

Neurodegeneration in toxin-mediated demyelinating
animal models of Multiple Sclerosis

Dissertation

for the award of the degree
“Doctor of Philosophy” (Ph.D.)
Division of Mathematics and Natural Sciences
of the George-August-Universität Göttingen

submitted by

Natalia Manrique Hoyos

born in

Cali, Colombia

Göttingen 2012

Members of the Thesis Committee:

Prof. Dr. Mikael Simons, Reviewer

Max Planck Institute of Experimental Medicine
Department of Neurology, University of Göttingen

Prof. Dr. Wolfgang Brueck, Reviewer

Department of Neurobiology, Max Planck Institute for Biophysical Chemistry

Prof. Till Marquardt, Ph.D.

Department of Neurogenetics, Max Planck Institute of Experimental Medicine

Date of the oral examination: 18 October, 2012

Affidavit

I hereby declare that this PhD thesis “**Neurodegeneration in toxin-mediated demyelinating animal models of Multiple Sclerosis**” has been written independently with no other aids or sources than quoted.

- T Thymine

Acknowledgements

I would like to thank my supervisor Mikael Simons for giving me the opportunity to join his group, supporting me during my PhD, and introducing me with remarkable patience to the world of scientific research. Thank you Mika, for your encouragement and unrelenting enthusiasm.

My most sincere gratitude to Michael Hörner and Sandra Drube from the IMPRS Neuroscience coordination office for their constant support throughout all these years.

I deeply appreciate the funding and educational support by the Max Planck Society, the IMPRS Neuroscience, the Göttingen Graduate School for Neurosciences, Biophysics, and Molecular Biosciences (GGNB) and the Georg-Augusta University.

I am enormously grateful to Doron Merkler and his group (Tanja, Mario and Mariann) for temporarily "adopting" me, teaching me their techniques and always being willing to share their knowledge with patience and friendliness.

I thank Prof. Wolfgang Brück and Prof. Till Marquardt for the fruitful discussions as members of my PhD thesis committee.

I also appreciate all the help from our collaborators: Henning Urlaub, Mads Groenborg, Aniket Ghosh and Tanja Kuhlmann.

I thank all the help from Giselheid and Karla and their loving willingness to help me communicate with my struggling German.

I would like to mention the colleagues and friends in AG Simons, who provided what is possibly the liveliest and friendliest working environment possible: Giselheid Schulz, Larisa Yurlova, Lena Steshenko, Dirk Fitzner, Nicolas Snaidero, Aniket Ghosh, Holger Budde, Chieh Hsu, Katrin Strauß, Mareike Schnaars, Mostafa Bakhti, Sebastian Schmitt,

Shweta Aggarwal, Johannes Zimmermann, Tina Kling, Shima Safaiyan, Schanila Nawaz, Nils Halbsgut and Marie-Theres Weil. I specially appreciate all the support and friendship from Shweta, Dada and Mosi, as well as our existential conversations over coffee about work and life.

My dear friends who accompanied me throughout all this experience and made Göttingen my second home: Mayur, Alonso, Jonas, Adema, Amanda, Adi, Sanaz, Steph, Andrea, Matthieu, Patricia. Also my classmates from the IMPRS Neuroscience for a wonderful first year.

My precious mini-group of unconditional support: Alwaleed and my sis Derya.

Andrew for sharing wonderful moments with me and for his amazing patience during my whiniest of days.

My parents for their unconditional love and enormous efforts to give us the best life and education possible. My sister Carolina for staying close throughout the distance and the oceans between us. My brother Juan Carlos and my nephew Tomas, for reminding me of the things that really matter in life. My lovely Mona, just for being adorable and making me feel so welcome when I come home. And special thanks to my mom and her youthful heart, for constantly pointing out how life is so short and should be enjoyed above all.

Abstract

Myelin is produced by a specialized membrane of oligodendrocytes in the CNS. This multilayered structure enwraps axons, providing them with trophic support and facilitates the fast transmission of electric signals. To study the short-term impact of demyelination, histological analysis was performed in a mouse model where myelinating oligodendrocytes are ablated by the expression of diphtheria toxin receptor in mature oligodendrocytes and systemic diphtheria toxin injection. We observed that it results in a fatal disease where demyelination of white matter tracts is accompanied by microglia activation and axonal damage. We demonstrated that this model is therefore well suited for studying demyelination-mediated axonal injury and myelin degradation in the short term.

To investigate the impact of episodes of reversible demyelination on long-term locomotor performance and neuro-axonal integrity, cuprizone-treated animals were monitored using motor skill sequence (MOSS), to observe whether a functional recovery was attained and maintained in the long-term. Despite complete apparent recovery, treated animals exhibited late-onset motor impairment and ongoing acute axonal damage. This model mimics many of the aspects of axonal pathology observed in chronic progressive MS and might therefore be useful in studying the factors initiating, sustaining or compensating axonal damage.

Finally, since myelin neuroprotection most likely involves a direct communication between axons and oligodendrocytes, proteomic analysis of myelin fractions enriched in axo-glial regions was performed to identify novel candidates involved in axo-glial interaction in the context of myelin biogenesis. A battery of functional assays was established and used to evaluate identified candidates to determine their role in axoglial communication and myelin formation. We identified that some members of the IgLON family bound to both oligodendrocytes and axons. We observed that these proteins have no effect on the

migration, proliferation, differentiation of oligodendrocyte precursor cells. However, we observed that one member, Ntm negatively impacts the early stages of myelination.

Chapter 1

Introduction

1.1 CNS Myelin biology

1.1.1 CNS organization

The central nervous system (CNS), composed of the brain and the spinal cord, controls the behavior of bilaterian organisms. It integrates sensory inputs and conveys signals produced by specialized cells to either generate a motor output, communicate to the endocrine system, or carry out learning and memory processes (Kandel et al., 2000). The CNS is comprised of a heterogeneous population of cells, classified into neurons and glia (Virchow, 1846; Verkhratsky and Butt, 2007). Neurons convey messages by the transmission of electric signals along specialized processes, called axons. This triggers a release of neurotransmitters at a specialized junction between neurons called the synapse, where information is transmitted directionally from the pre-synaptic axon terminal to the post-synaptic neuron. The type and abundance of neurotransmitter released and receptors present on the postsynaptic membrane determines the response elicited in the apposing cell (Cajal, 1894; Jessell and Kandel, 1993).

Despite the fundamental role of neurons, the majority of the CNS is composed of glial cells. They form a heterogeneous group of cells that closely interact with neurons. In the vertebrate CNS, glial cells are traditionally classified into microglia, and macroglia; the latter mainly composed of ependymal cells, astrocytes and oligodendrocytes (Verkhratsky and Butt, 2007). Microglia are of mesodermal origin, migrating into the brain early during

development, and perform both as immune cells and macrophages in the CNS (Kreutzberg, 1996). Ependymal cells line the ventricles and central canal and are responsible for the production of cerebrospinal fluid (CSF). Astrocytes interact closely with synapses, maintaining ionic balance and providing trophic support, among other functions (Kandel et al., 2000). Finally, oligodendrocytes form myelin by wrapping their processes around axons in the CNS (Bunge et al., 1962).

1.1.2 Myelination process

Myelin, a specialized membrane, wraps repeatedly around axons and is produced by oligodendrocytes in the CNS (Bunge et al., 1962). Oligodendrocyte precursor cells (OPCs), also termed oligodendrocyte-type 2 astrocyte (O-2A) progenitors, originate during development mainly from the subventricular zones in the brain and the ventral region of the spinal cord (Reynolds and Wilkin, 1988; Compston et al., 1997). OPCs express the gangliosides GD3 and A2B5, as well as the intermediate filament Vimentin. They can also be identified by their expression of NG2 chondroitin sulphate proteoglycan or platelet-derived growth factor α receptor (Levine et al., 2001). They proliferate and migrate throughout the brain and spinal cord. Upon axonal contact, a transition into a premyelinating state is induced, identified by the expression of the surface marker O4, as well as GalC, PLP, and its smaller isoform, DM20 (Levine et al., 2001; Verkhratsky and Butt, 2007).

Following axonal ensheathment, several layers are loosely wrapped around the axon, followed by a drastic cytoplasmic extrusion and compaction of the layers of myelin, called lamellae. The compacted cytoplasmic region between two membranes is called the major dense line, and the space between two opposed membranes, facing the extracellular space, is called the intraperiod line. In mice, this process begins at birth and fully compacted myelin can be found few days later. Myelination peaks at around postnatal day 20 and most myelination is complete by postnatal day 60 (Baumann and Pham-Dinh, 2001). In humans, myelin formation begins mid-gestation and is complete around the third postnatal year (Parazzini et al., 2002). In the peripheral nervous system (PNS), where myelin is formed by Schwann cells, an axonal diameter of minimum 0.2 μm is a critical parameter for an axon to become myelinated. In the CNS, even though an axon with a diameter smaller than 0.2 μm is also unlikely to be myelinated, it is believed that additional factors contribute to the onset of myelination. For instance, the adhesion protein NCAM

has been found to inhibit myelination and its downregulation is necessary for myelination onset, while L1 increases oligodendrocyte survival and myelination *in vitro* (Verkhatsky and Butt, 2007; Fewou et al., 2007; Laursen et al., 2009).

1.1.3 Myelin structure

As the myelin sheath extends along an axon, it undergoes molecular and structural specialization. A single segment is composed of domains differing in their structure, level of compaction, size, and protein/lipid composition. The formation of myelin involves the close apposition between the oligodendrocyte and axonal membranes, as well as the coordinated establishment of intercellular protein complexes. The axo-glial communication facilitates the formation of the molecular and structural domains that characterize a myelin segment, such as the clustering of sodium channels at the internode, the formation of the paranodal loops and the segregation of potassium channels to the juxtaparanodes (Poliak and Peles, 2003; Salzer et al., 2008). The paranodes are found at each edge of the myelin segment and are of special interest as they contain adhesion proteins that form axo-glial contact sites (Baumann and Pham-Dinh, 2001).

For instance, Neurofascin155 is expressed in the paranodes by oligodendrocytes and interacts with the Contactin-Caspr1 complex (Tait et al., 2000), expressed on the axonal side. Neurofascin loss results in the disorganization of the paranodes, degeneration of myelinated axons, ataxia and premature death (Pillai et al., 2009). Therefore, these proteins are crucial in the correct formation of myelin, and the survival of those axons. In general, myelin can be classified into compacted and non-compacted areas. The compacted areas are found between the inner and outer tongue along the internode, and consist of closely apposed layers of myelin, with a minimal cytoplasmic content. The non-compacted areas comprise the inner and outer tongue of myelin, paranodes and juxtaparanodes.

1.1.4 Myelin composition

Myelin is formed by a specialized membrane, which has a specific protein and lipid composition. In contrast to the plasma membrane, regularly composed of 50% lipids and 50% proteins in dry weight, myelin is enriched in lipids, which make up to 80% of the dry weight, with the remaining 20% contributed by proteins (Pfeiffer et al., 1993). Lipids enriched in myelin include galactocerebroside and sulfogalactosylceramide. Cholesterol is

also a very abundant lipid in myelin, as cholesterol, phospholipids, and glycolipids are found in molar ratios ranging from 4:3:2 to 4:4:2 (Baumann and Pham-Dinh, 2001).

The major proteins enriched in myelin are proteolipid protein (PLP) and myelin basic protein (MBP), which together comprise around 80% of the total myelin protein composition (Campagnoni and Macklin, 1988). Other proteins found in myelin are myelin oligodendrocyte glycoprotein (MOG), myelin-associated glycoprotein (MAG), and myelin-associated oligodendrocytic basic protein (MOBP), 2',3'-Cyclic-nucleotide 3'-phosphodiesterase (CN-Pase), Neurofascin155 and Claudin 11 (Baumann and Pham-Dinh, 2001). The distribution of these proteins varies between areas. The layer closely in contact with the axon, or adaxonal membrane, is enriched in MAG and runs along the internodal length. MBP and PLP are found mostly in compacted areas of myelin, while the paranodes and juxtaparanodes present Neurofascin 155 and Tag1, respectively, as depicted in Figure 1.1 (Poliak and Peles, 2003; Salzer, 2003; Aggarwal et al., 2011). *In vitro*, this distribution is in part determined by the restriction of proteins with a bulky cytoplasmic termini to non-compacted areas of myelin (Aggarwal et al., 2011). However, the mechanism for protein segregation in the multilayered myelin structure in *in vivo* is still unclear.

1.1.5 General function of myelin

Due to its tight and compacted structure, myelin provides high resistance electric insulation for axons, which results in the fast and saltatory conduction of electric signals from one myelin-free area to the next (Pfeiffer et al., 1993). These areas within the axon are called nodes of Ranvier, where an accumulation of voltage-gated sodium channels can be found. This facilitates the renewal of the action potential at the nodes and the further transmission of the electric signals along the axon (Salzer, 1997).

In addition to contributing to the amplification and faster propagation of the action potential along the axon, myelin can influence other internal processes in the axon, such as fast axonal transport and axonal diameter regulation (de Waegh et al., 1992). Most importantly, it has been found that myelin can be relevant for short- and long-term axonal preservation and survival. It has been found that a late-onset neurodegeneration occurs in mice lacking several myelin proteins, even when at a structural level, myelin appears

Figure 1.1: General myelin structure and protein distribution at the axo-glial junction. Structural and molecular architecture of myelin in the CNS. Direct axo-glial junctions can be found in the paranodal and juxtaparanodal areas, where intercellular protein contents are located. Caspr, contactin-associated protein; Cntn, contactin (Cntn2 is also known as Tag1); Cx29, connexin 29 kDa; KCh, fast potassium channels; MAG, myelin-associated glycoprotein; MBP, myelin basic protein; MOBP, myelin oligodendrocyte basic protein; NaCh, voltage-gated sodium channels; NECL, nectin-like protein/synCAM; NF155/186, neurofascin 155 kDa/186 kDa; OSP, oligodendrocyte specific protein or Claudin 11; PLP, proteolipid protein. The figure is adapted from Nave (2010). Reprint by permission from Macmillan Publishers Ltd: Nature, copyright (2010).

normal (Nave and Trapp, 2008). This suggests that it has a nurturing role in addition to serving as an insulating surface.

1.2 Myelin disorders

The suboptimal formation of myelin during development, or dysmyelination, results in several clinically relevant disorders (Verkhratsky and Butt, 2007). For instance, a duplication or missense mutation of the *Plp1* gene, results in Pelizaeus-Merzbacher disease, characterized by hypomyelination and presenting a wide phenotypic range, from mild spasticity to an early lethality (Pham-Dinh et al., 1993). Also, myelin alterations have been associated to different psychiatric diseases, including depression and schizophrenia (Fields, 2008).

Proper myelin function depends not only on its formation, but also on the efficiency of its repair mechanisms. During normal aging, several myelin anomalies have been identified. These are mainly vacuolization, accumulation of cytoplasm along the major dense line, formation of redundant myelin and lamellae disruption (Peters, 1996). This results in an altered insulation and abnormal electric propagation along the axon, which can affect neural circuits necessary for complex behavior (O'Sullivan et al., 2001). A decrease in neuronal connectivity between brain regions could be responsible for the cognitive decline observed in aging (Peters, 2002). However, most of the attention directed towards myelin formation and repair has been due to disabling diseases such as multiple sclerosis.

1.2.1 Multiple sclerosis

1.2.1.1 Immunopathology

Multiple sclerosis (MS) is the most common disabling disease in young adults. In its early stages, this autoimmune disease is characterized by an inflammatory reaction against myelin in the CNS. The infiltration of lymphocytes and monocytes across the blood-brain barrier (BBB), which initiate an inflammatory response, results in demyelination and axonal loss along multifocal lesions in the CNS, as shown in Figure 1.2 (Trapp et al., 1998; Noseworthy et al., 2000; Friese et al., 2006). A major contribution comes from autorreactive CD4+ T cells that generate proinflammatory cytokines and chemokines, resulting in the activation of local microglia and infiltrated macrophages (Martin et al., 1992; Sospedra and Martin, 2005).

CD8+ T cells also have been found to invade the CNS and contribute to the cytotoxicity and inflammation observed in MS (Friese and Fugger, 2005). Different lesion patterns have been described, and in many lesions demyelination seems to be caused by the inflammation mediated by T-cell and macrophages/microglia with or without antibody deposition (lesion pattern I-II). However, lesions where demyelination seems to take place due to a primary oligodendroglial dysfunction (lesion patterns III-IV) were also found (Lucchinetti et al., 2000). This could suggest the existence of independent mechanisms of demyelination across different subgroups or stages of MS. Although the etiology of MS is still unclear, it is believed that a combination of genetic predisposition and environmental factors and

viral infections ultimately contribute to trigger the disease (Hemmer et al., 2002; Gold et al., 2006).

Figure 1.2: Demyelination in the CNS. Following demyelination and oligodendrocyte death, a thinner and shorter myelin sheath can be formed in the nude regions of affected axons by remyelination. The axons that remain demyelinated are prone to degenerate. The figure is adapted from Franklin and Ffrench-Constant (2008). 1.2.1.2 Symptoms and progression

The most frequent symptoms in MS are loss of motor function, sensory impairment, fatigue and cognitive deterioration (Nosworthy et al., 2000). The Kurtzke Extended Disability Status Scale or EDSS is used to quantify the level of disability and ambulatory state of

MS patients, and ranges from 0.0 (normal) to 10.0 (death due to MS). It defines seven functional systems (FS): pyramidal, cerebellar, brainstem, sensory, bowel/bladder, visual, cerebral and other which are analysed separately (Kurtzke, 1983). It is used to describe the course of MS and is often used as a readout of the effectiveness of therapeutic approaches in clinical trials.

Approximately 85% of patients initially present a series of discrete inflammatory episodes with reversible clinical symptoms, called relapsing-remitting MS (RRMS) (Confavreux et al., 1980; Weinshenker et al., 1989). MS is usually detected in the second or third decade of life and after a median time of 19 years after initial diagnosis, approximately 70% of the patients suffer a transition into secondary progressive MS (SPMS) (Noseworthy et al., 2000). Secondary progression is usually defined as a period of continuous clinical worsening, persisting for at least six months. Only about 10-15% of patients present a progressive increase in neurological disability from the initial onset, called primary progressive MS or PPMS (Sospedra and Martin, 2005).

Since progressive MS results in the patient's permanent disability, it is clinically relevant to elucidate the mechanisms triggering the transition into the progressive stage. One of the most significant factors associated with progressive MS is age, with the conversion occurring at a mean age of 39 years (Kremenchtzky et al., 2006). In addition, location of new lesions can help predict future disability, with lesions in the frontal lobe correlated with cognitive deficits and in the brain stem with motor defects (Wybrecht et al., 2012). Once a disability threshold is reached, measured as a score of 4 in the EDSS, these variables no longer influence the course of the disease (Confavreux et al., 2003; Vukusic and Confavreux, 2007). Surprisingly, the speed at which patients develop neurological deficits in progressive MS is remarkably similar between patients (Confavreux et al., 2000; Rovaris et al., 2006).

Thus, the onset of progressive MS does not appear to be exclusively determined by the inflammatory load that arises during the relapsing-remitting course of the disease. Even though the initial relapsing-remitting stage of the disease is considered to be highly vari-

able and unpredictable, the progressive phase seems to follow a common path (Antel et al., 2012). All of these findings raise the question of how chronic progressive MS is triggered and whether non-inflammatory mechanisms play a crucial role independent from the number of relapses. In addition, it is likely that aging processes themselves might be relevant for the initiation of the progressive phase of the disease (Tutuncu et al., 2012). However, the exact pathways involved in this transition remain unclear.

1.2.1.3 Therapeutic approaches

Several therapies have been developed and approved to ameliorate MS symptoms. Currently, the drugs approved for the treatment of MS treatments include glatiramer acetate and IFN- β , along with second-generation drugs such as sphingosine-1-phosphate receptor agonist (Fingolimod), a humanized monoclonal antibody against alpha 4 integrin called Natalizumab and Mitoxantrone (Rovaris et al., 2006; Yadav and Bourdette, 2012).

Glatiramer acetate, also known as Copolymer 1 or Copaxone, is a mixture of synthetic polypeptides that reduces the inflammatory response and was found to decrease relapse frequency and severity in RRMS patients (Johnson et al., 1995). IFN- β is a cytokine which reduces the number and appearance of active lesions and the overall disease burden defined as the cumulative lesion area in MS patients (Group, 1993; Paty et al., 1993). Fingolimod (FTY720) is a sphingosine-1-phosphate receptor agonist that sequesters lymphocytes in lymph nodes, inhibiting their distribution and infiltration of the CNS. This anti-inflammatory property has been shown to reduce relapse frequency in RRMS patients, however it does not improve disease progression (Cohen et al., 2010).

A humanized monoclonal antibody against alpha-4 integrin commercially known as Natalizumab has been re-approved for MS treatment due to its effective immunomodulatory function despite its rare but potentially fatal side effects. It binds to $\alpha 4\beta 1$ and $\alpha 4\beta 7$ integrin molecules on the surface of lymphocytes and blocks their interaction with endothelial cells, preventing their transmigration across the blood-brain barrier and immune cells infiltration of the CNS (Polman et al., 2006). Finally, mitoxantrone is a synthetic compound approved for the treatment of leukemia that inhibits T cell, B cell and macrophage proliferation, as well as decreases pro-inflammatory cytokine secretion and antibody production

(Fox, 2004). Most of the approved treatments target the modulation of the autoimmune response and are therefore mostly directed towards controlling the acute inflammatory episodes of relapsing-remitting or early MS. However, they do not appear to have a neuroprotective or a disease-modifying effect in non-relapsing progressive MS stages (Rovaris et al., 2006; Ransohoff, 2012).

1.2.2 Demyelinating animal models

To study demyelination and its consequences *in vivo*, several animal models have been established to resemble different traits of MS. Among the diverse models, the most common approach involves the induction of an autoimmune reaction against myelin components or the use of cytotoxic substances that result in loss of oligodendrocytes.

1.2.2.1 Experimental Autoimmune Encephalomyelitis (EAE)

The most widespread MS model is the Experimental Autoimmune Encephalomyelitis or EAE. It is based on the induction of auto-reactive T cells to proliferate and cross the blood-brain barrier. This is attained by either an “active” or a “passive” immunization. The active immunization involves injecting mice, rats or non-human primates with either myelin protein epitopes (frequently the 35-55 amino acid residues of the MOG peptide), or myelin/spinal cord preparations, usually in Complete Freund’s Adjuvant (Steinman, 1999; Friese et al., 2006). T cells that are reactive against these components proliferate and cross the brain-blood barrier, where they are reactivated by MHCII-expressing macrophages or dendritic cells, which act as antigen-presenting cells (APC). This reactivation triggers a T cell-mediated inflammatory reaction against myelin, resulting in focal demyelinating lesions and cytokine release. There is an important contribution from microglial activation and proliferation, which release NO and other cytotoxic factors and contribute to the severity of the disease (Heppner et al., 2005). Passive immunization consists of the transfer of isolated autoreactive T cells to a naive recipient, which results in a similar BBB infiltration and inflammatory response (Mokhtarian et al., 1984).

