse: Krumme Stücke 14, 38446 Wolfsburg
Staatsangehörigkeit: italienisch
Familienstand: ledig

Ausbildung

1986-1990 Eichendorff-Schule I (Grundschule)
1990-1992 Eichendorff-Schule II (Orientierungsstufe)
1992-1999 Ratsgymnasium Wolfsburg
1999-2005 Diplom-Studium der Physik an der Georg-August Universität zu Göttingen
2006-2008 Promotionsstudium an der Georg-August Universität zu Göttingen

Berufliche Tätigkeiten

2002-2004 Werksstudent der Volkswagen AG Wolfsburg (PM-5/PM-V Verfahrenstechnik, F&E)
2002-2005 Nebentätigkeiten während des Studiums: Studentische Hilfskraft im physikalischen Anfängerpraktikum
2006-2008 Wissenschaftlicher Mitarbeiter am II. Physikalischen Institut der Georg-August Universität zu Göttingen