EAE is one of the most widely used MS models due to the induction of an autoimmune reaction specifically against myelin components which results in demyelination and motor phenotype that resembles the clinical symptoms of MS patients. Certain variations of the EAE model, depending on the epitope and the mice strain used, can result either in a

single or repeated demyelinating events, which resemble the common relapsing-remitting pattern of MS. This makes EAE seem ideal for the trial of novel therapeutical approaches. However, most of the treatments that have been described to have a beneficial effect in preclinical EAE studies have been shown to have either none or sometimes even adverse effects in MS patients (Steinman, 1999; Friese et al., 2006). However, it has been useful in the development of glatiramer acetate, Mitoxantrone, and Natalizumab, described in the previous section (Teitelbaum et al., 1971; Ridge et al., 1985; Yednock et al., 1992).

Another disadvantage of the EAE model for MS is that the assessment of remyelination is difficult since demyelinating lesions are variable in localization and timing. In addition, it seems to overestimate the role of CD4+ T cells, as B and CD8+ T cells show a minimal involvement in EAE, opposed to what has been observed in MS patients (Ransohoff, 2012). Due to the nature of the model, EAE has been useful in testing and developing therapies that ameliorate the acute inflammatory stages of the disease via immunomodulation, but has provided little contribution to the understanding of MS progression (Nakahara et al., 2012). Clearly, additional models of MS are necessary to understand processes that are not sufficiently represented in EAE.

1.2.2.2 Cuprizone

Cuprizone (bis-cyclohexanone-oxaldihydrazone) is a chemical compound commonly used as a copper-chelating agent. Feeding mice with 0.2-0.5% cuprizone for at least three weeks results in oligodendrocyte death and demyelination. The induced demyelination is most prominent in the corpus callosum and superior cerebellar peduncle, where more than 90% of axons are affected (Blakemore, 1973a). As a result of the myelin debris that results from oligodendroglial death, there is a massive proliferation and activation of astrocytes and microglia (McMahon et al., 2002). This reaction occurs without disruption of the blood-brain barrier or infiltration of the immune system (Matsushima and Morell, 2001). This resembles, to a certain extent, pattern III MS lesions of a primary oligodendropathy (Lucchinetti et al., 2000). After cuprizone is removed from the diet, an extensive formation of new myelin, or remyelination, can be observed in 5 to 6 weeks (Merkler et al., 2005; Blakemore, 1973b). However, if the cuprizone treatment is increased to 12 weeks or more, insufficient remyelination and epileptic seizures can be observed (Hoffmann et al., 2008).

The exact mechanism of cuprizone-induced apoptosis in oligodendrocytes remains unknown, but it is believed to be related to a copper deficiency caused by the chelating property of the toxin. Cuprizone has been shown to inhibit copper-dependent enzymes like cytochrome oxidase and monoamine oxidase, and appears to decrease the activity of several mitochondrial respiratory complexes, in particular complex IV (Matsushima and Morell, 2001; Pasquini et al., 2007). It also arrests OPCs maturation, inhibiting remyelination and therefore, increasing the severity and duration of the demyelinating insult (Cammer, 1999). Since this model involves minimal infiltration by the immune system and acts to preserve the integrity of the blood-brain barrier, it is widely used as a model of de- and re-myelination. Due to its reliable timing and location it is especially useful in elucidating the mechanisms involved in myelin clearance and remyelination, independent of the side effects commonly observed in an immune-derived inflammation and cytotoxicity.

1.2.2.3 Diphtheria-toxin oligodendrocyte ablation and other models

Necrotic lesions can be induced by the local injection of diphtheria toxin (DT). The susceptibility to this toxin varies among species: humans, rabbits and guinea pigs have been found to be very sensitive to the toxin, while rats and mice have been shown to be highly resistant (Pappenheimer and Gill, 1973). This susceptibility depends on the expression of high-affinity DT receptors, which are either scarce or absent in the cells of resistant species (Middlebrook and Dorland, 1977; Naglich et al., 1992). Elevated concentrations of diphtheria toxin are necessary to induce cytotoxicity in resistant cells, requiring more than 100-fold concentration of the toxin to elicit the same response as in sensitive cells. The toxin acts by binding to its receptor and triggering its internalization. The toxin is subsequently cleaved and one of the proteolytic products, Fragment A, is liberated into the cytoplasm. This fragment inactivates the elongation factor EF-2 by ADP-ribosylation (Collier, 1967; Honjo et al., 1969), resulting in translation arrest and inhibition of new protein synthesis, ultimately leading to apoptotic cell death. It has been found that a single DT molecule is capable of killing a eukaryotic cell (Yamaizumi et al., 1978).

Resistant cells can be sensitized to DT by inducing the expression of the primate diphtheria toxin receptor, the heparin-binding epidermal growth factor-like (HB-EGF) precursor (Naglich et al., 1992; Saito et al., 2001). iDTR transgenic mice have been created by the introduction of a gene encoding the DT receptor with a lox-P flanked stop cassette in its

open reading frame. Upon Cre-mediated recombination, the stop cassette is removed and the functional DT receptor is expressed. By crossing these mice with lines expressing Cre recombinase under cell-lineage specific promoters, targeted cell ablation can be induced through the injection of DT (Buch et al., 2005).

In another approach, a floxed LacZ within the gene encoding DT Fragment A allows the expression of the catalytically active DT-A upon Cre-mediated recombination. This active DT Fragment A has the capacity of inducing cell death in the absence of a functional receptor, since the expression takes place from within the targeted cell (Brockschneider et al., 2004). Mice carrying the *iDTR* gene and expressing Cre under the *Mog* promoter express a functional diphtheria toxin receptor solely in mature oligodendrocytes. The injection of DT in these mice has been shown to result in a massive oligodendrocyte death and systemic demyelination (Buch et al., 2005). On the other hand, the expression of diphtheria toxin A subunit in an inducible PLP-Cre mouse line results also in the apoptotic death of mature oligodendrocytes (Traka et al., 2010). Other cytotoxic demyelinating models include the local injection of ethidium bromide (Blakemore, 1982) or lysolecithin (Hall, 1972).

Viruses have been proposed to be a factor contributing to the onset of MS, presumably creating an autoimmune response triggered by a molecular mimicry or recognition of some myelin proteins epitopes as foreign due to an infection in the past (Chastain and Miller, 2011; Owens et al., 2011). Some of the evidence supporting this idea originates from viral models of inflammatory demyelination, including the infection with human endogenous retrovirus (HERV) expressing recombinant syncitin (Antony et al., 2004), the A59 strain of mouse hepatitis virus (Lavi et al., 1984), the Semliki-Forest virus (Amor et al., 1996) and Theiler's murine encephalomyelitis virus (Sato et al., 2009).

1.3 Neuroprotective function of myelin

In addition to its insulating properties, myelin has been found to be essential for long-term axonal survival. Alterations in myelin composition can trigger neurodegeneration (Nave and Trapp, 2008). For instance, mice lacking myelin-associated glycoprotein (MAG),

2',3' - cyclic nucleotide 3-phosphodiesterase (CNPase) and proteolipid protein (PLP) form structurally almost normal myelin, but develop late-onset, chronic progressive neurodegeneration (Griffiths et al., 1998; Yin et al., 1998; Lappe-Siefke et al., 2003). Axonal swelling, transections and an impairment of axonal transport occur in these mice, highly reminiscent of the changes found in MS lesions (Ferguson et al., 1997; Trapp et al., 1998; Kornek et al., 2000). Interestingly, *shiverer* mice, which lack myelin basic protein (MBP), form only small amounts of myelin. Even though this results in severe behavioral phenotype, with epileptic seizures, tremors and premature death (Roach et al., 1983; Popko et al., 1987), they do not exhibit conspicuous signals of axonal damage or degeneration (Griffiths et al., 1998). This raises the possibility that, although unmyelinated axons can survive on their own, axons that indeed are myelinated require an intact sheath for their maintenance, and they may require trophic support due to their isolation from external metabolite sources (Nave and Trapp, 2008).

1.3.0.4 Remyelination and myelin repair

Following demyelination, the damaged myelin is not repaired but can be replaced through a process called remyelination, which restores saltatory conduction and trophic support to the axon (Smith et al., 1979). Immature oligodendrocyte precursors migrate to demyelinated areas, and after a process closely resembling OPC maturation during development, they extend processes that surround the unmyelinated axons and form a new myelin sheath (see **Figure 1.3**). This myelin is normally thinner, with shorter internodes (Franklin and French-Constant, 2008). Remyelination efficiency decreases with time in MS (Wolswijk, 1998; Franklin, 2002), and different demyelinating animal models show that age negatively influences the recruitment and differentiation of OPCs after demyelination (Shields et al., 1999; Sim et al., 2002).

Two steps are crucial for remyelination to occur: the recruitment of OPCs to the demyelinated area, followed by their differentiation and maturation into myelinating cells. Several factors leading to differentiation inhibition and therefore remyelination impairment have been identified (Huang et al., 2011). For instance, myelin debris inhibits OPC differentiation; therefore its clearance is crucial for remyelination efficiency (Kotter et al., 2006; Pohl et al., 2011). This inhibition seems to involve the activation of Fyn-Rho-ROCK and protein Kinase C pathways (Baer et al., 2009). Hyaluronan deposition has been found

in EAE and chronic MS lesions, and inhibits OPC differentiation through its binding to toll-like receptor 2 (TLR-2) in OPCs (Sloane et al., 2010). In addition, semaphorins have been suggested as regulatory molecules in remyelination. While Semaphorin 3A has been identified as a repulsive signal and differentiation inhibitor for OPCs, Semaphorin 3F serves as a chemoattractant (Williams et al., 2007; Piaton et al., 2011). Therefore, through a balance and timing of the expression of these two molecules, the recruitment and differentiation extent of OPCs within a demyelinated lesion can be coordinated.

Diverse pathways inducing OPC differentiation have been identified. While LINGO-1, Wnt and Notch1 pathways inhibit differentiation (John et al., 2002; Mi et al., 2005), activation of retinoid X receptors (RXR) induce it (Huang et al., 2011). In MS, remyelination failure has been associated to OPC differentiation impairment and to a lesser extent to insufficient recruitment (Wolswijk, 1998; Chang et al., 2002; Sim et al., 2002). As it is crucial to elucidate ways to promote remyelination as a therapeutic approach in MS, targeting these pathways can help modulate the onset and extent of OPC differentiation and help determine the factors that may pose as barriers or inhibitors of this process.

1.3.0.5 Axonal damage in myelin diseases

A decrease in the efficiency of remyelination has been associated to increased axonal damage (Kuhlmann et al., 2002; Irvine and Blakemore, 2006; Hampton et al., 2012). Failure in remyelination results in a greater extent of axonal loss after demyelination, supporting the idea that myelin also provides the axons with trophic support (Irvine and Blakemore, 2008). There is abundant evidence showing that chronically demyelinated axons will degenerate due to a lack of glial support (Lindner et al., 2009). Since remyelination is initiated by recruited OPCs that undergo differentiation, the steps involved in migration, proliferation and maturation of OPCs can determine the clinical outcome of a demyelinating event. Remyelination has been found to fail in advanced stages of MS, but the reasons are unclear. It has been proposed that either the glial scar formed in lesions affects myelination by mature, differentiated OPCs or the OPCs have an intrinsic problems achieving complete differentiation and myelination (Levine et al., 2001).

Nature Reviews | Neuroscience

Figure 1.3: Remyelination in the CNS. Following demyelination, oligodendrocyte precursor cells (OPC) migrate to the demyelinated area and undergo differentiation and remyelination. When recruitment or differentiation of OPC is inhibited, remyelination will be arrested or delayed. The figure is adapted from Franklin and Ffrench-Constant (2008). Reprint by permission from Macmillan Publishers Ltd: Nature, copyright (2008)

Axonal dysfunction and transection has been widely identified in MS lesions (Ferguson et al., 1997; Trapp et al., 1998; Bitsch et al., 2000; Kuhlmann et al., 2002). It has also been shown that small axons are more vulnerable to damage than bigger axons (Evangelou et al., 2001). In fMRI studies, a decrease in the relative concentration of N-acetylaspartate (NAA), measured as the NAA/Creatine ratio (Na/Cr), is thought to reflect axonal injury and is measured using brain MRSI (Matthews and Arnold, 2001). This method has also detected axonal injury not only in areas of demyelination but also in normal appearing white matter (NAWM) (Narayanan et al., 1997; Miller et al., 2003). The accumulation of amyloid precursor protein or APP, is widely used as an evidence of defects in fast axonal

transport and reflects acute axonal dysfunction. APP accumulation has been detected in MS acute lesions as well as on the border of chronic lesions (Ferguson et al., 1997). Axonal damage, evidenced by APP accumulation, is also observed in animal models after acute as well as chronic demyelination (Kornek et al., 2000; Lindner et al., 2009).

The damage induced in axons as a consequence of demyelination can be exacerbated when accompanied by inflammation. Inflammation levels have been shown to directly correlate with the extent of axonal loss (Ferguson et al., 1997; Trapp et al., 1998; Frischer et al., 2009). Inflammation itself can induce mitochondrial dysfunction and irreversible axonal damage even if demyelination does not occur (Nikic et al., 2011). Therefore, an early control of inflammation can reduce the subsequent axonal loss (Bitsch et al., 2000). However, even though anti-inflammatory treatments help to mitigate the severity of damage in the primary stages of MS, it is not clear whether they are able to delay the transition into a secondary progressive stage of MS. Thus, it seems that the natural course of the disease is not solely dependent on inflammation (Confavreux et al., 2003; Brück, 2005).

Reactive oxygen and nitrogen species (ROS and RNS) derived from macrophages/microglia can result in mitochondrial pathology and initiate focal axonal degeneration (Smith et al., 2001; Nikic et al., 2011). It is believed that the nitric oxide (NO) and other cytotoxic products produced by microglia contribute significantly to the blockade of axonal signal transmission and oligodendrocyte death observed in demyelinating lesions (Pasquini et al., 2007).

Even though some axonal damage has been found to be reversible (Stefano et al., 1995; Meyer zu Hoerste et al., 2010), it is believed that the vast majority of the axonal injury in plaques and normal appearing white matter is irreversible (Evangelou et al., 2000). The terminal formation of ovoid structures in axons stained for neurofilament has indicated the transection of axons in demyelinated lesions (Trapp et al., 1998).

1.3.0.6 Mechanisms of functional recovery

Despite the fact that remyelination restores trophic support and normal axonal function to a great extent, axonal loss does occur during the initial stages of MS and its animal models (Kuhlmann et al., 2002; Merkler et al., 2006). However, a functional recovery of clinical symptoms has been observed to occur after demyelination, despite the irreversible axonal loss in the CNS, where axonal regeneration is limited. Similar to what occurs in spinal cord injury, an important fraction of the recovery after demyelination is due to the resolution of inflammation and the reversibility of the conduction blockage in axons. In addition, remyelination and an increased axonal sodium channel expression are mechanisms that have been proposed to contribute to the functional recovery after inflammatory brain injuries (Waxman and Ritchie, 1993; Brück et al., 2003).

If axonal transection occurring as the result of an inflammatory attack is substantial and irreversible, these mechanisms cannot completely account for the functional recovery in patients. Despite considerable axonal loss in initial inflammatory stages of MS, the clinical recovery observed in RRMS patients indicate that symptoms do not directly correlate to initial loss of axons (Compston and Coles, 2008). Only in progressive MS stages, a correlation between ongoing neurodegeneration and irreversible clinical disability is evident (Trapp et al., 1999; Bjartmar and Trapp, 2003). This suggests the existence of compensatory mechanisms that allow for the re-establishment of the circuits necessary for complex motor and cognitive performance. It has been found that cortical adaptation may help compensate the outcome of axonal injury in MS and mitigate the clinical phenotype (Reddy et al., 2000).

Neuroplasticity is thought to allow the formation of circuits in the learning and execution of complex motor tasks. Reddy and colleagues (2000) found that as axonal injury increases, there is a decreased lateralization of sensorimotor cortex (SMC) activation of MS patients when performing a finger tapping exercise. No mirror movements in the opposite hand were detected to account for a contribution of ipsilateral SMC activation. This suggests that there is an increase in the ipsilateral SMC activation during the control of the fingers in order to perform the task at a speed comparable to healthy patients. This decrease in contralateral activation is markedly correlated with an increased axonal

injury, indicating that this reorganization is a mechanism to maintain a normal cognitive and motor performance and can serve as a marker of short term disability (Faivre et al., 2012).

Other evidence of functional reorganization in MS patients has been reported. The hyper-activation of task-related and additional brain structures has been reported to compensate for areas with impaired activation and to preserve cognitive performance. However, it has been proposed that an accumulation of structural damage can result in a ‘burn-out’ of the possible adaptive mechanisms and limit the extent of cortical reorganization (Rocca et al., 2010). In simple motor tasks, initially a higher activation of the associated area is observed, and with the disease progression this increase in activity becomes bilateral, and finally additional, compensatory brain areas are recruited to perform the same simple task (Rocca et al., 2005).

Axonal loss may be compensated for many years during relapsing demyelination before a threshold is reached and compensatory mechanisms are exhausted. Axonal loss might therefore be one of the crucial factors responsible for the conversion of RRMS to SPMS and the resulting progression of clinical disability (Trapp and Nave, 2008). Remyelination is thought to reduce the reliance on compensatory mechanisms and prolong the conversion progressive MS by at least temporarily restoring axonal function and maintenance, however the long-term impact of remyelination on functional recovery and thus neuronal integrity is not well understood.

To study the short-term impact of demyelination, histological analysis was performed in a mouse model where myelinating oligodendrocytes are ablated by the expression of diphtheria toxin receptor in mature oligodendrocytes and systemic diphtheria toxin injection. In addition, cuprizone-treated animals were monitored using motor skill sequence (MOSS), to investigate the impact of episodes of reversible demyelination on long-term locomotor performance and neuro-axonal integrity. Through this study we attempted to elucidate the impact of demyelination in axonal preservation and the role of remyelination in the functional recovery in the long term.

Chapter 2

Materials and Methods

2.1 Materials

2.1.1 Chemicals and consumables

The chemicals used in this study were purchased from Sigma-Aldrich or AppliChem, unless otherwise specified. Cell culture consumables and biochemistry reagents were purchased from Falcon and Eppendorf.

2.1.2 Antibodies

Table 2.1: Antibodies used during this study

Target	Application	Reference
APP	Mouse IgG	Chemicon
β III Tubulin	Mouse IgG	Promega
CD3	Rat	Serotec
CNPase	Mouse IgG	Sigma
Fc (human)	Rabbit	Jackson Laboratories
GFAP	Rabbit	Promega
Iba1	Rabbit	Wako Chem. GmbH
Mac3	Rat	Pharmingen
MAG (clone 513)	Mouse	(Poltorak et al., 1987)
MBP	Rabbit	DakoCytomation
MOG (clone 8-18-C5)	Mouse IgG	Millipore
myc-tag	Mouse IgG	Cell Signalling
myc-tag	Rabbit	Upstate

Nerofilament200, clone N52	Mouse IgG	Sigma
Neurofilament 160	Mouse IgG	Novocastra
Neurofilament 200	Mouse IgG	Novocastra
Neurofilament 68	Mouse IgG	Chemicon
Neurofascin	Rabbit	Abcam
NeuN	Mouse IgG	Chemicon
NogoA, clone 11C7	Mouse IgG	(Liebscher et al., 2005)
O1	Mouse IgM	(Sommer and Schachner, 1981)
PLP (3F4)	Mouse IgG	K. Nave, MPI of Exp. Med., Göttingen, Germany
PLP (AA3)	Mouse IgG	K. Nave, MPI of Exp. Med., Göttingen, Germany

Anti-mouse, anti-rat and anti-rabbit horse radish peroxidase (HRP)-conjugated secondary antibodies used for Western blot were purchased from Dianova. Fluorescence secondary antibodies were purchased from Dianova and Invitrogen.

2.1.3 Commercial Kits

Table 2.2: Commercially available kits

Kit	Application	Producer
Spin Tissue Midi Kit	DNA extraction for genotyping	Invitek
In situ cell detection kit	TUNEL assay	Roche
CytoSelect 24-Well Cell Migration Assay, 8 μ m	Migration assay	CellBioLabs
NucleoSpin Plasmid Quick-Pure	DNA purification, Miniprep	Macherey-Nagel
NucleoBond Xtra EF	DNA purification, Midiprep	Macherey-Nagel
NucleoSpin Gel and PCR clean up	DNA extraction and purification	Macherey-Nagel
Protein A HP Spin Trap Columns	Fc-fusion protein purification	GE Healthcare

2.1.4 DNA plasmids and primers

2.1.4.1 DNA plasmids

Vectors, commercial and previously published plasmids are listed below.

Table 2.3: Acquired DNA constructs used in this study

Construct	Vector	Description/Application	Source
EGFP-Tmem10	pcDNA3.1(-)	Expression of EGFP tagged Tmem TMD, used for cloning of EGFP-tagged proteins	Shweta Aggarwal
myc-Tmem10-MBP	pcDNA3.1(-)	myc-tagged Tmem TMD and MBP sequence, used for cloning of myc-tagged proteins	Shweta Aggarwal
EGFP-C1	EGFP-C1	expression of EGFP in mammalian cells	Clontech
Necl1-Fc	pSX	Expression of Fc fusion Necl1	(Spiegel et al., 2007)
Necl4-Fc	pCX	Expression of Fc fusion Necl4	(Spiegel et al., 2007)
pcDNA3.1(+)	pcDNA3.1(+)	vector for mammalian expression	Invitrogen
Lsamp	pENTR233.1	Lsamp cDNA <i>Mus musculus</i>	Genecopoeia

2.1.4.2 DNA primers for cloning

The primers for cloning were designed using the software ApE. The general rule for primer design used was selecting a sequence that would have between 18 and 30 bp, if possible over 50 %GC content and that would end in C or G. The list of used primers is shown ahead. Designed primers were synthesized by ACGT Lab, DNA core facility at the Max Planck Institute of Experimental Medicine.

Primer	Sequence	Description
22040	5'-AAAAAAGCTTACCATGGGCGTCCCT AGCC -3'	Igsf8 ECD fwd for pCX

2.1.5 Commercially available components, buffers and media

2.1.5.1 Commercial solutions and media

Media	Producer
B27 supplement	Gibco/Invitrogen
DMEM for Primary cell culture	Gibco/Invitrogen
DMEM for cell line culture	PAA
Fetal Calf Serum (FCS)	PAA
GlutaMAX™-I supplement	Gibco/Invitrogen
Horse Serum	PAA
Trypsin/EDTA	Lonza GmbH
Luxol Fast Blue Solvent	ClinTech
LB Medium	AppliChem
LB-Agar plate	AppliChem
OptiMEM-I Media	Invitrogen
PBS	PAA
Poly-L-Lysine (PLL)	Sigma
Penicillin/Streptomycin (Pen/Strep) 100×	Gibco/Invitrogen
Protease inhibitors cocktail Complete	Roche

10× PBS (phosphate buffered saline)

80 g NaCl
2 g KCl
14.4 g Na₂HPO₄ (or 18.05 g Na₂HPO₄ · 2H₂O)
2.4 g KH₂PO₄
Add dH₂O to 1 L and adjust pH to 7.05-7.11

2× HBSS (Hanks' balanced salt solution)

4 g NaCl
0.1775 g KCl
0.095 g Na₂HPO₄ · 7H₂O
0.675 g Glucose
2.5 g Hepes-free acid
Add dH₂O to 250 mL and adjust pH to 7.05-7.11

The modified SATO medium, termed Super SATO, was used for the culture of primary oligodendrocytes and neurons.

Super SATO medium

2 % B27-supplement
1 % Horse serum
110 µg/mL pyruvate
500 pM tri-iodo-thyronine
520 nM L-thyroxine
1× Pen/Strep
1× GlutaMAX™

in DMEM (Gibco/Invitrogen) with high glucose and without glutamine

2.1.6 Software

The software used for primer design, sequence analysis, data acquisition and processing are stated in Table 2.6.

Table 2.6: Software used in this study

2.2 Methods

2.2.1 Molecular Biology

DNA amplification for genotyping of mice used in the study, as well as for the cloning of expression plasmids was performed by polymerase chain reaction (PCR) (Mullis et al., 1986). The concentration of double stranded DNA was performed by diluting the samples 1:100 in ddH₂O in UV cuvettes (Eppendorf), and the absorbance at 260 nm with a BioPhotometer plus spectrophotometer (Eppendorf).

2.2.1.1 Genotyping

A small fraction of the mice tail tips were taken for genotyping. The extraction of DNA was performed using the Invitex Spin Tissue Kit following the manufacturer's recommendations. The DNA was eluted in 50 μ L and kept at -20 °C for further use. For genotyping

the DNA was amplified using polymerase chain reaction, or PCR (Mullis et al., 1986), using GoTaq DNA polymerase (Promega, Mannheim, Germany) employing the primers found in Table 2.5. Designed primers were synthesized by ACGT Lab, DNA core facility at the Max Planck Institute of Experimental Medicine.

PCR mix was prepared per sample as follows:

12.3 μL bidistilled water
 4 μL 5X buffer
 0.96 μL MgCl_2 (25mM)
 1 μL dNTPs (10mM mix of 2,5mM each)
 0.5 μL from each primer (10pmol/ μL stock)
 0.8 μL DNA (0.05-1 μg)
 0.2 μL Taq polymerase (5u/ μL)

The PCR protocol used for genotyping was performed using a T3000 Thermocycler Kombi (Biometra), as follows:

Table 2.7: Primers for *MOGiCre/iDTR* genotyping

Stage	Temperature	Time
Initial denaturation	94°C	2 minutes
35 cycles of:		
Denaturation	94°C	30 seconds
Annealing	According to primer pair	1 minute
Extension	72°C	1 minute
Final Extension	72°C	5 minutes

The following pairs of primers were used for each allele:

MOGiCre

Primers: Mogicre1 & Cre7

Annealing temperature: 58°C

Expected length of amplified segment: 800 bp

MOG

Primers: MogEx2-1 & MogEx2-3

Annealing temperature: 58°C

Expected length: 370 bp

iDTR

Primers: WSS-F & DTR-R

Annealing temperature: 60°C

Expected length: 695 bp

R26Ri

Primers: RosaFA, SpliAcB & Rosa RA

Annealing temperature: 60°C Expected length: wildtype 624 bp. iDTR 242 bp. A heterozygous mouse would have both bands.

2.2.1.2 DNA amplification for cloning

For cloning the different constructs described in listed in the previous section (Table 2.8), we amplified DNA fragments by PCR using with Phusion polymerase (2X Phusion High-Fidelity PCR Master Mix with HF Buffer, Finnzymes).

Table 2.8: PCR with Phusion Polymerase mix

Component	Amount
2X Phusion mix containing:	25 μL
-0.2 mM dNTPs	
-1 X Phusion HF Buffer	
-1 X Phusion High-Fidelity DNA Polymerase	
Primer 1 (10 pmol/ μL stock)	2.5 μL
Primer 2 (10 pmol/ μL stock)	2.5 μL
DNA (10 ng/ μL)	1 μL
DMSO	1,5 ul (3%)
ddH ₂ O (add to 50 μL)	17.5 μL

3% DMSO is suggested as a PCR additive to facilitate the denaturation of templates rich in GC. The general PCR protocol used was:

Table 2.9: PCR protocol for cloning using Phusion polymerase

Component	Temperature	Time
Initial denaturation	98°C	3 min
25 cycles of:		
Denaturation	98°C	10 sec
Annealing	Lowest melting temperature (T _m) of primers+3°C	15 sec
Elongation	72°C	Low complexity DNA (e.g. plasmid) 15 sec/kb. Complex genomic DNA: 30 sec/kb
Final Elongation	72°C	10 min

Agarose gel electrophoresis

Plasmids and PCR products were run in 1-2% Agarose gel in 1 × TAE buffer with 0.5 mg/mL ethidium bromide (Sharp et al., 1973) for the separation and visualization of DNA fragments. Chambers assembled by the Feinmechanik Service Department at the Max Planck Institute for Experimental Medicine were used for electrophoresis in 1 × TAE buffer. The DNA was visualized by transillumination using Intas Gel Documentation System (Intas Science Imaging Instruments GmbH).

10X TAE (1 L)

48.4 g Tris base
 11.4 mL Acetic acid
 20.0 mL 0.5 M EDTA
 Adjust to 1 L with ddH₂O, pH ~ 8.5

After agarose gel electrophoresis, DNA fragments were extracted with NucleoSpin Gel and PCR Clean-up kit (Macherey-Nagel) following manufacturer's instructions, and eluted in 15 µL.

DNA concentration determination

The concentration of DNA fragments and plasmids was determined measuring the absorbance at 260 nm of 1 μL of DNA diluted in 49 μL of H_2O , using a BioPhotometer plus (Eppendorf). The formula used was:

$$\text{Concentration of DNA } (\mu\text{g}/\text{mL}) = A_{260} \times \text{dilution factor} \times 50 \mu\text{g}/\text{mL} \quad (2.1)$$

2.2.1.3 DNA digestion with restriction enzymes

Digestion of DNA fragments were done using restriction enzymes, due to their ability to cleave DNA fragments according to specific sequences (Arber and Linn, 1969). Restriction enzymes were purchased from New England Biolabs and Fermentas. A typical reaction was prepared as follows:

Table 2.10: Digestion with restriction enzymes

Component	Reaction	Vector	Control
10X buffer	3 μL	3 μL	3 μL
DNA	4 μg (1 $\mu\text{g}/\mu\text{L}$ Midiprep) or 15 μL PCR elution	4 μg (Midiprep)	4 μg (Midiprep)
BSA 10X	3 μL	3 μL	3 μL
Water	18-19 μL /8 μL	18-19 μL	19-20 μL
Enzyme(s)	1 μL each	1 μL each	

The mixture was left for 1 hour generally at 37°C unless specified for a particular enzyme. When required, vector dephosphorylation was performed by adding, after digestion, 3 μL 10X Antarctic phosphatase buffer and 1 μL Antarctic phosphatase (New England Biolabs) to the digestion mix, leaving at 37°C for 1 hour and heat inactivating for 5 minutes at 65°C .

2.2.1.4 DNA Ligation

Digested fragments were ligated using T4 DNA ligase (Fermentas) as follows:

Ligation reaction

10× buffer	1 μ L
T4 DNA Ligase	1 μ L
ATP(100mM)	1 μ L
Digested vector	50-400 ng
DNA	
Digested insert	1:1-5:1 to vector ¹
fill with H ₂ O	to 10 μ L

The mix was incubated for at least 1h at RT, or overnight at 4°C and used for bacterial transformation.

2.2.1.5 Transformation of *E. coli*

For transformation, 50-100 μ L of DH5_{alpha} *E. coli* (Subcloning Efficiency DH5_{alpha}, Invitrogen) were thawed on ice. 5-10 μ L of ligation (or 0.5 μ g of plasmid DNA for retransformation) were added, mixed gently and incubated 30 min on ice. The mix was subjected to a heat shock for 40 seconds at 42 °C and left for 2 minutes on ice. Then, 800 μ L of LB medium were added and the cells were shaken at 37°C for 1h. Afterwards, the cells were centrifuged for 2 minutes at 2000 rpm, most of the supernatant was removed, leaving \sim 200 μ L. The cells were resuspended and added to LB-Agar plates (LB-Agar 40 g dissolved in 1 L H₂O) containing 100 μ g/mL ampicillin, 50 μ g/mL kanamycin or 50 μ g/mL spectinomycin, according to the antibiotic resistance cassette incorporated to the vector of the mixture. The plates were incubated at 37°C for 16-18 h. For plasmid purification, *E. coli* samples of colonies grown in antibiotic-containing plates were picked with autoclaved pipette tips, added to appropriate antibiotic-containing LB media (25 g LB-Medium per 1 L H₂O) and grown at 37 °C for 16-18 h.

2.2.1.6 Plasmid DNA amplification and purification

Cultures of transformed DH5_{alpha} *E. coli* (Subcloning Efficiency DH5_{alpha}, Invitrogen) were grown in antibiotic-containing LB media (H₂O) with constant shaking. The cells

¹molar ratio

were centrifugated at 4 000 *g* for 15 min at 4°C and DNA purification was performed using NucleoBond Xtra Midi EF Kit (Macherey-Nagel) following manufacturer's instructions. Eluted DNA was reconstituted in sterile H₂O.

To check ligation effectivity by restriction enzyme digestion and sequencing, *E. coli* samples of colonies grown in antibiotic-containing plates were picked with autoclaved pipette tips and grown in 3 mL LB containing the appropriate antibiotic for selection and grown at 37°C for 16-18 h with constant shaking. Plasmid DNA was purified from these cultures using NucleoSpin Plasmid QuickPure Kit (Macherey-Nagel) according to manufacturer's recommendations.

2.2.2 Cell culture

2.2.2.1 Primary cultures

Primary oligodendrocyte cultures were prepared from the brain of postnatal day 0-2 rats or mice as described previously (Trajkovic et al., 2006). After removing the meninges, the neonatal brain hemispheres were digested with 0.25% trypsin, and cultured in Eagle's basal medium with 10% horse serum on poly-L-lysine (PLL)-coated flasks at 37 °C. Oligodendroglial cells were harvested from 8-10 day old mixed glia culture using mechanical dissociation. Cells were cultured on PLL-coated dishes or glass coverslips in Super SATO medium (DMEM containing 1% horse serum, B27 supplement, L-thyroxine, triiodothyronine, glutamine, pyruvate, and penicillin/streptomycin, see materials section for protocol).

To obtain primary neuronal cells, mixed brain culture from embryonic day 16 mice was prepared as previously described (Fitzner et al., 2006). Cells were cultured in Super SATO medium for two weeks to acquire confluent differentiated neurons.

To prepare a coculture of neurons and oligodendrocytes, neurons were cultured in a 12-well plate for 2 weeks as described above. The media was exchanged for fresh Super SATO media and 60 000 oligodendrocyte precursor cells were added per well and allowed to grow for 5 days.

2.2.2.2 Cell line culture

Human Embryonic Kidney (HEK) 293T cells (Graham et al., 1977) were used for production of Fc-fusion soluble proteins and binding assays. The cells were cultured in high glucose DMEM, 1 × GlutaMAX, 10% FCS and 100 U/mL penicillin and streptomycin. The cells were split 2-3 times per week after trypsinization with 0.05% trypsin/EDTA (Lonza GmbH). For Fc-fusion protein production, the media was exchanged for 1% FCS media.

2.2.2.3 Mammalian cells transfection and RNAi

Transfection of primary cultures and HEK cells was done using Lipofectamine® 2000 (Invitrogen). For cells cultured in 12 well plates, the following reaction was prepared per well: Per each coverslip in 12-well plates 1.6 µg of plasmid DNA was mixed with 100 µL OptiMEM-I (Invitrogen). Separately, 4 µL Lipofectamine2000 reagent were mixed with 100 µL OptiMEM. After 5 min incubation, both solutions were mixed and incubated for 20 min at RT. The 200 µL solution was added dropwise to the cells and left at least overnight before analysis.

Knockdown of exogenously expressed *Lsamp*, *Opcml* and *Ntm* (IgLON family) in HEK 293T cells was done in 6-well dishes by mixing 250 µL OptiMEM with 0.5 µg of myc-tagged IgLON protein and 3 µg shRNA plasmid (see Materials section for details). 250 µL of OptiMEM was mixed with 10 µL Lipofectamine 2000 in a separate vial and incubated for 5 min at RT. The two solutions were mixed gently, incubated for 20 min at RT and added dropwise to HEK 293T cells grown on PLL-coated 6-well dishes. After 3 days, the cells were scraped and prepared for analysis by Western blot.

2.2.2.4 Preparation of cell lysates for Western blot

To prepare cell lysates for analysis by Western blot, the culture medium was removed and the cells were washed once with PBS. An appropriate volume of Lysis buffer (2% NP-40, 0.2% SDS, 1 mM EGTA in PBS supplied with protease inhibitors) was added and the cells were detached using a cell scraper (Sarstedt), while being kept on ice. The samples were then centrifuged at 10 000 g for 10 min and the supernatant was used for protein concentration measurement using Bradford assay (Bradford, 1976). The samples were mixed with equal volume of 2 × sample buffer (20% glycerol, 4 mM EDTA, 4% SDS, 4%

2-mercaptoethanol, 0.05% Bromophenol blue and 100 mM Tris-HCl pH 6.8) and stored at -20°C until further analysis.

HEK cells were transfected with Calcium Phosphate method based on the formation of a calcium phosphate-DNA precipitate which is uptaken by cells by endocytosis (Wigler et al., 1977; Abrahams and Van der Eb, 1975). For soluble Fc-fusion production, cells were cultured in 20 cm culture dishes in 25 mL media per dish. A typical transfection reaction for one dish was prepared as follows:

Transfection reaction

DNA (1 $\mu\text{g}/\mu\text{L}$)	12 μg
pEGFP-C1 DNA (1 $\mu\text{g}/\mu\text{L}$)	0.5 μL
H ₂ O	887 μL
CaCl ₂ (2.5 M)	100 μL
2 × HBSS	1 mL

mix softly, add dropwise to cells

2.2.3 Fc-fusion protein purification

Soluble Fc-fusion proteins were purified using Protein A HP Spin Trap columns (GE Healthcare), following manufacturer's instructions. Briefly, HEK cells were transfected as described in the previous section. After 2-3 days, the supernatant was collected, and centrifuged for 15 min at 4 000 g at 4°C. 1× Complete Protease Inhibitor Cocktail (Roche) was added to the supernatant and then concentrated using Amicon Ultra-15 Centrifugal Filter Units (Millipore) according to manufacturer's recommendations. The final volume of 2 mL was diluted in equal volume of binding buffer (20 mM sodium phosphate, pH 7.0). Briefly, the storage solution from the column was removed by centrifugation for 30 s at 100 g. The column was equilibrated adding 600 μL of binding buffer, centrifuged for 30 s at 100 g. Then, 600 μL of the antibody solution were added, incubated for 4 min while gently mixing and then centrifuged for 30 s at 100 g. This procedure was repeated until all the volume was loaded on the column. Then the column was washed twice adding 600 μL binding buffer and centrifuging for 30 s at 100 g. Two collection tubes per sample were prepared for eluted fractions, each one containing 30 μL of neutralizing buffer. The proteins were eluted twice by adding 400 μL of elution buffer (0.1 M glycine-HCl, pH 2.7),

mixing by inversion, placing the column in a 2 mL microcentrifuge tube containing 30 μ L neutralizing buffer (1 M Tris-HCl, pH 9.0) and centrifuged for 1 min at 50 g. The proteins were aliquoted and kept at -20°C .

2.2.4 Myelin isolation and purification

We isolated different fractions of myelin from C57BL6 mice (1-6) or human sample (7):

1. Standard compact myelin preparation in discontinuous sucrose gradient, 0.32M/0.85M interphase.
2. Myelin isolated from postnatal day 14 (P14) brain homogenate, in discontinuous sucrose gradient, 0.32M/0.85M interphase.
3. Purified myelin solubilised with 1% TritonX overnight and bound to ConcanavalinA beads
4. Purified myelin bound to WGA beads.
5. Myelin isolated from brain homogenate subjected to an initial hyposmotic shock with water and then subjected to a continuous gradient, fraction 0.9-1M sucrose.
6. Myelin isolated from brain homogenate subjected to an initial discontinuous gradients and collected from 0.32-1.2M interphase and subsequently subjected to a continuous sucrose gradient. Collected from Fraction 3, or 0.9-1 M sucrose.
7. Glycoprotein from human myelin preparation, subjected to a lentil-lectin column (Mathey et al., 2007), was kindly provided by Edgar Meinel (Max Planck Institute of Neurobiology, Munich).

2.2.4.1 Myelin isolation by centrifugation in discontinuous sucrose gradient

Compact myelin from 3-months-old mice (sample 1, 3 and 4) and 14-days-old mice (sample 2) were isolated based on a protocol previously described (Norton and Poduslo, 1973), with slight modifications. All the steps were done on ice using a SW41 Ti rotor in an Optima XL-70 ultracentrifuge (Beckman Coulter, USA). Homogenized brain tissue was placed over a discontinuous sucrose gradient (0.32 M and 0.85 M sucrose for fractions in a preparation buffer containing 5 mM EDTA and 10 mM Hepes, pH 7.4) and centrifuged for 30 minutes at 75 000 g. The interface between the two sucrose gradients was recovered and diluted in ten volumes of ice-cold water, and centrifuged for 20 minutes at 75 000 g. The pellet was subjected twice to hypo-osmotic shock by resuspension in ice-cold water and 10 minutes centrifugation steps at 12 000 g. The pellet was resuspended on 0.32 M sucrose in preparation buffer and overlaid on 0.85 M sucrose (in preparation buffer) to

create a new gradient as the one mentioned above. The previous centrifugation steps were repeated and the final purified myelin pellet was resuspended in preparation buffer and kept at -20°C for further use.

2.2.4.2 Myelin isolation by centrifugation in continuous sucrose gradient

A continuous sucrose gradient was prepared as follows: Using a long needle, 1 mL of 0.6 M sucrose in preparation buffer (5 mM EDTA and 10 mM Hepes pH 7.4) was laid in the bottom of a ultracentrifuge tube (Thinwall, Ultra-Clear™, 344059, Beckmann Coulter). Then, successive 1.5 mL layers of sucrose with increasing molarity (0.7, 0.8, 0.9, 1.0, 1.1 and 1.2 M) were added. The tube was left for 3 hours at room temperature to allow the formation of a continuous gradient. Then, samples 5 and 6 were prepared by overlaying either brain homogenate (sample 5) or myelin from a 0.32 /1.2 M sucrose interphase (sample 6) onto the continuous sucrose gradient described above. The samples were centrifuged at 75 000 g for 1 hour using a SW41 Ti rotor in an Optima XL-70 ultracentrifuge (Beckman Coulter, USA). The overlay remains and the first mL of the continuous gradient were removed. Afterwards, 6 fractions of 1.5 mL each were taken, diluted in ice cold water and centrifuged for 1 hour at 75 000 g. Subsequently, the pellet was subjected twice to hypo-osmotic shock by resuspension in ice-cold water and 10 minutes centrifugation steps at 12 000 g, resuspended in preparation buffer and kept at -20°C for further use.

2.2.4.3 Glycoprotein enrichment by WGA and ConA columns

To isolate glycoprotein-rich myelin fractions using Wheat Germ Agglutinin (WGA) lectin resin, purified myelin from adult mice was obtained as stated in section 2.1.1. The myelin suspension was passed through a 26G gauge needle 10 times and bound to a Wheat Germ Agglutinin (WGA) column (Pierce Glycoprotein Isolation Kit, WGA, Thermofisher) following manufacturer's instructions. After washing, the beads were retrieved, resuspended in sample buffer and boiled for 10 minutes at 70°C . The supernatant was retrieved and kept at -20°C for further use. To isolate myelin glycoproteins using Concanavalin A lectin resin, purified myelin from adult mice was initially obtained as stated in section 2.1.1. The myelin was spun down and resuspended in a solution of 0.1% Triton X in PBS for solubilization. The supernatant was then loaded onto a ConA column (Pierce Glycoprotein Isolation Kit, ConA, Thermofisher) according to manufacturer's instructions. After

washing, the ConA beads were retrieved, resuspended in sample buffer and boiled for 10 minutes at 70°C .

2.2.4.4 Human myelin glycoprotein enrichment

Glycoproteins were isolated from human myelin preparation with lentil-lectin affinity chromatography according to the manufacturer’s guidelines (GE Healthcare) as described previously (Mathey et al., 2007).

2.2.5 SDS-PAGE and Western Blotting

Protein analysis by Western Blot was performed by SDS-PAGE as described earlier (Burnette, 1981; Laemmli, 1970). The polyacrylamide gels comprising of stacking and resolving gels were self-cast with composition described in Table 2.11. Equal amounts of protein from each sample were mixed in a 1:1 volume proportion with 2X loading buffer (10% glycerol, 2 mM EDTA, 2% SDS, 144 mM β -mercaptoethanol, 50 mM Tris-HCl and 0.02% bromophenol blue), heated for 10 min at 70°C and loaded onto 12% SDS-PAGE gel. For each gel, 3.5 μ L of pre-stained protein ladder was loaded into one of the lanes. Electrophoresis was performed at 100V in the running buffer (190 mM glycine, 25 mM Tris and 0.1% SDS). The proteins were transferred from the polyacrylamide gel onto a Protan nitrocellulose membrane (Whatman GmbH, Germany) using a semi-dry procedure, for 1 hr at 100 V in the transfer buffer (20 mM Tris base, 153 mM glycine, 20% methanol).

Table 2.11: Components for Western Blot gels

Stacking gel		Resolving gel	
H ₂ O	1.21 mL	H ₂ O	1.66 mL
30% Acrylamide solution	0.27 mL	30% Acrylamide solution	2.04 mL
Stacking buffer (0.5 M Tris-HCl, pH 6.8)	0.5 mL	Resolving buffer (1.5 M Tris-HCl, pH 8.8)	1.3 mL
10% SDS	20 μ L	10% SDS	50 μ L
10% APS	20 μ L	10% APS	50 μ L
TEMED	3 μ L	TEMED	2 μ L

The correct transfer of protein was confirmed by fast reversible staining of protein bands by immersing the membrane in 0.1% Ponceau S in 5% acetic acid solution for five minutes and thereafter washing it with distilled water. The blot was blocked with 4% milk powder in PBS for 1 hr at RT followed by overnight incubation with appropriate pri-

mary antibody diluted in PBS containing 0.1% Tween-20 (PBST). After washing three times for 10 minutes with 0.1% PBST, the membranes were incubated with the appropriate horseradish peroxidase-conjugated secondary antibody diluted in PBST for 1 hour at room temperature. The blots were washed three times for 10 minutes with PBST and subjected to a mixture of equal parts of peroxide solution and luminol enhancer solution detection reagents (Thermo Scientific, Pierce). The blots were later exposed to light sensitive CL-XPosure films (Thermoscientific) and developed in a Kodak X-OMAT 1000 image processor. Images of the films were prepared using Adobe Photoshop software (Adobe Systems, Mountain View, CA).

2.2.5.1 Protein concentration determination

The protein concentration of cell lysate preparations, myelin preparations and purified proteins was determined by using Bradford assay (Bradford, 1976), and BCA Protein Assay (Pierce, Thermo Scientific) following manufacturer's instructions. The absorbance at 562 nm of the mixtures was measured with a 96-well plate MRXTc Revelation reader (Dynex Technologies).

2.2.6 *In vitro* assays

2.2.6.1 Immunocytochemistry

For immunolabeling, cells were fixed with 4% paraformaldehyde (PFA) for 15 min at room temperature before permeabilization with 0.1% Triton X-100 in PBS for 1 min. The blocking solution (2% BSA, 0.2% Fish gelatine, and 2% FCS in PBS) was then added to fixed cells for 30 min at RT. The primary antibodies diluted in blocking solution were added for 1 h at RT or overnight at 4°C. After washing three times with PBS, cells were incubated with secondary antibodies for 1 h at RT. Finally, the coverslips were washed with PBS and mounted onto a glassslide with a drop of Mowiol solution (2.4 g Mowiol, 6 g Glycerol, 6 mL H₂O, 12 mL 0.2 M Tris/HCl pH 8.5) and were kept in at 4°C in the dark. When required, nuclei were stained with 4',6-diamidino-2-phenylindole (DAPI).

2.2.6.2 Paraformaldehyde (PFA) solution for fixation

Paraformaldehyde (PFA) 16% stock solution was prepared by dissolving 16 g PFA in 70 mL H₂O, heating at 60°C adding NaOH pellets until the solution became clear. Then, 10 mL 10 × PBS were added and pH was adjusted to 7.4. Water was added to a total

volume of 100 mL. Aliquots of the solution were then stored at -20°C . Working solution of 4% PFA in PBS was prepared by diluting 50 mL of PFA stock solution in 150 mL of $1\times$ PBS and stored at 4°C .

2.2.6.3 Mowiol solution for immunocytochemistry

Mowiol was used as the mounting medium after immunocytochemistry. The solution was prepared in the following way: 2.4 g Mowiol was added to 6 g glycerol and 6 mL H_2O . The mixture was stirred for several hours at room temperature. Then, 12 mL 0.2 M Tris-HCl (pH 8.5) was added and then incubated at 60°C for 10 min. The solution was centrifugated at 4000 g for 15 min, aliquoted and kept at -20°C until further use.

2.2.6.4 Binding assay

For binding assays, supernatant from transfected HEK cells were retrieved and centrifuged 10 min at 5000 rpm. Per each 18 mm coverslip of neuronal or oligodendroglial culture, 150 μL of media were mixed with 1.5 μL of Cy3-conjugated anti-human Fc antibody (Dianova) and incubated for 30 min at RT. Then, the mix was added to each coverslip and incubated for 20 min at RT in a humid chamber (Feinmechanik Service Department, Max Planck Institute for experimental medicine). Finally, the coverslips were washed 3 times with PBS and the cells were fixed with 4% PFA for 15 min at RT.

2.2.6.5 Proliferation assay

For proliferation assays, 30 000 oligodendrocyte precursor cells (OPC) per well were plated in a 24-well plate on PLL-coated coverslips. 10 $\mu\text{g}/\text{mL}$ of the Fc-fusion proteins were then added to the wells. The cells were allowed to settle down and were fixed after 8 hours, and stained for the OPC marker A2B5. We used 100 ng/mL PDGF as a positive control of proliferation.

2.2.6.6 Migration assay

Migration assays were performed using CytoSelect 24-Well Cell Migration and Invasion Assay (8 μm , Colorimetric Format). Briefly, the chamber membranes were coated by placing each insert on 400 μL PLL (100 $\mu\text{g}/\text{mL}$) for 1 h at 37°C and washed 2 times with PBS. A cell suspension of 1 000 000 oligodendrocyte precursor cells per mL was prepared in serum-free Super SATO. 500 μL of serum-free super SATO media containing 10 $\mu\text{g}/\text{mL}$

Fc-fusion proteins, 100 ng/mL PDGF or equal volume PBS were added to the lower well of the migration plate. Next, 300 μ L of OPC suspension were added to the inside of each insert, and incubated 8 hours at 37 °C . Then, the media from the inside of the insert was removed, cotton-tipped swabs were used to remove the interior of the inserts to remove non-migratory cells. The insert was transferred to a clean well containing 400 μ L of Cell Stain Solution and incubated for 10 minutes at room temperature. After allowing the inserts to air dry, migratory cells were counted with a Nikon Ti-E brightfield microscope.

2.2.6.7 Differentiation assay

To observe whether the presence of soluble IgLON in the media can influence the growth and differentiation of oligodendrocytes *in vitro*, OPC were grown for 4 days in media with 30 μ g/mL of IgLON Fc-fusion proteins on PLL-coated coverslips, and then fixed with 4% PFA.

2.2.6.8 Adhesion assay

Glass coverslips in a 24-well plate were coated with 500 μ L of a solution with 10 μ g/mL of donkey anti-human Fc antibody (Dianova) in 50 mM Tris-HCl (pH 9.0) and left overnight at 4°C. Then, the coverslips were washed 3 times with supplement-free DMEM and 500 μ L of a solution containing 10 μ g/mL of Fc-fusion protein in 0.2% BSA/PBS. After 1h of incubation at 37°C , the coverslips were washed 3 times with DMEM and fresh Super SATO media was added. PLL coating (100 μ g/mL was used as a positive control to verify the quality of the primary oligodendrocyte preparation. After washing and placing new media, 25 000 OPC were plated and allowed to grow for four days, and fixed with 4% PFA.

2.2.6.9 Myelination assay

Primary neurons were plated on a 12-well plate and grown for two weeks in super SATO media. After exchanging for new media, 60 000 OPC were added to each well and allowed to grow for 5 days, before fixation with 4% PFA.

2.2.7 Toxin-induced oligodendrocyte death and demyelination

2.2.7.1 Diphtheria toxin-mediated oligodendrocyte ablation

Animal experiments were conducted in accordance with animal protection laws approved by the Government of Lower Saxony, Germany. 10-week-old MOGi-Cre/iDTR mice (Buch et al., 2005; Hovelmeyer et al., 2005) were injected intraperitoneally with 400 ng of diphtheria toxin (DT, Merck) in PBS once a day for seven days. Age- and sex-matched MOGi-Cre/iDTR mice injected with PBS, and MOGi-Cre mice (lacking the iDTR allele) injected with DT were used as controls.

2.2.7.2 Cuprizone-induced de- and remyelination

8-weeks-old C57Bl6 male mice were used in the experiment here described. The animals were divided into three groups, named according to the applied treatment as double demyelination (DD), single demyelination (SD) and Control. DD animals were fed with 0.25% cuprizone (Sigma, St Louis, MO, USA) in milled chow (Ssniff) for 5 weeks, followed by normal diet for 4 weeks to allow recovery. Subsequently they received 0.25% cuprizone diet for 5 weeks, which was then replaced by normal diet for the remaining of the experiment. Animals in SD group received normal diet for 9 weeks (until the start of the second demyelinating event of group DD) and then were fed with 0.25% cuprizone for 5 weeks and finally with normal diet for the remaining of the experiment. Age-matched controls received normal diet without cuprizone throughout the entire experiment (see **Figure 3.10**).

2.2.7.3 Behavioral test: Motor Skill Sequence

Assessment of motor performance following remyelination was done using Motor Skill Sequence (MOSS) as previously described (Liebetanz and Merkler, 2006). Separate analysis were performed 6, 20 and 28 weeks after cuprizone was removed from the diet following the first demyelination in SD group and second demyelination in DD group. For every analysis, each animal was transferred to an individual cage containing a running wheel, and for 14 days the animals were allowed to run voluntarily in training wheels composed of regularly-spaced crossbars.

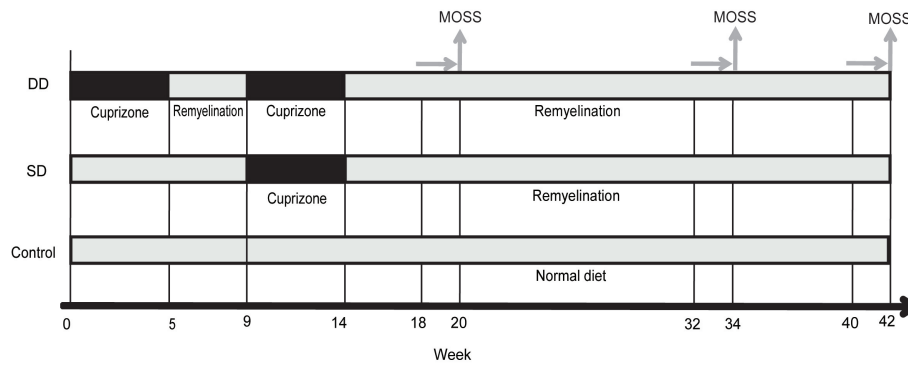

Figure 2.1: Experimental design of cuprizone treatment. 8-week-old mice were fed cuprizone for 5 weeks, were then allowed to recover for 4 weeks and finally received cuprizone for 5 more weeks (double demyelination, or DD). A second group of mice (single demyelination, or SD) were fed cuprizone for 5 weeks simultaneous to the second demyelination of the DD group as indicated. Animals were switched to a normal diet for 28 weeks until the end of the experiment. Age-matched controls were fed with a normal diet throughout the experiment. Motor Skill Sequence analysis (MOSS) was performed at the times indicated. Animals were first habituated to training wheels composed of regularly spaced crossbars for two weeks. Subsequently, running performance on complex wheels was recorded for an additional week.

Following the training period, the training wheel was replaced by a “complex” wheel containing irregularly-spaced crossbars and the animals were allowed to run voluntarily for seven consecutive days. Activity in the individual wheels was recorded automatically with a rotation sensor connected to the wheel axis. The following parameters were monitored continuously: maximum running velocity in revolutions/minute (V_{max}), accumulative distance in meters (Distac), the number of individual runs (Nrun) and the maximum distance per run (Distmax). Each parameter was calculated online and the results were logged once daily (12 am). Thus, Distac and Nrun represent the values accumulated during the last 24 h, whereas V_{max} and Dmax represent maximum values achieved within the last 24 h.

2.2.8 Perfusion and tissue processing

Animals were sedated with a 14% chloral hydrate intraperitoneal injection, perfused transcardially and fixed with 4% paraformaldehyde (PFA) with a Heraeus SR70 peristaltic pump (0.2-0.5 mL/sec). After perfusion the brain and spinal cord were immersed in 4% PFA overnight. Tissue was processed as described previously (Merkler et al., 2005; Mason et al., 2001). After paraffin embedding in a HMPII embedder (Microm), paraffin blocks

were created in a Microm AP280 Embedding Center. Then, 3 μm thick sections of the brain, spinal cord, spleen and liver were obtained with a Microm HM400 microtome, laid on glass slides and left overnight at 37°C

2.2.8.1 Human brain tissue

Human brain biopsies of four patients with MS were obtained from the collection of the Department of Neuropathology at the Georg-August University. Its use for scientific purposes was in accordance with the guidelines of the institutional ethics committee and the study was approved by the ethics committee of the University of Göttingen (Göttingen, Germany).

2.2.8.2 Histological analysis

The extent of demyelination induced by diphtheria toxin injection or cuprizone treatment was assessed scoring the animals from 0 (no demyelination) to 3 (complete demyelination) in sections stained with Luxol fast blue–periodic acid Schiff (LFB–PAS) (Hiremath et al., 1998).

Bielchowsky’s silver staining for axons (Cobb and Bielschowsky, 1925) was performed as follows: Paraffin embeded tissues were deparaffinize and hydrated in distilled H_2O . After washing 3 times in dH_2O , sections were placed in 50 mL 20% silver nitrate solution for 20 min and washed 3 times in dH_2O . 10 mL of concentrated 32% ammonium hydroxide were added dropwise while stirring to 50 mL 20% silver nitrate solution to form silver hydroxide solution. Then, the section were incubated in silver hydroxide solution for 15 min in the dark and washed in 0.1% ammonium hydroxide 3 times. Then 1.4 mL of developer solution (20 mL 37% formaldehyde, 100 mL dH_2O , 2 drops 65% nitric acid and 0.5 g citric acid) to 50 mL 20% silver hydroxide solution, and the sections were stained in this solution until they turned brown with a golden background. The reaction was stopped washing with dH_2O 3 times. Then the sections were placed in 2% sodium thiosulfate for 2 min. Finally, the sections were washed with dH_2O , dehydrated with alcohol and xylene and mounted with DePeX (Serva).

2.2.8.3 Immunohistochemistry

Immunohistochemistry was performed using antibodies against neuronal nuclei (NeuN Chemicon), mature oligodendrocytes (NogoA, (Liebscher et al., 2005)), macrophages or activated microglia (Mac3, Pharmingen), astrocytes (GFAP, Promega), T-cells (CD3, Serotec) and axonal damage with amyloid precursor protein (APP, clone 22C11; Chemicon) followed by labelling with biotinylated secondary antibodies. Avidin-biotin technique with 3,3-diaminobenzidine was used for visualization.

A general protocol for 3,3-diaminobenzidine (DAB) visualization method was the following: The sections were deparaffinized, and hydrated in distilled H₂O. When necessary, epitope retrieval was done in 10 mM sodium citrate buffer (pH 6.0), microwaved 5 times for 3 minutes and allowed to cool down. After washing with dH₂O, endogenous peroxidase were blocked by incubation in 3% H₂O₂ for 20 min at 4°C and washed with PBS. When relevant, 1:100 Fab Goat-anti-Mouse antibody in 10% FCS was added to the sections and incubated for 1 h at RT in a humid chamber, and washed with PBS. Blocking was performed with 10% FCS/PBS for 1h at RT and primary antibodies were added to the sections overnight at 4°C . Then, the sections were washed with PBS and incubated with biotinylated secondary antibodies for 1h at RT. After washing with PBS, the sections were incubated with 1:1000 ExtrAvidin-Peroxidase (Sigma) in 10% FCS for 1h at RT. The sections were washed with PBS and placed in a solution of 49 mL PBS, 1mL DAB (25 mg/mL, Sigma) and 40 μ L 30% H₂O₂. After washing with distilled H₂O, the slides were immersed 5 times in Haemalum (Harris) Solution (Sigma-Aldrich), and then washed with running tap water for 10 min. After washing with distilled H₂O, the sections were dehydrated with increasing percentage of alcohols, placed in Xylol (Chemie Vertrieb GmbH) and mounted with DePeX.

For fluorescence immunohistochemistry, the following protocol was used: The sections were deparaffinized, and hydrated in distilled H₂O. When necessary, epitope retrieval was done in 10 mM sodium citrate buffer (pH 6.0), microwaved 5 times for 3 minutes, allowed to cool down and washed with dH₂O. When relevant, 1:100 Fab Goat-anti-Mouse antibody in 10% FCS was added to the sections and incubated for 1 h at RT in a humid chamber, and washed with PBS. Blocking was performed with 10% FCS/PBS for 1h at RT and primary antibodies were added to the sections overnight at 4°C . Then, the sections were washed with PBS and incubated with 488- or Cy3-conjugated antibodies (Invitrogen or

Dianova) and incubated for 1h at RT. After washing with PBS, nuclei were stained by placing 100 μ L per slide of DAPI (4'6-diamidino-2-phenylindole-2HCl) 1:10 000 dilution for 15 minutes at RT. The sections were washed with PBS, distilled H₂O and mounted in fluorescence mounting medium (Dako).

Histopathological analysis was performed on PFA-fixed sections from brain biopsies of patients with documented progressive MS. All tissue blocks (n= 6 blocks from 4 patients) were selected if signs of remyelination (judged by LFB/PAS staining) were observed. Fluorescence immunohistochemistry was performed for MBP and APP as described above.

To assess axonal preservation, images of each side of the midsagittal line of the corpus callosum from coronal sections stained with NF200 were obtained under equal acquisition parameters with a confocal microscope (LSM 510, Carl Zeiss MicroImaging, Inc) and the signal intensity was analysed with Image J. Histological sections stained with anti-APP counterstained with Haemalaum Solution (Sigma-Aldrich), and of NeuN antibody and were scanned using the Mirax Midi System (Carl Zeiss MicroImaging, Jena, Germany). Confocal microcopic images were aquired with Carl Zeiss LSM 510 microscope with a 63 \times oil plan-Apochromat objective, or with a Leica TCS SP2 AOBS confocal laser scanning setup.

2.2.8.4 Semi-automated axonal counts

Callosal axons were evaluated on sagittal neurofilament stained brain sections (Pan-Neuro filament using a pool of anti-NF 160 (Novocastra), anti-NF200 (Novocastra) and anti-NF60 (Chemicon). Images of transversally cut axons were obtained by a Zeiss LSM 510 laser scanning microscope coupled to a Zeiss Axiovert 100 M inverted microscope equipped with a 63x/1.4 oil immersion objective. Callosal axons were captured in 3 to 5 randomly selected, non-overlapping areas (146.2 x 146.2 μ m²) per animal. Confocal stacks (thickness of 1.2–3.7 μ m; interval of 0.41 μ m) were scanned in the z-direction (Software LSM 510; Zeiss) and 3 to 5 overlapping stacks composed 1 layer using Fiji. Axons were counted in an area of at least 5 600 μ m² per animal using a custom-programmed script in Cognition Network Language–based on the Definiens Cognition Network Technology platform (Definiens Developer XD software; Definiens).

In brief, neurofilament- positive axons were detected based on their contrast to the image background signal. To adapt for potential variable background staining levels, the area surrounding potential axonal structures was segmented and the mean intensity difference between the structures was calculated. Neurofilament- positive structures displaying a signal difference higher than 8 from their surroundings were classified as axons (for detailed formula see the Definiens Developer XD 1.5.2 Reference book). Complementary, adjacent sections were stained using Bielschowsky's silver impregnation technique and sections were scanned using Zeiss Mirax Virtual Slide Scanner (Carl Zeiss MicroImaging GmbH). The thickness of the corpus callosum was then measured using a Mirax Slide Viewer (Carl Zeiss MicroImaging GmbH). Axonal numbers were subsequently calculated by multiplying axonal densities (expressed as axons per square millimeter) with the thickness of the corpus callosum of a given animal. Staining and analysis were performed by Tanja Jürgens, Geneva University Hospital.

2.2.8.5 Neuronal numbers semi- automated analysis

Sections stained for neuronal nuclei with NeuN antibodies were scanned as described above. Neuronal numbers were automatically counted using a script in Cognition Network Language based on Definiens Cognition Network Technology [®] platform (Definiens Developer XD software, Munich, Germany). Briefly, the cortical region of interest was drawn manually and NeuN positive cells were detected based on color criteria. After finer segmentation to discriminate between nucleus and cytoplasm, the object was classified as a NeuN-positive cell if the soma was below a certain size and had 0-1 nucleus. If more than one nucleus was detected within one soma, the object was split using each nucleus as seed to grow into the surrounding cytoplasm, stopping if growing borders converged or the cytoplasmic border was reached. Finally, the total number and density of NeuN-positive cells was calculated. Quantification was performed by Mario Kreutzfeldt, Geneva University Hospital.

2.2.8.6 Electron microscopy

Electron microscopy (EM) was performed according a modified protocol as earlier described (Merkler et al., 2005). Briefly, mice were fixed by transcardial perfusion with 4% paraformaldehyde and 2.5% glutaraldehyde in 0.1 M phosphate buffer containing 0.5% NaCl. The tissue was embedded in epon and corpus callosum were cut and stained with

toluidine blue. The tissue was then trimmed and reoriented so that ultrathin cross sections of midline corpus callosum could be cut and treated with uranyl acetate and lead citrate. The sample area was selected at low magnification in the electron microscope (2500x) before systematically recording images of the corpus callosum at 16000x magnification using a CCD camera (MegaView III, Soft Imaging System). Axon diameters and myelin sheath thicknesses of at least 300 axons ($>0.35 \mu\text{m}$ in diameter) were measured from each animal using CellF software (Olympus Soft Imaging Solutions GmbH, Germany), and were used to calculate the g-ratio (axon diameter/fibre diameter) as described previously (Coetzee et al., 1996).

2.2.9 Proteomic analysis

2.2.9.1 Mass spectrometry

Mass spectrometry analysis of myelin samples were analyzed by nanoliquid chromatography coupled to tandem mass spectrometry (LC-MS/MS) on a Thermo LTQ XL Orbitrap (Thermo Fisher Scientific, Bremen, Germany) coupled to an Agilent 1100 series LC-system. Peak lists of all MS samples were searched against the National Center for Biotechnology Information (NCBI) non-redundant RefSeq database www.ncbi.nlm.nih.gov/RefSeq/ (Pruitt et al., 2003) using Mascot (Matrix Science, London, UK). Mascot was set up to search the nr_240211 database (selected for Homo sapiens, 558660 entries) (only “mascot_daemon_merge (F009486)”) assuming the digestion enzyme trypsin and the nr_240211 database (selected for Mus, 471874 entries) (only samples “mascot_daemon_merge (F009472)”, “mascot_daemon_merge (F009473)”, “mascot_daemon_merge (F009474)”, “mascot_daemon_merge (F009475)”, “mascot_daemon_merge (F009476)” and “mascot_daemon_merge (F009477)”) also assuming trypsin. Mascot was searched with a fragment ion mass tolerance of 0,60 Da and a parent ion tolerance of 10,0 PPM. Oxidation of methionine and iodoacetamide derivative of cysteine were specified in Mascot as variable modifications. Mass spectrometry analysis was done by Monika Raabe, department of Analytical Mass Spectrometry, Max Planck Insititute for Biophysical Chemistry, Goettingen.

For protein identification, Scaffold (version Scaffold_3.0.9.1, Proteome Software Inc.) was used to validate MS/MS based peptide and protein identifications. Peptide identifications were accepted if they could be established at greater than 80% probability as specified by the Peptide Prophet algorithm (Keller et al., 2002). Protein identifications were accepted

if they could be established at greater than 50% probability and contained at least 2 identified peptides. Protein probabilities were assigned by the Protein Prophet algorithm (Nesvizhskii et al., 2003). Proteins that contained similar peptides and could not be differentiated based on MS/MS analysis alone were grouped to satisfy the principles of parsimony.

2.2.9.2 In-silico screening

A candidate list from the results of the proteomic analysis of myelin was made by selecting proteins predicted to have transmembrane regions using the software TMHMM <http://www.cbs.dtu.dk/services/TMHMM/> (Krogh et al., 2001) and/or signal peptide using the software Phobius <http://phobius.sbc.su.se/> (Käll et al., 2004). Functional information was searched at the UniProt database (The UniProt Consortium, 2008).

2.2.10 Statistical analysis

For two-groups comparison, a Student's *t*-test was used. For more than two groups, a one-way ANOVA was performed, followed by a Tukey test for pairwise comparisons, when applicable. A *p* level of <0.05 was considered significant in all tests. All values are expressed as mean ±SEM. To analyse the effect of the cuprizone treatment on wheel running skills (MOSS) a two-factorial repeated measurements ANOVA, with treatment and time course as the independent variables and the respective wheel-running parameter serving as dependent variable was applied. If ANOVA indicated significant differences for the main effect of treatment, Fisher's LSD post hoc tests were applied. For histological analysis a one-way ANOVA was performed, followed by Tukey test for pairwise comparisons, when applicable. A *p* value of >0.05 was considered significant in all tests. Statistics were calculated using SPSS 11.0 (IBM), GraphPad Prism (GraphPad Software, Inc.) or SigmaPlot software (Systat software, Inc.).

Chapter 3

Results

Multiple Sclerosis (MS) is a demyelinating disorder that results in motor and cognitive decline. Axonal loss occurs throughout the disease, especially in the initial inflammatory stages, where the immune system breaches the blood-brain barrier (BBB) and starts to attack the myelin sheath. Even though axonal loss appears to be driven by the cytotoxic inflammatory reaction against myelin, axons continue to present signals of damage and be lost in chronic stages of the disease when inflammation is minimal (Kuhlmann et al., 2002). This could suggest that a long-term damage could be induced by the disruption of the axo-glial contact and integrity of myelin.

The purpose of this study was to observe the consequences of oligodendrocyte death and myelin loss on axonal preservation. To discern the consequences of the myelin loss from the cytotoxic effect of an autoimmune reaction against myelin, which occurs in experimental autoimmune encephalomyelitis (EAE), we used toxin-based demyelinating models that did not involve infiltration of the immune system in the CNS. To study the short- and long-term effect of demyelination on axons, we induced mature oligodendrocyte ablation by diphtheria toxin and cuprizone.

3.1 Targeted Ablation of Oligodendrocytes Triggers Axonal Damage

3.1.1 Diphtheria-toxin-induced oligodendrocyte ablation and demyelination in MOGi-Cre/iDTR mice

Diphtheria toxin causes apoptosis of cells that express a functional DT receptor or cells that express the catalitically active fragment A of diphtheria toxin. In order to induce mature oligodendrocyte death, we used MOGi-Cre/iDTR mice, which express the DT receptor in myelinating cells. We used heterozygote mice for both the MOGi-Cre and iDTR alleles (see genotyping sample of MOGi-Cre/iDTR mice in **Figure 3.1**). It has been shown previously that intraperitoneal injection of these animals 3 times a day for 7 days with 100 ng of DT results in massive oligodendrocyte death after ~ 30 days (Buch et al., 2005). To explore the consequences of this process on axonal integrity, we injected 10-week-old MOGi-Cre/iDTR mice with 400 ng DT daily for 7 days. We modified the protocol to reduced the frequency in mice injection, and therefore decided to increase the amount of DT injected. As controls, we injected the same volume of PBS to age- and sex-matched MOGi-Cre/iDTR mice and the same amount of DT to MOGi-Cre mice, lacking the iDTR allele.

Figure 3.1: Genotyping of MOGi-Cre/iDTR mice animals used in diphtheria toxin-induced oligodendrocyte ablation. Sample of MOGi-Cre/iDTR mice genotyping of heterozygote animals used in diphtheria toxin-induced oligodendrocyte ablation. PCR products were run in 2% agarose gel at 100V and visualized by transillumination and ethidium bromide. See the methods section for details.

We observed, in accordance with Buch et al. (2005), that after approximately 30 days, MOGi-Cre/iDTR mice injected with DT presented clinical symptoms such as weight loss, tremor and unbalanced gait and occasional death. Due to the severity of the disease, the

animals were sacrificed and processed for tissue analysis. A similar phenotype was observed in animals that were injected with 200 ng DT once a day for seven days, although clinical symptoms were observed around 45 days post injection (data not shown).

To confirm the ablation of oligodendrocytes, coronal sections were stained for the oligodendrocyte marker NogoA and NogoA positive cell densities in the corpus callosum were quantified (**Figure 3.2**). Indeed, the density of oligodendrocytes in MOGi-Cre/iDTR mice (280 ± 25) was significantly reduced compared to MOGi-Cre/iDTR mice injected with PBS (878 ± 82) and MOG-iCre mice injected with DT (707 ± 29), indicating the successful oligodendrocyte ablation induced by DT in MOGi-Cre/iDTR mice.

Figure 3.2: Oligodendrocyte ablation induced with Diphtheria Toxin in MOGi-Cre/iDTR mice. MOGi-Cre/iDTR mice were injected with 400 ng diphtheria toxin (DT) daily, for 7 days. After 30 days, the number of oligodendrocytes was assessed by NogoA staining. A decrease in oligodendrocyte number was observed in MOGi-Cre/iDTR mice treated with DT (left panel), compared to DT-treated MOGi-Cre animals as control (middle panel) and MOGi-Cre/iDTR animals treated with PBS (right panel). For quantification one-way ANOVA was performed, followed by pairwise Tukey test. Statistical significance is represented with asterisks ($n=3-9$, $**p=0.01$, $***p=0.001$). Scale bar, 100 μm .

The extent of demyelination 30 days after injection was assessed by staining coronal sections with LFB-PAS and classifying the signal in the corpus callosum using a standardized scale, from 0 (no demyelination) to 3 (complete demyelination) (Hiremath et al., 1998). Moderate demyelination was observed in MOGi-Cre/iDTR mice treated with DT, in accordance with the reduction of oligodendrocyte abundance (**Figure 3.3**).

Figure 3.3: Demyelination induced with Diphtheria Toxin in MOGi-Cre/iDTR mice. The level of myelination was assessed 30 days after DT treatment by LFB-PAS staining in coronal sections of MOGi-Cre/iDTR mice (left panel), DT-treated MOGi-Cre animals as control (middle panel) and MOGi-Cre/iDTR animals treated with PBS (right panel). For quantification one-way ANOVA was performed, followed by pairwise Tukey test. Statistical significance is represented with asterisks (n=3-9, **p<0.01, ***p<0.001). Scale bar, 100 μ m.

3.1.2 Astrogliosis and immune system response

To evaluate the reaction by other glial populations upon oligodendrocyte death and demyelination, we measured astrogliosis by staining with GFAP antibodies (**Figure 3.4**). We observed a significant increase in astrocyte population in demyelinated animals (378 ± 24 GFAP+ cells per mm^2) in comparison with MOGi-Cre animals treated with DT (152 ± 13 GFAP+ cells per mm^2) and MOGi-Cre/iDTR animals treated with PBS (120 ± 23 GFAP+ cells per mm^2).

A typical feature of demyelinating lesions is an increase population of activated microglia/macrophages. We quantified the macrophage/microglia activation by staining coronal sections with Mac3 antibodies (**Figure 3.5**). We detected a significant increase of this population in DT-treated MOGi-Cre/iDTR mice in demyelinated animals (513 ± 75 Mac3+ cells per mm^2) in comparison with MOGi-Cre animals treated with DT (101 ± 8 Mac3+ cells per mm^2) and MOGi-Cre/iDTR animals treated with PBS (84 ± 21 Mac3+ cells per mm^2).

Figure 3.4: Astroglial density in Diphtheria toxin-induced oligodendrocyte ablation. Coronal sections from MOGi-Cre/iDTR mice treated with DT (left panel), DT-treated MOGi-Cre animals as control (middle panel) and MOGi-Cre/iDTR animals treated with PBS (right panel) were stained for astrocytes (GFAP). Quantification of astrocyte density in central corpus callosum is shown as mean \pm SEM ($n=3-7$). If ANOVA indicated significant differences in the main effect ($p<0.05$), Tukey test pairwise comparison was applied. Statistically significant differences are indicated by asterisks (** $p < 0.01$, *** $p < 0.001$). Scale bar: 50 μm .

Finally, to determine whether a demyelinating event is sufficient to trigger an infiltration of the immune system through the BBB, we used CD3 antibodies to stain T cells. No infiltration of T cells was observed in any of the groups (data not shown).

3.1.3 DT-induced ablation of oligodendrocytes triggers axonal damage

To analyze the changes in the axonal composition and integrity of the corpus callosum, we stained coronal sections with antibodies against high-molecular weight neurofilament (NF200) and measured its thickness. In addition, we measured the NF200 signal, which has been shown to be decreased in demyelinated MS lesions and can reflect a cytoskeletal disorganization in axons (Lovas et al., 2000).

We did not observe evidence of corpus callosum atrophy (ANOVA $p>0.05$). However, there was a decrease in neurofilament signal density in MOGi-Cre/iDTR mice injected with DT (signal density 31.5 ± 2.9 gray value per μm) compared to MOGi-Cre/iDTR mice injected with PBS (878 ± 82 gray value per μm) and MOGi-Cre mice injected with DT (707 ± 29 gray value per μm), which indicates axonal abnormality (**Figure 3.6**).

Damaged axons can be identified by the accumulation of amyloid precursor protein (APP), possibly as a consequence of axonal transport disruption or even the irreversible transection of an axon in the CNS. APP positive axons are frequently found in MS lesions and are taken as a measure of axonal damage (Kuhlmann et al., 2002; Trapp and Nave, 2008). We

Figure 3.5: Microglia activation in Diphtheria toxin-induced oligodendrocyte ablation. Coronal sections from MOGi-Cre/iDTR mice treated with DT (left panel), DT-treated MOGi-Cre animals as control (middle panel) and MOGi-Cre/iDTR animals treated with PBS (right panel) were stained for macrophages and activated microglia with Mac3 antibodies. Quantification of macrophage/microglia density in central corpus callosum is shown as mean \pm SEM (n=3-7). If ANOVA indicated significant differences in the main effect ($p < 0.05$), Tukey test pairwise comparison was applied. Statistically significant differences are indicated by asterisks (** $p < 0.01$, *** $p < 0.001$). Scale bar: 50 μ m.

observed a massive accumulation of APP in the corpus callosum of MOGi-Cre/iDTR mice treated with DT (89 ± 15 positive axons per μm^2), while it was virtually absent in the control groups. (**Figure 3.7**). This indicated that demyelination of the corpus callosum results in axonal damage and possible loss.

3.1.4 No neuronal death detected upon oligodendrocyte ablation

Since there was significant axonal damage in MOGi-Cre/iDTR mice treated with DT, we next examined whether this resulted in detectable neuronal death. We stained neuronal nuclei using NeuN antibodies, and counted the total number of cortical neurons in coronal sections. We did not observe a significant reduction in neuronal abundance (**Figure 3.8**). However, it should be considered that small amounts of localized neuronal death may not be detected when assessing the total number of neurons in our semi-automated method. Therefore, we assessed the number of apoptotic neurons. We stained coronal sections with NeuN antibodies for neuronal nuclei and performed a fluorescein-12-deoxy-UTP nick-end labeling (TUNEL) staining to detect apoptotic cells. We did not observe any apoptotic neurons in any of the groups (**Figure 3.9**). Therefore, DT-induced oligodendrocyte depletion triggered massive axonal damage, but did not result in neuronal death.

Figure 3.6: Reduction in neurofilament signal density in DT-induced demyelination. A decrease of neurofilament signal density (NF200), was observed in MOGi-Cre/iDTR mice treated with DT (left panel), compared to DT-treated MOGi-Cre animals as control (middle panel) and MOGi-Cre/iDTR animals treated with PBS (right panel). Quantifications are shown as mean and SEM (n=3-10). One way ANOVA was performed, followed by pairwise Tukey test. Significance is represented with asterisks (**p<0.01, ***p<0.001). Scale bar, 100 μm. ns: non-significant.

Figure 3.7: Axonal damage as a consequence of Diphtheria toxin treatment in MOGi-Cre/iDTR mice. An increase in axonal damage (evidenced by APP accumulation) was observed in MOGi-Cre/iDTR mice treated with DT (left panel), compared to DT-treated MOGi-Cre animals as control (middle panel) and MOGi-Cre/iDTR animals treated with PBS (right panel). Quantifications are shown as mean and SEM (n=3-10). One way ANOVA was performed, followed by pairwise Tukey test. Significance is represented with asterisks (**p<0.01, ***p<0.001). Scale bar, 100 μ m.

Figure 3.8: Oligodendrocyte depletion with DT does not affect cortical neuronal density. Coronal sections were stained for neuronal nuclei with NeuN antibodies, scanned with Mirax Midi System and automatically counted using Definiens Developer XD software in the indicated region of interest (ROI). One way ANOVA was performed, no statistically significant difference in neuronal density was observed between the groups. Also, no significant difference was found in cortical volume between the groups (p>0.05). An average of 10104 NeuN+ were counted per animal. Quantifications represent mean and SEM (n= 8 MOGi-Cre/iDTR mice treated with DT, 5 DT-treated MOGi-Cre animals as control (middle panel) and 3 MOGi-Cre/iDTR animals treated with PBS, ns: not significant).

Figure 3.9: No neuronal apoptosis observed after DT-induced oligodendrocyte ablation. Coronal sections of cortex from MOGi-Cre/iDTR mice treated with DT (left panel), DT-treated MOGi-Cre animals as control (middle panel) and MOGi-Cre/iDTR animals treated with PBS (right panel) were stained for TUNEL and NeuN 30 days after injection. Sections of the spleen of the respective groups were used as positive control for the TUNEL stainings. Colocalisation of DAPI and TUNEL-positive cells is shown as an inset for each group. Scale bar: 50 μ m, for inset 10 μ m.

3.2 Late motor decline after accomplished remyelination in murine cuprizone model

3.2.1 Long-term analysis of cuprizone-induced de- and remyelination

We used the toxin cuprizone to study the long-term effect of demyelination on axonal preservation and motor functional recovery. Feeding mice with 0.2-0.3% cuprizone (Sigma-Aldrich) for 5-6 weeks results in massive demyelination of white matter tracts in the brain, mainly the corpus callosum. Removing cuprizone from the diet for more than 3 weeks results in extensive remyelination. To observe the difference in the effect of a single or repeated demyelinating events, we submitted a group of male mice for 2 cycles of 5 weeks of 0.25% cuprizone, allowing 4 weeks of recovery in between (named “DD” or “double demyelination” group). In addition, another group of age- and sex-matched mice (named “SD” or “single demyelination” group) were submitted to a single demyelinating event by feeding them with cuprizone for 5 weeks (simultaneous with the second cycle of cuprizone in the DD group). A control group received normal milled chow. For a scheme of the experimental design, see **Figure 3.10**.

Figure 3.10: Experimental design of cuprizone treatment. 8-week-old mice were fed cuprizone for 5 weeks, were then allowed to recover for 4 weeks and finally received cuprizone for 5 more weeks (double demyelination, or DD). A second group of mice (single demyelination, or SD) were fed cuprizone for 5 weeks simultaneous to the second demyelination of the DD group as indicated. Animals were switched to a normal diet for 28 weeks until the end of the experiment. Age-matched controls were fed with a normal diet throughout the experiment. Motor Skill Sequence analysis (MOSS) was performed at the times indicated. Animals were first habituated to training wheels composed of regularly spaced crossbars for two weeks. Subsequently, running performance on complex wheels was recorded for an additional week.

The effectivity of the demyelinating paradigm using cuprizone was evaluated by staining coronal sections with Luxol Fast Blue - Periodic Acid Schiff (LFB-PAS) staining and assessing myelination level with a scale ranging from 0 (no demyelination) to 3 (complete demyelination). We confirmed that demyelination occurred after each cuprizone treatment, and extensive remyelination was observed 28 weeks after the cuprizone was removed from the diet. As expected, the control group, which received normal milled chow, presented no demyelination (**Figure 3.11**).

Figure 3.11: Cuprizone-induced demyelination and remyelination. (A) Representative LFB/PAS-stained corpus callosum of untreated control (left) and after 5 weeks of cuprizone treatment (right). Extensive callosal demyelination is evident in the right panel. Scale bar: 200 μ m. (B) Semi-quantitative analysis of callosal demyelination ($n=3-9$ animals per group) and compared to age-matched control ($n=2-6$). A score of 3 corresponds to maximal demyelination, a score of 0 represents no detectable demyelination. For the first demyelination (left), a t -test was applied. For second demyelination (center) and final time point (right), if ANOVA indicated significant differences in the main effect ($p<0.05$), Tukey test pair-wise comparison was applied. $^{***}p < 0.01$. Data shown as mean + SEM. DD: Double demyelination, SD: Single demyelination. First demyelination: week 5, second demyelination: week 14, final time point: week 42 (see also Fig. 1a).

3.2.2 Late motor decline after accomplished remyelination

To understand whether demyelination can have long-term consequences on the function of the affected axons despite remyelination, we used a motor skills test called Motor Skill Sequence (MOSS). It has been shown that MOSS is useful in assessing behavioral outcome as an indication of the changes in the functional state of the corpus callosum (Schalomon and Wahlsten, 2002; Liebetanz and Merkler, 2006). In this test, mice are allowed to voluntarily run in “complex” wheels with irregularly spaced crossbars following a 2-week training period in regular wheels in individual cages. Since the animals need to constantly adapt the step length in the complex wheels, this movement requires a bi-hemispherical coordination that involves the corpus callosum, as it is the largest white matter tract connecting both cortical hemispheres. The time, velocity and running events are recorded automatically 24 hours a day during seven days. The number of runs, time spent running and accumulated distance are considered to reflect the animal’s motivation and fitness, whereas the maximum velocity (Vmax) and maximum distance (Dmax) accomplished during a running bout reflect the highest performance in bi-hemispherical motor coordination.

We assessed the running performance of the mice on three occasions during recovery: 6 weeks, 20 weeks and 28 weeks after cuprizone was removed from the diet (see **Figure 3.10**). At the first time point of MOSS analysis (6 weeks after cuprizone removal), the maximal velocity and maximal accumulated distance in one run were reduced in treated animals compared to controls (**Figure 3.12**, left panel). This confirms previous findings that showed reduced maximal coordination capacity after 6 weeks of recovery in the cuprizone model, measured by MOSS (Liebetanz and Merkler, 2006). No differences were observed between the SD and the DD groups. At 20 weeks of recovery, there was no significant difference in any of the parameters measured by MOSS between the treated and control animals (**Figure 3.12**, central panel). This may indicate that extended remyelination or compensation mechanisms through cortical plasticity contribute to a functional recovery after cuprizone treatment. Strikingly, in the final time point of MOSS evaluation, 28 weeks after recovery, animals treated with cuprizone once again exhibited a decreased performance in the Vmax and Dmax measurements (**Figure 3.12**, right panel). No difference was detected between the SD and DD groups. This indicates that, regardless of the number of demyelinating events, in the long-term cuprizone treated animals entered a phase of motor decline, revealing latent functional deficits as a consequence of oligodendrocyte death and myelin loss.

Figure 3.12: Late-onset latent motor deficits as measured by wheel running performance after remyelination. Animals received one (shown in red) and two (shown in green) cycles of cuprizone to induce demyelination and were allowed to recover for 28 weeks during which MOSS performance was compared to age- and sex-matched controls (shown in black). Recording was preceded by a two-week training session (day -1: performance of last day on training wheels, for details see material and methods). Complex wheel performance (day 1 to 7) is shown as follows: 6 weeks (left panels), 20 weeks (central panels) and 28 weeks (right panels) after cuprizone withdrawal. Differences between the cuprizone and control group with regard to wheel running performance were calculated by repeated measurements ANOVA. If ANOVA indicated significant differences in the main effect ($p < 0.05$), Fisher's LSD post-hoc tests were applied. * $p < 0.05$, ** $p < 0.01$, rpm: revolutions per minute ($n = 8-12$ animals per group). DD: Double demyelination, SD: Single demyelination. Dist_{ac}: distance in meters accumulated in 24 hours; D_{max}: maximum distance per run; Nrun, number of individual runs in 24 hours; V_{max}: maximum running velocity in revolutions per minute in 24 hours.

3.2.3 Cortical thickness and neuronal preservation after cuprizone treatment

To assess the anatomical and histological aspects of the late-onset motor decline observed in cuprizone-treated animals, we measured the cortical thickness, as atrophy could be related to the functional impairment observed in this study. We measured three regions, which we defined as medial, paramedial and lateral (**Figure 3.13**). We only observed a significant difference in the paramedial thickness, which could be induced by the conspicuous ventricular enlargement observed in the treated animals rather than structural atrophy of the cortex.

Figure 3.13: NeuN-positive neuronal cell bodies within the cerebral cortex are not lost following 28 weeks after stopping cuprizone treatment. (A) Sections were stained for neuronal nuclei with NeuN antibodies, scanned and automatically counted using Definiens Developer XD software in the indicated ROI. (B) Number of cortical neurons in treated groups and controls are shown as the mean + SEM. (C) Density of cortical neurons is shown as the mean + SEM.

To confirm whether the cuprizone treatment resulted in a significant neuronal loss, we stained coronal sections with NeuN antibodies to indicate neuronal nuclei. The abun-

dance of neurons in the cortex at a global level within a particular section was calculated semiautomatically using a custom-made software (for further information refer to the methods section). Similar to the DT model, we did not observe any difference in neuronal numbers between the treated samples nor compared to control (**Figure 3.14**).

Figure 3.14: Cortical thickness is largely unchanged after cuprizone treatment. (A) Scheme showing the different regions where cortical thickness was determined, defined as medial (M), paramedial (P) and lateral (L). Cortical thickness was measured in the medial (B), in the paramedial (C) and the lateral region (D). Scale bar: 1mm (n =5-9, error bars represent SEM. Statistically significant differences are indicated by asterisks. If ANOVA indicated significant differences in the main effect ($p < 0.05$), Tukey test pairwise comparison was applied. ns: not significant, * $p < 0.05$, ** $p < 0.01$. ANOVA: analysis of variance; DD: double demyelinated group, ROI: region of interest; SD: single demyelinated group; SEM: standard error of the mean.

3.2.4 Ultrastructural evaluation after cuprizone treatment

We used electron microscopy to evaluate the ultrastructural consequences of cuprizone treatment and remyelination efficiency 28 weeks after cuprizone removal. This allows for the analysis of myelin at a single-axon level and a more quantitative assessment of remyelination efficiency (see **Figure 3.15**).

Figure 3.15: Overview of remyelination after cuprizone treatment. Electron microscopy of the corpus callosum after 6 weeks of remyelination, as well as after 28 weeks of recovery for double demyelinated (DD), single demyelinated (SD) and control animals are shown. Scale bar = 1 μm

We quantified the percentage of myelinated axons after 6 weeks of remyelination, 28 weeks after remyelination in the SD and DD group, as well as in the control (see **Figure 3.16**, panel A). We defined a threshold of myelin sheath thickness of 15 nm in order to consider an axon to be myelinated (considering that the axonal membrane thickness is of approximately 5-10 nm). In addition, as axons below 200 nm tend to be unmyelinated in the CNS, we set up a conservative threshold and only considered axons that had a diameter larger than 350 nm. We observed an increase in the fraction of unmyelinated axons after 6 weeks of remyelination ($23.3\% \pm 2.5$), as well as the DD group after 28 weeks of recovery ($26\% \pm 8.7$), compared to control ($5.9\% \pm 1.2$). After 28 weeks of recovery, the SD group also presented a tendency of increase in the fraction of unmyelinated axons, but did not reach statistical significance ($20\% \pm 8.4$, $p=0.68$).

In addition, we measured the g-ratio (axon diameter/ fiber diameter) of axons with a diameter larger than 350 nm, which described the myelin thickness relative to the axonal diameter. The g-ratio tends to increase after remyelination, reflecting how the newly formed myelin tends to be thinner than the original. Indeed, we observed an increase of the g-ratio after remyelination (ANOVA $p < 0.05$, 6 weeks: 0.80 ± 0.008 , DD: 0.8 ± 0.012 , SD: 0.77 ± 0.018 , control: 0.73 ± 0.010). The g-ratio increase was statistically significant in remyelinated animals after 6 weeks of recovery and after 28 weeks of recovery (DD group), compared to control. There was a trend towards an increased g-ratio in the SD group as well, but it did not reach statistical significance ($p=0.12$). There was no statistical significance between the cuprizone-treated groups.

Figure 3.16: Ultrastructural analysis of long-term effects of cuprizone-induced demyelination of myelin in corpus callosum. (A) Percentage of non-myelinated fibers as compared to controls (mean + SEM) (B) Axonal diameter to the fiber diameter (g-ratio) in treated groups and controls is shown as the mean + SEM. If ANOVA indicated significant differences in the main effect ($p < 0.05$), Tukey test pair-wise comparison was applied (* $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$) DD: double demyelinated; SD: single demyelinated; SEM: standard error of the mean.

Although cuprizone-treated animals tended to present thinner myelin sheaths (as seen by the displacement of the g-ratios distribution towards higher values), there was a prominent increase in the population of fibers with a g-ratio of approximately 1 in the treated groups compared to control, corresponding to unmyelinated or hypomyelinated axons (see **Figure 3.17**).

3.2.5 Corpus callosum atrophy and axonal loss

We studied the integrity of the corpus callosum at 28 weeks of recovery. First, we stained coronal sections with heavy-molecular weight neurofilament antibodies (NF200) and measured the thickness of the corpus callosum around the midline. In addition to a significantly decreased thickness of the corpus callosum in the treated groups, a reduction of the neurofilament signal intensity was evident (**Figure 3.18**).

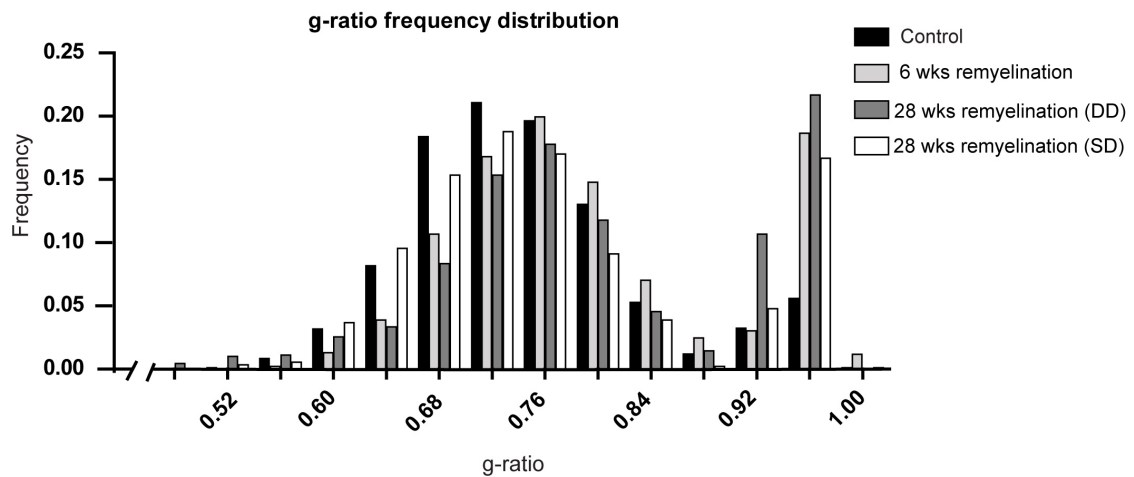

Figure 3.17: G-ratio distribution shows incomplete remyelination. Distribution of g-ratios in the corpus callosum after cuprizone-induced demyelination is shown for treated and control groups. $n=3-11$ animals per group, >300 axons, >350 nm in diameter per animal.

Figure 3.18: Effect of demyelination on corpus callosum integrity. Cuprizone-induced demyelination results in a decrease in neurofilament signal and corpus callosum atrophy, as seen 28 weeks after cuprizone treatment removal. (A) Representative images (overview: 100x, insets: 400x magnification) of coronal sections stained for neurofilament 200 (NF200) from double demyelinated (DD), single demyelinated (SD) and control animals are shown. Insets show high magnification of NF200-stained corpus callosum. (B) Quantitative analysis of corpus callosum thickness as determined MBP staining and image analysis. Mean (C) and integrated (D) density of NF200 signal in the corpus callosum of the different groups is shown as the mean \pm SEM ($n=5-9$). Statistically significant differences are indicated by asterisks. If ANOVA indicated significant differences in the main effect ($p < 0.05$), Tukey test pair-wise comparison was applied (** $p < 0.01$, *** $p < 0.001$). Scale bar = $100\mu\text{m}$.

We then calculated the number of axons crossing the corpus callosum at the midline. For this, we used sagittal sections, where myelin was stained with the Bielschowski method, and axons were stained using pan-Neurofilament antibodies (**Figure 3.19**). The number of axons per area were determined by densitometry, and the total axons were calculated by multiplying the axonal density by the corpus callosum thickness. As expected, axonal numbers in remyelinated animals after 6 weeks of recovery were decreased compared to control. Interestingly, the axonal abundance was further decreased after 28 weeks of recovery, compared to the 6 weeks recovery time point.

Figure 3.19: Extensive axonal loss in cuprizone-induced demyelination. (A) Upper panel: The thickness of the corpus callosum (CC) was determined on sections stained by Bielschowsky's silver impregnation (Biel, extent of CC indicated by double arrows). Lower panel: Axonal densities were determined on confocal images of pan-neurofilament (PAN-NF)-stained adjacent sections within CC. (B) Callosal axonal numbers were calculated by multiplying axonal densities (expressed as axons per mm²) by the thickness CC of a given animal. Bars represent mean + SEM. Statistically significant differences are indicated by asterisks. If ANOVA indicated significant differences in the main effect ($p < 0.05$), Tukey test pair-wise comparison was applied (* $p < 0.05$, ** $p < 0.01$). RM= Remyelination; wks= weeks; ns= not significant). Scale bar upper row in A = 120 μm , lower row = 25 μm . The quantifications were performed by Tanja Jürgens, Medical University Geneva, Switzerland.

Furthermore, we observed enlarged mitochondria in axons, supporting the idea of ongoing axonal pathology ~ 6 months after cuprizone had been removed from the diet (see **Figure 3.20**).

Figure 3.20: Mitochondrial size and density in remyelinated axons. Mitochondrial transverse area and frequency was quantified with electron microscopy. (A) Sample image of mitochondria in micrograph. Scale bar: 250 nm. (B) Mitochondrial area was measured for treated (DM and SM) and control groups. (C) The mitochondrial density was defined as the number of mitochondria found per axonal area (mitochondria/axonal μm^2). An area of $681.4 \mu\text{m}^2$ was analysed per animal. $n=3$ animals per group, error bars represent standard error of the mean (SEM). (If ANOVA indicated significant differences in the main effect ($p < 0.05$), Tukey test pairwise comparison was applied $*p < 0.05$, $***p < 0.001$, ns: not significant).

3.2.6 Long-term axonal damage in cuprizone-treated mice

Previous studies have shown that cuprizone treatment results in axonal damage, as determined by the accumulation of the acute axonal injury marker APP within axons (Irvine and Blakemore, 2008). APP accumulation is regarded as a transient and reversible feature, and is regarded as a transient feature. After 6 months of normal diet following cuprizone treatment, APP-positive axons were still detectable in the corpus callosum of mice, albeit at a low level (see **Figure 3.21**). Therefore, we found evidence for ongoing axonal degeneration long after the demyelinating trigger had been removed.

Figure 3.21: APP-positive axons can be detected in chronic remyelinated lesions. Coronal sections were analyzed in the medial part of the corpus callosum by immunohistochemistry with an antibody against amyloid precursor protein (APP). Arrowheads indicate examples of APP-positive structures. Scale bar: 20 μ m. Quantification of APP-positive axons in central corpus callosum is shown as mean \pm SEM ($n=5-9$). Statistically significant differences are indicated by asterisks; if ANOVA indicated significant differences in the main effect ($p<0.05$), Tukey test pair-wise comparison was applied (** $p < 0.01$, ns: not significant).

Since remyelination is considered to protect axons from degeneration (Irvine and Blakemore, 2008), we quantified the proportion of damaged (APP+) axons that were unmyelinated in cuprizone-treated animals 28 weeks after cuprizone removal, when remyelination would be expected to be accomplished. Interestingly, we observed that a fraction of the APP+ axons (within a 1 μ m-thick sagittal section) were surrounded by an MBP+ myelin sheath (19% for DD and 27% for SD; see **Figure 3.22**).

3.2.7 Axonal damage in MS chronic lesions

To compare our models to what occurs in MS, we also evaluated the proportion of unmyelinated versus myelinated APP+ axons in remyelinated lesions in 6 lesions within 4 different MS patients with documented progressive MS (average disease duration $17.2 \pm$

Figure 3.22: Myelin ensheathment of APP-positive axons. Sections were stained by immunohistochemistry with antibodies against APP (green) and MBP (red). Left image shows an example of an MBP-positive ring surrounding an APP-positive axon. Right image displays an example of an APP-positive axon lacking MBP. Scale bar: 2 μ m. (D) Quantification of the percentage of myelinated and unmyelinated APP-positive axons in central corpus callosum of cuprizone-treated groups, n=5–9 per group. DD: double demyelination group, SD: single demyelination.

4.7 years). We found that around 14% of APP+ axons were surrounded by an MBP+ myelin sheath, similar to what we observed in our cuprizone-treated animals (see **Figure 3.23**).

Figure 3.23: APP-positive axons can be detected in chronic remyelinated lesions in MS. MS autopsy lesions showing extensive remyelination and with known long clinical history of progressive MS (average disease duration 17.2 ± 4.7 years) were stained by immunohistochemistry with antibodies against APP (green) and MBP (red). Left image shows an example of an MBP-positive ring surrounding an APP-positive axon. Right image displays an example of an APP-positive axon lacking MBP. Scale bar: 2 μ m (F) Quantification of the percentage of myelinated and unmyelinated APP-positive axons in lesions of progressive MS patients, n=5 MS cases. Quantifications performed by Doron Merkle, Geneva University Hospital, Switzerland).

3.2.8 Astrogliosis and microglia activation ~ 6 months after cuprizone treatment

To understand associated cellular responses in the context of ongoing axonal damage and functional deficits 28 weeks after cuprizone removal, we carried out different histological analysis to assess the other glial populations in the corpus callosum. Astrogliosis was still evident at this final time point in treated animals compared to control (**Figure 3.25**). In addition, macrophage/microglia activation was still relatively elevated in cuprizone-treated groups (**Figure 3.24**). Once more, we did not detect any differences between the SD and DD groups.

Figure 3.24: Microglia activation ~ 6 months after cuprizone-induced demyelination. (A) Coronal sections from double demyelinated (DD), single demyelinated (SD) and control animals were analyzed in the medial part of the corpus callosum and stained for microglia/macrophages (Mac3). Arrowheads indicate examples of positively stained cells. (B) Quantification of microglia/macrophage density in central corpus callosum is shown as mean + SEM (n=5–9). Statistically significant differences are indicated by asterisks (If ANOVA indicated significant differences in the main effect ($p < 0.05$), Tukey test pair-wise comparison was applied, $*p < 0.05$, $**p < 0.01$, ns: not significant). Scale bar: 20 μm .

Microglia help in the clearance of myelin and cell debris that arise as a consequence of demyelination, but can also secrete pro-inflammatory molecules that can have a cytotoxic effect both in oligodendrocytes and axons. Indeed, it is thought that in MS the levels of axonal damage are somewhat correlated to microglia activation levels. We observed an apparently similar trend in microglia activation and axonal damage through the duration of the experiment (**Figure 3.26**). As to whether an increase in these populations is either a cause or a consequence of degenerative processes is still under debate. Therefore, it should be carefully interpreted in the context of the prolonged axonal damage described in this study.

Figure 3.25: Astrocytosis ~ 6 months after cuprizone-induced demyelination. (A) Coronal sections from double demyelinated (DD), single demyelinated (SD) and control animals were analyzed in the medial part of the corpus callosum and stained for astrocytes (GFAP). Arrow heads indicate examples of positively stained cells. (B) Quantification of astrocyte (GFAP) density in central corpus callosum is shown as mean + SEM (n=5–9). Statistically significant differences are indicated by asterisks (If ANOVA indicated significant differences in the main effect ($p < 0.05$), Tukey test pair-wise comparison was applied, ** $p < 0.01$, *** $p < 0.001$, ns: not significant). Scale bar: 20 μm .

Figure 3.26: Longitudinal APP accumulation and microglia activation after cuprizone. Immunohistochemistry for APP as a marker of axonal damage (A) and Mac3 as a marker of macrophages and activated microglia (B) during cuprizone treatment and recovery. Coronal sections were analysed in the medial part of the corpus callosum.

It is believed that the cuprizone model preserves the integrity of the blood-brain barrier. However, to assess if demyelination can trigger by itself an infiltration of immune cells

into the CNS, we searched for the presence of T cells staining with CD3 antibodies in the brain. As in the DT model, we did not observe any conspicuous T cell infiltration in the treated groups compared to control (data not shown).

In summary, our findings indicate that late-onset locomotor dysfunction can be observed long after cuprizone-induced de- and remyelination. This is accompanied by a reduction of callosal axons and a low level of still ongoing axonal degeneration.

3.3 Protein screening for candidates involved in myelination

Proteins localized at contact sites between axons and myelin have been found to be important in the formation and stability of myelin and axonal survival. These sites are usually enriched with adhesion molecules involved in axo-glial communication and molecular organization of the axonal and myelin membranes. Some of these proteins have been identified and are well characterized, such as Neurofascin 155 in oligodendrocytes and the Contactin/Caspr complex at the axonal membrane (Peles and Salzer, 2000). To explore at a cellular level the interaction between oligodendroglia and axons, we isolated fractions of myelin enriched in glycoproteins, as well as periaxonal, and paranodal/juxtaparanodal regions, which are in close apposition to the axolemma.

3.3.1 Myelin fractions isolation and purification

Based on its specific density, myelin can be isolated by subjecting it to centrifugation in a discontinuous sucrose gradient (Matthieu et al., 1973). The majority of the myelin fraction can be collected at the interphase between 0.32 and 0.85 M of sucrose solution (Norton and Poduslo, 1973), and most of it is composed by compact myelin, of which MBP and PLP are the major proteins. In this fraction, an enrichment of myelin proteins can be observed compared to brain homogenate (**Figure 3.27**, panel A). However, the regions in direct contact with the axons (paranodes, juxtaparanodes and periaxonal area) are composed of non-compacted areas with cytoplasm and cytoskeletal components, and therefore tend to float in slightly heavier fractions (**Figure 3.27**, panel B).

As myelin tightly wraps around axons, a close contact between the glial and axonal membrane is created. In these regions, specialized cell adhesion molecules coordinate the formation of the node of Ranvier, paranodes and juxtaparanodes. Many proteins involved in cell-to-cell adhesion and communication contain heavily glycosylated extracellular domains, and therefore can be isolated using lectin proteins such as Concanavalin A or Wheat Germ Agglutinin (WGA), which bind strongly to glycosylated motifs in these proteins (**Figure 3.28**).

Figure 3.27: Myelin isolation by sucrose gradient centrifugation. (A) Myelin is isolated by adding brain homogenate to a discontinuous 0.32 M and 0.85 M sucrose gradient and retrieving the resulting interphase after centrifugation. The recovered material is then diluted in water and centrifuged. The pellet is submitted to two subsequent hypotonic shocks with water, obtaining "crude myelin". The pellet is re-suspended and overlaid on a new gradient, repeating the previous steps to obtain "purified" myelin). The Western blot shows the enrichment of myelin-associated proteins (MAG and PLP) and de-enrichment of astrocyte (GFAP) and neuronal (β III tubulin) material. (B) Myelin can be fractionated according to the floatability properties of the different domains of myelin, with compacted areas (rich in PLP and MBP) floating at lower densities than non-compact areas (enriched in MAG, CNP and Neurofascin). Briefly, crude myelin can be subjected to a continuous sucrose gradient and centrifuged. The different fractions are retrieved using equal volumes and the components are washed with water and centrifuged to obtain a pellet. MAG: myelin associated glycoprotein, PLP: proteolipid protein, MBP: myelin basic protein, GFAP: glial fibrillary acidic protein, MOG: myelin oligodendrocyte glycoprotein, CNP: 2',3'-Cyclic-nucleotide 3'-phosphodiesterase.

Figure 3.28: Myelin-associated glycoprotein isolation using lectin beads. Myelin proteins are solubilized with 0.1% Triton and spun down. For comparison, both the insoluble pellet and the supernatant were bound to lectin beads (Glycoprotein Isolation Kit, Concanavalin A, Thermofisher). Enrichment of non-compact proteins (MAG and CNP) can be observed compared to PLP. MAG: myelin associated glycoprotein, PLP: proteolipid protein, CNP: 2',3'-Cyclic-nucleotide 3'-phosphodiesterase.

Taking advantage of the different densities of compact and non-compact myelin, and the glycosylation of cell adhesion molecules associated to it, we used several different approaches to enrich these fractions. We used continuous and discontinuous sucrose centrifugation, WGA and ConA columns for glycoprotein isolation, as well as myelin isolated at postnatal day 14, before compaction of myelin is complete. We evaluated the distribution of compact and non-compact myelin proteins compared to the classical myelin preparation (Norton and Poduslo, 1973) where compact myelin proteins are preferentially enriched. This sample was not included in proteomic analysis, but rather kept as a sample for comparison in the quality control of the preparations (**Figure 3.29**).

In summary, we isolated different fractions of myelin from C57/BL6 mice (1-6) or human brain samples (7):

1. Standard compact myelin preparation in discontinuous sucrose gradient, 0.32 M/0.85 M interphase (Norton and Poduslo, 1973).
2. Myelin isolated from postnatal day 14 (P14) brain homogenate, in discontinuous sucrose gradient, 0.32M/0.85M interphase.
3. Purified myelin solubilised with 1% Triton X-100 o/n and bound to ConA beads
4. Purified myelin bound to WGA beads.

5. Myelin isolated from brain homogenate subjected to an initial hyposmotic shock with water and then subjected to a continuous gradient, fraction 0.9-1 M sucrose.
6. Myelin isolated from brain homogenate subjected to an initial discontinuous gradients and collected from 0.32-1.2 M interphase (crude myelin) and subsequently subjected to a continuous sucrose gradient. Collected from Fraction 3, or 0.9-1 M sucrose.
7. Glycoprotein from human myelin preparation, subjected to a lentil-lectin column (Mathey et al., 2007), kindly provided by Edgar Meinl (Max Planck Institute of Neurobiology, Munich).

Figure 3.29: Western blot of myelin-enriched fractions for proteomics. Enrichment of non-compact proteins (Neurofascin, MAG, CNP and MOG) compared to compact myelin protein (PLP) and axonal proteins (β III tubulin). Sample 1: Adult myelin, 0.32/0.85 M interphase. Sample 2: P14 myelin 0.32/0.85 M interphase. Sample 3: Adult myelin treated with Triton X 0.1% and bound to ConA beads. Sample 4: Adult myelin bound to WGA beads. Sample 5: Adult brain homogenate subjected to sucrose continuous gradient, fraction corresponding to 0.9-1.0 M. Sample 6: Adult myelin taken from 0.32/1.2 interphase and then subjected to a sucrose continuous gradient, fraction corresponding to 0.9-1.0 M. Sample 7: Human myelin glycoproteins eluted using a lentil-lectin column. MAG: myelin associated glycoprotein, PLP: proteolipid protein, MOG: myelin oligodendrocyte glycoprotein, CNP: 2',3'-Cyclic-nucleotide 3'-phosphodiesterase.

3.3.2 Proteomic analysis

The samples were analyzed by mass spectrometry and 6 lists, with a total of 1904 proteins, were obtained. As stated above, the compact enriched myelin fraction (Sample 1) was not analyzed as it was used for quality control comparison by western blot. We then screened the lists by identifying the proteins predicted to have a transmembrane domain with the TMHMM Software or have a signal peptide with the Phobius software. We selected the proteins that were present in two or more lists, except for the human sample list, which was analyzed separately. We then manually selected candidates according to literature search or functional information available at the UniProt database (The UniProt Consortium, 2008). We discarded the proteins that have already been intensively described, as MAG, Contactin, Caspr and Necl4, among others. A summary of the selected candidates is presented below.

Accession number	Identified Proteins	List	Unique peptides (sum)
gi 119571963	ADAM metallopeptidase domain 11, isoform CRAa	human	5
gi 1709301	amyloid precursor-like protein 1	human	9
gi 16306530	cadherin-10 preproprotein	human	2
gi 119571613	carboxypeptidase D, isoform CRAb	human	7
gi 119613874	CD46 antigen, complement regulatory protein, isoform CRAf	human	2
gi 18640734	contactin-associated protein-like 5 precursor (CNTP5)	human	5
gi 13435361	desmocollin-1 isoform Dsc1a preproprotein (DSC1)	human	2
gi 32189434	immunoglobulin superfamily member 8	4 (+human)	29 (+19)
gi 109658490	Insulin receptor	human	2
gi 116295258	integrin alpha-2 precursor (CD49B)	human	6
gi 27363458	leucine-rich repeat and fibronectin type-III domain-containing protein 4 (LRFN4)	human	6
gi 148665587	limbic system-associated membrane protein (Lsamp)	4	22
gi 14192943	multiple epidermal growth factor-like domains protein 10 precursor (MEG10)	human	4
gi 145701025	multiple epidermal growth factor-like domains protein 8	human	9
gi 163965382	neural cell adhesion molecule 2 isoform a (NCAM2)	2	9
gi 119630409	neural cell adhesion molecule 2, isoform CRAa	human	44
gi 27151644	neurotrimin (HNT)	(+human)	8 (+2)

Accession number	Identified Proteins	List	Unique peptides (sum)
gi 148707097	nicastrin	2	5
gi 119608548	olfactomedin 1, isoform CRAa	human	18
gi 152013069	PCDH9 protein	human	13
gi 119606585	plexin domain containing 2, isoform CRAc	human	2
gi 189065500	predicted: melanoma cell adhesion molecule (MCAM)	human	11
gi 156523248	proline-rich transmembrane protein 2	3	10
gi 148699102	protein tyrosine phosphatase, receptor type, D	2	9
gi 119603966	protein tyrosine phosphatase, receptor-type, Z polypeptide 1, isoform CRAa	human	19
gi 148728162	receptor-type tyrosine-protein phosphatase isoform 1 precursor (PTPRJ)	human	10
gi 5729718	trophoblast glycoprotein (TPBG)	human	2
gi 110626109	tyrosine-protein phosphatase non-receptor type substrate 1 isoform 1	3 (+ human)	13(+26)
gi 158256874	unnamed protein product	human	4
gi 221041684	unnamed protein product	human	2
gi 22760207	unnamed protein product	human	8
gi 170014689	VPS10 domain-containing receptor SorCS2 precursor (SORC2)	human	6

3.3.3 Expression of candidates in HEK 293T cells and binding assay

From our proteomic analysis of glycoprotein-enriched and non-compact myelin fractions we generated a list of candidate proteins by transmembrane and signal peptide prediction. We then created a soluble version of each candidate, cloning the signal peptide and predicted extracellular domain and tagging it with a human Fc fragment for detection. The exclusion of the transmembrane domain thus results in the protein being secreted by transfected HEK 293T cells, and the soluble proteins were then retrieved by collecting the supernatant.

Subsequently, a binding assay was used as a screening method to detect potential interaction of selected candidates with neurons or oligodendrocytes (as some of the axonal components may be isolated along with myelin). The assay was performed by adding the soluble version of the candidate proteins to neurons and oligodendrocyte-enriched cultures. As positive controls, we used Necl1-Fc and Necl4-Fc, which bind strongly to oligodendrocytes and axons, respectively (Spiegel et al., 2007).

We evaluated the expression and secretion of Necl1, Necl4 and candidate proteins by analysis of the supernatant of transfected HEK cells by western blot (see example in **Figure 3.30**).

Figure 3.30: Western blot of Fc-fused candidate proteins. pcDNA is the empty vector, used as negative control. The soluble proteins consisted of the signal peptide and extracellular domain, fused to a human Fc fragment for detection. The proteins are retrieved from the supernatant of transfected HEK 293T cells and detected using an antibody against human Fc fragment. Necl: Nectin-like protein, Lsamp: limbic system-associated membrane protein, Opcml: opioid binding protein/cell adhesion molecule-like, Ntm: neurotrimin, MCAM: melanoma cell adhesion molecule, Plekhhb1: pleckstrin homology domain containing, family B (evectins) member 1; LGI3: leucine-rich repeat LGI family, member 3.

To evaluate whether the expressed soluble proteins retained their normal interaction properties, we took the supernatant from transfected HEK 293T cells, incubated it with Cy3-conjugated anti-Fc antibody and added it to live cells for 20 minutes. **Figure 3.31** shows a sample of a binding assay using Necl1 and Necl4 as controls. Using this binding assay as a screening tool, we screened for the candidates as Igsf8, MCAM, Plekhhb1 and LGI3, and did not observe binding (see example for Igsf8 in **Figure 3.32**).

We decided to take MCAM-Fc as a negative control for the functional assays, to discard unspecific effect of a soluble Fc-fusion protein. However, we saw binding of one of our candidates, limbic system-associated membrane protein to both neurons and oligodendrocytes (Lsamp, **Figure 3.33**).

The Lsamp-Fc fusion protein did not appear to bind to astrocytes. Uptake by microglia was observed, but was considered unspecific as it occurred with all proteins that were added microglia and can, thus, be attributed to its phagocytic properties (**Figure 3.34**). This suggests that the binding to oligodendrocytes and neurons observed is specific.

Figure 3.31: Binding assay of Necl1-Fc and Necl4-Fc as controls. Soluble versions of Necl1 and Necl4, consisting of the extracellular domain fused to a human Fc fragment were tagged with Cy3-conjugated anti-Fc antibodies and added to neuronal and oligodendrocyte cultures. As described previously, Necl1-Fc binds extensively to oligodendrocytes, stained with MBP, whilst Necl4-Fc binds to neurons, stained with β III tubulin (Spiegel et al., 2007). Scale bar: $50\mu\text{m}$.

Figure 3.32: Immunoglobulin family member 8 (Igsf8) binding assay. Binding assay of Igsf8 to neurons and oligodendrocytes, using Necl1-Fc and Necl4-Fc as controls. Soluble Fc-fusion proteins were added to neuronal and oligodendrocyte cultures. No binding of Igsf8 was observed to oligodendrocytes (MBP) nor neurons (β III tubulin). Transfected HEK 293T cells were stained with Cy3-conjugated anti-Fc antibodies to reveal the expression of the proteins within the cell. Scale bar: $50\mu\text{m}$.

Figure 3.33: Limbic system-associated membrane protein (Lsamp) binding assay. Binding assay of Lsamp to primary neuronal and oligodendrocyte culture, using Necl1-Fc and Necl4-Fc as controls. Soluble versions of the proteins, consisting of the extracellular domain fused to a human Fc fragment were tagged with Cy3-conjugated anti-Fc antibodies and added to neuronal and oligodendrocyte cultures. Positive binding of Lsamp to both oligodendrocytes (MBP) and neurons (β III tubulin) was observed. Scale bar: 50 μ m

Figure 3.34: *Lsamp* does not bind to astrocytes and is uptaken by microglia. Binding assay of *Lsamp* to primary astrocytes and microglia culture present in primary neuronal cultures, using MCAM-Fc as control. No binding to astrocytes (GFAP) was observed. Microglia uptake of both *Lsamp*-Fc and MCAM-Fc is shown. Scale bar: 50 μm

Both candidate proteins *Lsamp* and Neurotrimin (here termed *Ntm*) belong to the GPI-anchored family IgLON, and *Lsamp* has been previously identified in other myelin proteomic and transcriptomic analysis (Nielsen et al., 2006; Jahn et al., 2009a). We therefore decided to include a third member of the family *Opcml*, to analyze whether the binding property is shared among the family. *Opcml* was found in the proteomic screening but failed to pass the first transmembrane prediction by TMHMM and Phobius and was not initially included in the candidate list.

However, as the IgLON family is GPI-anchored, they are anchored to the membrane and can be involved in cellular communication as they can associate to transmembrane proteins to trigger intracellular responses (Simons and Toomre, 2000). *Lsamp*, *Opcml* and *Ntm* have previously been described as neuronal proteins that appear to regulate neurite growth and interact with members of the same family, forming both homophilic and heterophilic complexes (Lodge et al., 2000; Gil et al., 2002; Reed et al., 2004). Concordantly, we observed that the three proteins bound to neurons (**Figure 3.35**).

Figure 3.35: Neuronal binding assay with proteins of the IgLON family. Proteins of the IgLON family, Lsamp, Opcml and Ntm were used for binding assays with primary neuronal culture, using MCAM-Fc as negative control. Soluble versions of the proteins, consisting of the extracellular domain fused to a human Fc fragment were tagged with Cy3-conjugated anti-Fc antibodies and added to neuronal and oligodendrocyte cultures. Positive binding of Lsamp, Opcml and Ntm to neurons (β III tubulin) was observed. Scale bar: 50 μ m

The confirmation of the interaction of IgLON candidates with neurons primary culture shows that our fusion proteins were biologically functional. We therefore proceeded to repeat the binding assay with Lsamp, Opcml and Ntm in oligodendrocytes, using MCAM-Fc as a negative control. To protect the integrity of the oligodendrocyte lipid-rich myelin sheets for our binding assay, we did a surface staining against the oligodendrocyte marker O1, which requires no permeabilization. We saw binding of Lsamp, Opcml and Ntml (**Figure 3.36**).

Figure 3.36: Oligodendrocyte binding assay with proteins of the IgLON family. Proteins of the IgLON family, Lsamp, Opcml and Ntm were used for binding assays with primary oligodendroglial culture, using MCAM-Fc as negative control. Soluble versions of the proteins, consisting of the extracellular domain fused to a human Fc fragment were tagged with Cy3-conjugated anti-Fc antibodies and added to neuronal and oligodendrocyte cultures. Positive binding of Lsamp, Opcml and Ntm to oligodendrocytes (MBP) was observed. Scale bar: 50 μm

To confirm that the IgLON proteins are interacting with other members of their family, we transfected HEK 293T cells with full length Lsamp tagged with EGFP. Then we added the soluble proteins and visualized them with a Cy3-conjugated Fc antibody. We indeed observe how there is interaction of Lsamp with the other members of the family, as well as itself (**Figure 3.37**). No binding was observed adding MCAM-Fc or adding the IgLON

proteins to HEK 293T cells transfected only with EGFP, confirming the specificity of the interaction. Similar results were observed when expressing the full length of Opcml and Ntm (data not shown).

Figure 3.37: IgLON fusion proteins interact with members of their family. Lsamp-Fc, Opcml-Fc and Ntm-Fc were added to HEK 293T cells transfected with full length Lsamp-EGFP, using MCAM as negative control. IgLON proteins bound to HEK 293T cells expressing full length Lsamp but did not bind to HEK cells transfected with EGFP. Scale bar $100\mu\text{m}$

To test the specificity of commercially available antibodies we transfected HEK 293T cells with myc-tagged full length proteins, and tested different shRNA to knockdown the expression of the proteins, using scramble shRNA and untransfected HEK 293T cells as negative controls. Unfortunately, the antibodies commercially available have not been useful in elucidating the expression of the IgLON candidates the different cell types, as they seem to give unspecific signals which do not facilitate the expression analysis (**Figure 3.38**).

To analyze the distribution of exogenously expressed Lsamp, Opcml and Ntm in oligodendrocytes, we transiently transfected primary oligodendrocytes with full-length version of these proteins, with a myc tag in the N-terminus. We observed that the proteins entered the compact, MBP positive myelin-like sheets (**Figure 3.39**).

Figure 3.38: Knockdown of exogenously expressed IgLON proteins in HEK 293T cells. HEK 293T cells were transfected with myc-tagged full length Lsamp, Opcml and Ntm. Knockdown was attempted using four shRNA constructs, a scramble shRNA as control. Knockdown was assessed staining against myc, and commercially available antibodies for Lsamp (Biozol), Opcml (Biozol) and Ntm (Millipore) were used to validate the specificity of their signal. Only Ntm seemed to reflect the pattern obtained by myc antibodies, but presents a strong unspecific band at approximately 50 KDa.

Figure 3.39: Exogenous expression of IgLON proteins in oligodendrocytes. Myc-tagged full length Lsamp, Opcml and Ntm localized to MBP-positive myelin sheets in mature oligodendrocytes in vitro. Scale bar: 50 μ m.

3.3.4 Functional assays

We proceeded to establish different functional assays to determine whether IgLON proteins can influence the intrinsic processes in oligodendrocyte life cycle, or the interaction with neurons for myelination. We tested the effect of *Lsamp*, *Opcml* and *Ntm*, as well as MCAM (as negative control) to test the effect of the presence of these proteins in the media on oligodendrocyte proliferation, differentiation, migration, adhesion and myelination.

Proliferation assay

First, we plated 30 000 oligodendrocyte precursor cells (OPC) per well in a 24-well plate on PLL-coated coverslips. We added 10 $\mu\text{g}/\text{mL}$ of the Fc-fusion proteins to the wells, fixed the cells after 8 hours and stained them for the OPC marker A2B5. We used 100 ng/mL PDGF as a proliferative agent. We did not see any effect of the IgLON proteins on the proliferation of OPC or the proportion of OPC in culture (**Figure 3.40**).

Figure 3.40: IgLON family proteins do not influence OPC proliferation OPC were seeded after shaking and fixed after 8 hours. No effect in cell numbers or OPC proportion was observed. PDGF was used as proliferative factor. OPC: Oligodendrocyte precursor cell (n=3). Scale bar: 100 μm

Migration assay

We used a modified Boyden-chamber to study the effect of IgLON candidates on the migration of OPC (CytoSelect 24-Well Cell Migration and Invasion Assay, 8 μm Colorimetric Format). We added 300 000 OPC to each inner well in the migration chamber and allowed the cells to settle down. The membrane in the well has pores with 8 μm diameter, that allow the cells to migrate towards chemoattractants on the other side. We added 10 $\mu\text{g}/\text{mL}$ of the Fc-fusion proteins to the wells to the media on the outer part of the well. We used 100 ng/mL PDGF as a chemoattractant. PBS was used as a negative control. After 8 hours we did not see any effect of IgLON proteins in the migration of the OPC (Figure 3.41).

Figure 3.41: Proteins of the IgLON family do not induce OPC migration OPC were seeded after shake in a boyden chamber with 8 μm wide pores and allowed to freely migrate for 8 h in the presence of 10 $\mu\text{g}/\text{mL}$ of Fc-fusion IgLON proteins. No effect was observed in the migration of OPC compared to negative control. PDGF (100 ng/mL) was used as a chemoattractant and PBS was used as a negative control (n=4).

Differentiation assay

To observe whether the presence of soluble IgLON in the media could influence the growth and differentiation of oligodendrocytes *in vitro*, we allowed OPC to grow on PLL-coated coverslips for 4 days in the presence of 30 $\mu\text{g}/\text{mL}$ of IgLON Fc-fusion proteins. We did not see any change in the proportion and density of oligodendrocytes, nor in the normalized MBP signal per cell, suggesting that cell size also was not affected (**Figure 3.42**).

Figure 3.42: IgLON proteins do not influence OPC differentiation. OPC were seeded after shake and were allowed to grow for four days in the presence of 30 $\mu\text{g}/\text{mL}$ IgLON-Fc fusion proteins, using MCAM-Fc and PBS controls. No difference in cell number, OPC proportion nor MBP integrated signal per cell as cell size indication was observed ($n=3$). Scale bar: 100 μm .

Adhesion assay

We hypothesized that a neuronal molecule involved in axoglial contact would provide an adhesive surface for oligodendrocytes. Therefore, we coated coverslips with the Fc-fusion candidates. As controls, we used PLL to verify the quality of the culture and the axonal protein Necl1-Fc, to confirm the functionality of the assay. OPC were allowed to grow for 4 days (**Figure 3.43**). We observed that the number and size of oligodendrocytes in the Necl1-Fc sample was comparable to that to PLL coated coverslips, indicating the robustness of the assay. Even though the oligodendroglial size in the IgLON samples showed a tendency to increase, it did not reach statistical significance.

Figure 3.43: IgLON family proteins adhesion assay. Coverslips were coated with 5 μ g/mL Fc-fusion proteins and OPC were plated and allowed to adhere and grow for 4 days. PLL and Necl1-Fc coating were used as positive controls. The purified supernatant of HEK 293T cells transfected with an empty vector (pcDNA) and MCAM-Fc were used as negative control. ANOVA <0.05 , Dunnet post-hoc test with pcDNA as control ($n=3$). * $p < 0.05$, ** $p < 0.01$. Scale bar: 100 μ m.

Myelination assay

A myelinating co-culture can be established *in vitro* by adding OPC to primary neuronal culture previously grown for two weeks. Myelinating oligodendrocytes are identified by counting the percentage of MBP+ oligodendrocytes that form tubular, perpendicular structures, following the axonal path. Non-myelinating oligodendrocytes tend to form myelin sheets, display ramified processes that bifurcate at angles smaller than 90 degrees or do not develop processes at all (**Figure 3.44**).

Figure 3.44: Example of myelinating and non-myelinating coculture. Myelinating oligodendrocytes form perpendicular, MBP-positive tubular structures. Non-myelinating oligodendrocytes typically form MBP-positive sheets, numerous processes bifurcating repeatedly and at less than 90 °C, or no processes at all. Examples are indicated with arrow heads. Scale bar: 100 μm .

To assess the ability of oligodendrocytes to initiate myelination in the presence of IgLON soluble proteins, we added 10 $\mu\text{g}/\text{mL}$ of protein to primary neuronal cultures prepared at E16 and allowed them to grow for two weeks. We then added OPC to the neurons and continued to culture for 5 days. We observed a decrease in myelination efficiency in the presence of Ntm-Fc (**Figure 3.45**). This indicates a possible role of Ntm in the

communication between axons and glia that may have impact on myelination *in vitro*. It is known for proteins of the IgLON family to be involved in the guidance and extension of neurites but this is the first evidence of their function involving glial cells. Further studies can test the effect of IgLON downregulation in an *in vivo* mammalian system.

Figure 3.45: Myelination assay in co-culture system with IgLON proteins. Neuron and oligodendrocyte cocultures were allowed to grow for 5 days in the presence of 10 $\mu\text{g}/\text{mL}$ IgLON-Fc fusion proteins. The purified supernatant of HEK 293T cells transfected with an empty vector (pcDNA) and MCAM-Fc were used as negative control. ANOVA <0.05 , Dunnet post-hoc test was performed comparing the samples against pcDNA as control. ** $p < 0.01$, ns: not significant. Scale bar: 100 μm .

Chapter 4

Discussion

In this study, we analysed the short-and long-term consequence of oligodendrocyte ablation and demyelination on axonal preservation in two animal models of MS. It has been proposed that myelin may have a nurturing role in addition to its structural function as an insulating surface that allows the fast transmission of electric signals along the axon (Nave and Trapp, 2008). We used models that preserved the integrity of the BBB to prevent the infiltration of the immune system into the CNS. We focused on the corpus callosum because it is the main white matter tract in the brain connecting the two cortical hemispheres. Disruption of this structure results in functional deficits that can be assessed using sensitive motor tests (Liebetanz and Merkler, 2006). We observed that both cuprizone- and diphtheria toxin-induced oligodendrocyte death led to significant demyelination in the corpus callosum. This was accompanied by axonal damage, evidenced by APP accumulation and a decrease in neurofilament signal in both of the models. In the long term, cuprizone-induced demyelination was followed by remyelination and a transient functional performance similar to control animals, which ultimately gave way to a late motor decline, analyzed by the MOSS complex wheel running paradigm.

4.1 Acute axonal damage as a consequence of oligodendrocyte ablation

Multiple sclerosis (MS) is a disease that involves an autoimmune attack against myelin, accompanied by inflammation and axonal damage. In most of the cases it initiates with discrete episodes of infiltration of immune cells into the CNS and a localized breakdown of the blood-brain barrier. This is accompanied by clinical symptoms that include motor and sensory impairment and fatigue. Acute episodes result in the formation of multifocal lesions, giving the disease its name. However, these acute episodes are usually followed by a partial or complete recovery, in a pattern termed relapsing-remitting multiple sclerosis (MS). With time, patients tend to enter a progressive phase, characterized by a steady worsening of symptoms without recovery, including decreased mobility and cognitive decline (Trapp et al., 1998; Noseworthy et al., 2000; Friese et al., 2006). It appears this late stage is somewhat independent of inflammation, and is instead related to a ongoing axonal loss and neurodegeneration, accounting for the clinical worsening of the patients (Confavreux et al., 2003; Brück, 2005). It has been proposed that remyelination serves as a neuroprotective mechanism, which not only prevents axonal loss related to a demyelinating event by protecting the axon from a toxic environment but also seems to provide axons with required trophic support (Trapp et al., 1998).

It has been widely accepted that MS is initiated by an autoimmune response against myelin epitopes, the consequence of which is demyelination, oligodendrocyte loss and axonal damage. However, in recent years, this hypothesis of MS pathogenesis has been questioned, as evidenced by oligodendrocyte abnormality and demyelination in early MS lesion, before immune infiltration can be detected (Barnett and Prineas, 2004). This has opened the debate as to whether the inflammatory response is the cause or the consequence of the demyelination and axonal pathology observed. Many anti-inflammatory therapies have been developed to reduce the relapse rate and severity in early stages of MS. However, these therapies do not necessarily delay the onset and advancement of the progressive stages of the disease, pointing to the possibility that MS initiation and progression is not entirely dependent on inflammatory processes (Brück, 2005; Nakahara et al., 2012).

To study the different aspects of multiple sclerosis, numerous animal models have been developed in the recent decades. Each of these models have proven to be useful in under-

standing the diverse aspects and mechanisms of myelin pathology. Most have addressed the control of an autoimmune response directed against myelin, as in EAE, or a direct insult against oligodendrocytes, as in toxin-mediated oligodendrocyte death. Although the main underlying question regarding the origin and mechanism of the autoimmune response against myelin remains, the different studies to date have tried to address the four major aspects in the therapeutic approach to MS: how to decrease demyelination, promote remyelination, control immune-driven cytotoxicity and inflammation, and how to protect axons from permanent damage.

4.1.1 Diphtheria toxin-mediated oligodendrocyte ablation

One recent approach involves the coordinated induction of oligodendrocyte death using diphtheria toxin (DT) in mice. As murine cells are naturally resistant to the toxin, it is necessary to either force the expression of the DT receptor, or induce the expression of the diphtheria toxin catalytically active fragment A, or DT-A, to trigger cell death. Brockschneider and colleagues (2004) reported the expression of DT-A, by Cre-mediated recombination under the control of the CNP promoter. As CNP is readily expressed in mature oligodendrocytes and oligodendrocyte precursor cells (Chandross et al., 1999), this resulted in the overall arrest of developmental myelination and early lethality (Brockschneider et al., 2004). Therefore, several models of systemic diphtheria toxin-induced oligodendrocyte ablation have been developed in recent years that involve temporal control of demyelination onset and allow its study in adult mice (Buch et al., 2005; Traka et al., 2010; Pohl et al., 2011; Oluich et al., 2012). Buch and colleagues (2005) described a method of oligodendrocyte ablation through expression of DTR by recombination induced by Cre recombinase expressed under the MOG promoter. They reported a massive demyelination in the corpus callosum and cerebellum but did not explore the consequences on axonal preservation any further (Buch et al., 2005).

We used this model to specifically trigger the death of mature oligodendrocytes by injecting diphtheria toxin (DT) in MOG-iCre/iDTR mice, whose myelinating oligodendrocytes express the DT receptor (Buch et al., 2005). We observed that after approximately 30 days, most animals became severely ill, displaying tremor, hind limb paralysis and, on occasion, death (data not shown). We observed moderate demyelination, accompanied by a decreased number of mature oligodendrocytes in the corpus callosum of MOG-iCre/iDTR mice treated with DT but not in MOG-iCre/iDTR mice treated with PBS or MOG-iCre

mice (lacking DTR expression) treated with DT. This indicates the specific ablation of DTR-expressing mature oligodendrocytes and demyelination induction.

The demyelination level observed in diphtheria-toxin induced oligodendrocyte ablation has varied among studies. While some have reported extensive demyelination along the CNS (Buch et al., 2005; Traka et al., 2010; Pohl et al., 2011), others have reported that oligodendrocyte abundance in the corpus callosum was unchanged despite reductions in other regions of the CNS (Oluich et al., 2012). Injections of intraperitoneal DT may not diffuse uniformly and therefore may not reach all areas of the CNS evenly or at the same time. However, in our investigation, injection of DT was sufficient to induce a reduction in oligodendrocyte number and degree of myelination. The fact that we injected higher amount of DT (400 ng daily for 7 days vs a single 200 ng dose) could also explain the increased effect in our system.

Indeed, a recently published study (Locatelli et al., 2012a) explored DT models in further detail. In addition to observing widespread oligodendrocyte death, microglia activation and astrogliosis, in agreement with our study, no acute infiltration from the immune system was detected in any of DT-mediated demyelination models (Buch et al., 2005; Traka et al., 2010; Pohl et al., 2011; Locatelli et al., 2012a; Oluich et al., 2012). This casts doubt on the hypothesis of an oligodendrogliopathy as being sufficient to elicit an immune response, at least within this short time frame. However, we did observe, as did the other mentioned studies, an increase in microglia activation and proliferation. In most MS models, it is believed that in addition to the induced demyelination, microglia activation can contribute to the harm inflicted on oligodendrocytes and axons possibly through the production of NO, cytokines and ROS (Smith et al., 2001).

Indeed, we found a significant amount of acute axonal damage, evidenced by a significant accumulation of APP and decreased neurofilament signal. This is in accordance to most DT-induced demyelination studies published so far (Pohl et al., 2011; Oluich et al., 2012). Surprisingly, contradicting results have been reported using similar models of DT-A expression upon Cre-mediated recombination using either PLP-CreERT (Traka et al., 2010) or PLP-CreERT2 (Pohl et al., 2011). Traka et al. (2010) reported that despite the massive demyelination and microglia activation generated in their model, no axonal loss was observed in the optic nerve or the spinal cord, and remyelination was prompt and

widespread. Pohl et al. (2011), who used the same model, did observe axonal damage and loss, and a delay in myelin debris clearance, which was shown to correlate to a lower remyelination efficiency (Kotter et al., 2006; Baer et al., 2009). These discrepancies could be due to differences in either the recombination efficiency due the use of the more sensitive Cre recombinase Cre-ERT2 instead of Cre-ERT (Indra et al., 1999), higher amounts of tamoxifen injected, or simply the fact that slightly older animals were used in one of the studies (Pohl et al., 2011).

Traka et al. (2010) reported that older animals did not remyelinate efficiently and did not appear to recover in contrast to the phenotype they observed in younger animals. It is possible that the greater severity of symptoms in the models involving DT injection in comparison to those involving DT-A expression within the target cell, can be in part due to a delayed clearance of the DT. This delay could cause the continued depletion of oligodendrocyte precursors undergoing differentiation in an attempt to remyelinate. As a single molecule of DT is sufficient to induce apoptosis in a cell (Yamaizumi et al., 1978), the system is very sensitive to residual DT, possibly prompting the animal to miss the critical time window in which remyelination can protect axons from degeneration (Crawford et al., 2009). On the contrary, in the inducible models that involve tamoxifen-mediated recombination, once the effect of the tamoxifen treatment is over, the precursors can freely differentiate and remyelinate. However, it should be noted that in the other studies using Cre-ERT-induced DT-A expression, this recovery was not observed (Pohl et al., 2011). The amount of tamoxifen and the efficiency of recombination can therefore determine the clinical outcome of the model.

The clinical phenotype induced by diphtheria toxin-mediated oligodendrocyte ablation is not changed in mice lacking or with reduced functional lymphocytes, or when enhancers of inflammation were added (Pohl et al., 2011; Locatelli et al., 2012b). This indicates that in the DT-induced demyelination model, this process is independent of the adaptive immune system. Most importantly, these results show that, at least in the short term, oligodendrocyte death and demyelination are not sufficient to trigger an autoimmune response against myelin, but can trigger microglia activation and axonal damage. Interestingly, Pohl et al. (2011) report that the areas with the lowest levels of remyelination, presented the highest axonal pathology. Unfortunately, none of these studies can discard or quantify, at this point, the extent of the axonal damage induced by activated microglia. Rather they sup-

port the idea that remyelination indeed appears to have a neuroprotective function. The fact that we did not observe any axonal or clinical phenotype in DT-treated Mogi-Cre mice that lacked the DTR allele shows the robustness of the model and discards any unspecific cytotoxic effect of the toxin itself.

Due to the severity of the disease, the animals had to be sacrificed before we were able to study the remyelination and long-term consequences of demyelination in this model. This fatal monophasic phenotype has also been found in similar diphtheria toxin models, where no recovery was observed (Pohl et al., 2011; Oluich et al., 2012). Only Traka et al. (2010) reported a complete motor and clinical recovery in young animals. This discrepancy could be explained by the reasons stated above. Although our model has not allowed us to address the long-term consequences of demyelination in the future it could be useful in addressing the question of how to mitigate axonal damage as a consequence of demyelination.

4.2 Late motor decline and axonal damage in cuprizone model

To analyze the long-term consequences of myelin loss on axonal preservation and functional recovery, we attempted to understand the long-term consequences of early cuprizone-induced demyelination in mice. The aim of this study was to establish an animal model that mimics some aspects of progressive MS, characterized by late-onset progressive neurological deficits, often in the absence of active inflammation (Kremenutzky et al., 2006; Lassmann et al., 2007; Miller and Leary, 2007). Remyelination has been shown to be extensive in the cuprizone model (Blakemore, 1973b), but the long-term impact of myelin repair on neuro-axonal function is not known.

4.2.1 Functional recovery and late onset motor decline after remyelination

Due to the localized and reversible demyelination induced in the cuprizone model, it has been difficult to detect phenotypes related to the myelination and functional state of the corpus callosum, especially after remyelination. A deficit in the prepulse inhibition of acoustic startle response has been reported, but only during cuprizone feeding (Xu et al., 2009, 2010). After recovery, a decreased anxiety and increased interactive behavior, as well

as a higher frequency of falls in the rotarod test have been reported (Franco-Pons et al., 2007; Hibbits et al., 2009). However, the interactive behaviour test should be done in naive animals and is most likely not optimal for longitudinal studies (Bolivar et al., 2007). On the other hand, the rotarod test is not likely to be solely related to the myelination status of the corpus callosum, as differences were observed after 6 weeks of remyelination but not at 6 weeks of cuprizone feeding, when demyelination is much higher (Franco-Pons et al., 2007). In addition, it is difficult to target and follow the specific brain structures correlated with these behaviors.

Impaired performance in complex running wheel tests has been described in mice with genetically-absent or surgically removed corpus callosum (Schalomon and Wahlsten, 2002). The corpus callosum consists of the axons of cortical projection neurons and facilitates the communication of both the cerebral hemispheres, and the associative connectivity, to execute complex motor and cognitive tasks. Most of these axons are myelinated and therefore make up the largest white matter structure in the placental mammalian brain (Aboitiz and Montiel, 2003; Fame et al., 2010). One of the few methods shown to detect latent deficits in animals after remyelination in the cuprizone model is the motor skill analysis or MOSS (Liebetanz and Merkler, 2006). In this test, mice ran voluntarily in wheels with irregularly spaced crossbars, therefore requiring a constant step length adaptation and bi-hemispherical coordination.

To analyze the long-term effect and functional recovery of cuprizone-induced demyelination, a motor skills evaluation was performed three times over a period of 28 weeks using the MOSS running test (Liebetanz and Merkler, 2006). In this study, we reproduced earlier findings showing that latent motor deficits in MOSS parameters, such as maximum velocity (V_{max}) and maximum distance (D_{max}) are still evident after 6 weeks of recovery following cuprizone diet (Liebetanz and Merkler, 2006). We further re-examined the animals 14 weeks later (i.e. 20 weeks after cuprizone treatment removal). Locomotor performance of remyelinated animals was indistinguishable to age-matched controls by MOSS at this time point. These results indicate that remyelination together with, most probably, neuroplastic processes, can fully compensate functional disability after a demyelinating insult.

To further investigate whether functional recovery remained stable in the long-term, we repeated MOSS analysis at 28 weeks after cuprizone removal. At this latest time point, remyelinated animals, independent of single or repeated exposure to cuprizone, displayed deteriorated locomotor performance as compared to age-matched controls in the coordinative parameters Vmax and Dmax. Similar to earlier time points, no differences were detected in parameters assessing general motivation and/or fitness compared to controls and no differences in any of the parameters were observed between the treated groups.

These data show that mice fed with cuprizone recover completely as measured by MOSS, but develop late-onset functional deficits at advanced age. One possibility could be that after the initial deficiency detected after 6 months, the treated animals entered a steady state, and their performance level is ultimately reached by the decreased performance of control animals due to aging, and this could account for the similar performance of all groups 20 weeks after cuprizone removal. However, with time, cuprizone-treated animals exhibited a continued decline, evidenced in the last timepoint of the MOSS analysis. Although it is not possible to describe the rate of the decline beyond the three time points analyzed, the data show that there is indeed a late-onset motor decline observed in the treated mice between 20 and 28 weeks of cuprizone treatment.

A decline in performance after a period of stability in the first 20 weeks could be explained by two independent factors: compensatory mechanisms that facilitate the functional recovery and a steady accumulation of structural damage. A tipping of the balance between these two processes upon reaching a certain threshold may unmask latent damage. Such a mechanism has been proposed to explain the functional recovery in MS patients during relapsing-remitting stages of the disease and the irreversible clinical decline observed in the progressive phases (Trapp et al., 1998; Bjartmar and Trapp, 2003). Four components appear to be involved in maintaining this balance and contribute to the clinical readout: axonal damage, resolution of inflammation, remyelination, and cortical plasticity.

4.2.2 Axonal damage as a driver of motor decline

Most of the axonal damage induced by cuprizone-mediated demyelination occurs during the treatment, and decreases during recovery (Hoehn et al., 2008; Lindner et al., 2009). In our study, axonal damage, measured by APP accumulation, was at a maximum after 5 weeks of cuprizone treatment (Figure 3.26). It is intriguing, however that even at

~ 6 months after the treatment with cuprizone was ceased, APP-positive axons are still detected. Even more interestingly, some of these APP-positive axons were still surrounded by a myelin sheath. Furthermore, we also observed enlarged mitochondria in axons in this last time point, ~ 6 months after cuprizone had been removed from the diet, providing further evidence of persisting axonal pathology (Kiryu-Seo et al., 2010).

The axonal damage described in our model may be the result of several processes. First, it is possible that cuprizone-mediated toxicity is not selective to oligodendrocytes, but may also work directly against the axon, as many axons are lost during the treatment with cuprizone. There is mounting evidence that axonal damage most importantly decreases with remyelination efficiency and increases with the level of microglia activation (Irvine and Blakemore, 2008; Tshiperson et al., 2010; Yoshikawa et al., 2011). Inflammation level and axonal damage correlate in acute and chronic MS lesions (Bitsch et al., 2000; Kuhlmann et al., 2002). Microglia are known to perform dual roles that have beneficial positive and detrimental consequences for axonal survival. Accordingly, understanding the pathways that stimulate/inhibit one response over the other would be useful in modulating the net contribution of microglia to a demyelinating episode, in order to preserve axonal integrity (Hanisch and Kettenmann, 2007).

On one hand, microglia act as macrophages, clearing myelin debris, which is necessary for efficient remyelination to occur. On the other hand, activated microglia release cytokines and NO. These can contribute to a reversible blockage of axonal conduction, exacerbate the inflammatory effects and lead to axonal damage and subsequent loss (Smith et al., 2001; Aboul-Enein et al., 2006). Therefore, it is possible that the low yet sustained presence of astrocytes and microglia observed in our study can contribute to the low ongoing damage. The decrease of axonal counts observed in our study, suggests that microglia presence could be induced by an ongoing axonal degeneration and could be contributing to debris clearance without the production of harmful pro-inflammatory signals (Neumann et al., 2009).

Following axonal transection, regeneration in the CNS is considerably limited, due to the presence of inhibitory factors in the extracellular space. Oligodendrocyte molecules such as NogoA, MAG and OMgp have been identified as axonal growth inhibitors (Kotter et al., 2006; Baer et al., 2009). These three molecules bind to the Nogo receptor (NgR)

present in axons, which associates with the receptor p75 and LINGO-1 (Wang et al., 2002; Mi et al., 2004) and is responsible for neurite outgrowth inhibition and prevents axonal regeneration in the CNS (Fournier et al., 2001). In addition, myelin debris and associated proteins have also been found to inhibit oligodendrocyte differentiation, a crucial step for remyelination to occur (Kotter et al., 2006; Syed et al., 2008). A failure in remyelination has been repeatedly associated to an increased axonal loss in the cuprizone model and progressive MS, and is currently one of the major targets in MS treatment (Smith, 2006; Franklin and Ffrench-Constant, 2008; Irvine and Blakemore, 2008).

Further evidence that supports the idea that myelin integrity itself may be necessary for axonal maintenance stems from studies showing that mice lacking different myelin-specific proteins suffer from late-onset neurodegeneration, despite the fact the myelin appears structurally normal (Griffiths et al., 1998; Lappe-Siefke et al., 2003). In different demyelinating animal models, age can negatively affect the recruitment and differentiation of OPCs after demyelination (Shields et al., 1999; Sim et al., 2002), resulting in a decreased remyelination capacity and more extensive axonal damage (Hampton et al., 2012). In our study, we observed an extensive yet incomplete demyelination. In addition to the expected increase in the g-ratio, due to a thinner myelin sheath formed after remyelination, we observed that a population of axons (approximately 26%) remained unmyelinated.

Aside from decreasing neuronal energy demands by facilitating saltatory conduction, myelin regulates the axonal diameter (de Waegh et al., 1992), fast axonal transport (Edgar et al., 2004), and the molecular organization of the nodes of Ranvier (Peles and Salzer, 2000). Therefore, chronically demyelinated axons undergo alterations in structure and function, demand more energy and become more vulnerable to degeneration (Irvine and Blakemore, 2008; Lindner et al., 2009). Despite the axonal loss observed after cuprizone treatment, remyelination seems to contribute to the axonal preservation of remaining axons, as the majority of the APP-positive axons observed after 6 months appeared unmyelinated.

However, it is striking that, in both the cuprizone model at 6 months after treatment removal, as well as in chronic lesions from MS patients there was a constant fraction of axons that displayed APP accumulation yet had a surrounding myelin sheath. It could be possible that the axon is not myelinated along its entire length and the pathology is

caused by insufficient myelination in adjacent regions. This is difficult to prove due the fact that axons crossing the corpus callosum can be over 2 mm long (Wahlsten, 1984), and the tightly packed structure of the corpus callosum that precludes quantifying the fraction of an entire axon that is myelinated.

Another option is, that despite the fact that remyelination contributes to axonal preservation and functional recovery (Duncan et al., 2009), alterations to the newly formed myelin, such as the change in thickness, internodal length and protein or lipid composition, could compromise axonal survival in the long term. Minor alterations in myelin membrane composition can trigger neurodegeneration (Nave and Trapp 2008). Thus, it could be possible that the changes in myelin composition occurring after episodes of demyelination and remyelination are sufficient to induce neuronal dysfunction that only become apparent when mice age.

Interestingly, similar changes in the proteome of myelin from animals that have undergone remyelination and in myelin from old animals has been found (Manrique-Hoyos et al., 2011). This does not exclude the possibility that the minor alterations occurring in remyelinated myelin results in subtle changes in axonal function that may only become functionally relevant after a certain age. In addition, the induction of two episodes of cuprizone-induced demyelination in our study did not increase late-onset axonal dysfunction and motor decline in our model compared to a single demyelination. This finding indicates that the critical threshold is already reached after one round of demyelination and remyelination. Interestingly, in MS the onset of the progressive phase is independent of number of relapses and age is the most important risk factor that determines when chronic progressive MS is set off (Confavreux et al., 2003; Kremenchutzky et al., 2006).

While the reversible disability observed during initial inflammatory episodes is caused in part by a transient conduction block due to the edema that accompanies the infiltration through the BBB, in chronic stages or SPMS the progressive disability seems to be correlated with irreversible axonal degeneration. It is widely accepted that axonal loss is a key determinant for permanent disability beginning at disease onset and correlating with the degree of inflammation within lesions in patients with MS (Bitsch et al., 2000; Bjartmar and Trapp, 2003) and can be observed both in inflammatory and chronic demyelination (Trapp et al., 1998; Dutta et al., 2006). In this study, we showed that a cuprizone-induced

demyelination causes a massive axonal loss in the corpus callosum without a reduction of cortical neuronal soma. Interestingly, in MS axonal loss is more frequently found than loss of neuronal cell bodies (Trapp and Nave, 2008). We measured massive axonal loss, evidenced by the shrinkage of the corpus callosum thickness, a decrease in neurofilament signal and in axonal counts. This loss seems to continue occurring beyond 6 weeks of remyelination indicating a progressive axonal loss.

The capacity of cortical adaptation after injury has been demonstrated in both experimental models and in MS patients. These studies have shown cortical adaptive changes occurring concurrently with the progression of axonal injury (Reddy et al., 2000; Faivre et al., 2012). Once structural damage is so extensive that compensation mechanisms are insufficient to correctly execute a given task, functional deficit will become evident. If the axonal pathology is indeed more frequent early in disease, it is possible that the brain has a greater capacity to compensate and is able to recover from early axonal damage. As axonal loss continues and the brain ages, a critical threshold may be reached, where compensatory mechanisms are exhausted, and clinical symptoms reappear, unmasking the long-term consequences of the demyelinating insult (Bjartmar and Trapp, 2003; Trapp et al., 1999). The mechanisms limiting the extent of compensation of axonal pathology that ultimately triggers the transition from RRMS to SPMS remain unclear.

4.2.3 Relevance of MS animal models and final remarks

A major difficulty when studying animal models of MS is that the etiology of the disease and its progression mechanisms are largely unknown. The translation of experimental findings into effective treatment of MS patients has been mostly limited to the inflammatory stages of the disease (Steinman, 1999; Steinman and Zamvil, 2006). The different animal models of MS attempt to recreate the different components and courses of the disease but none has satisfactorily captured all aspects of MS and therefore do not guarantee successful translation of experimental results to applications in a clinical setting. In addition, the inbred nature of most of the animals used in MS models generates a rather homogeneous immunological background and response, which does not reflect the reality of the human population afflicted by MS.

Since each MS model appears to address different aspects of the disease, combinations of several models have been used as attempts to integrate the different mechanisms and

processes observed in MS. However, the outcome is frequently unexpected and complicates the analysis and interpretation of the results. For instance, the combination of selective ablation of a cell lineage in mice using diphtheria toxin is limited to models that do not involve an immunization of mice like EAE, since it has been found that immunization of mice results in the sensitization to DT (Holmes, 2000; Meyer zu Hoerste et al., 2010). On the other hand, the clinical course of DT-induced demyelination is not modified by the repression or exacerbation of the immune response, as the demyelination and axonal loss appears to occur independently of the adaptive immune system (Pohl et al., 2011; Locatelli et al., 2012a). Surprisingly, in one combinatorial experiment it was found that a pre-treatment with cuprizone prior to EAE induction by MOG injection significantly ameliorated the clinical score and decreased the autoimmune inflammation (Maña et al., 2009).

While the use of several models may be able to capture more features of a highly complex disease such as MS, each model carries distinct disadvantages. In our case, one of the disadvantages of the cuprizone model is that the exact underlying mechanism is not clear. Although it appears to selectively trigger oligodendrocyte death, it can also affect liver metabolism, as well as some T cell activity (Emerson et al., 2001). This may complicate investigations of the immune reaction in demyelination caused by primary oligodendropathy. The DT model presented in this work allows for highly specific widespread oligodendrocyte death but its severity does not allow the study of remyelination and functional recovery, which is extensive in MS. Therefore, it is crucial to further explore and develop new models that resemble MS in its immunopathology and clinical course, or carefully interpreting the results when combining more than one of the existing models.

In the past, several hypothesis regarding the etiology of the MS have been proposed. However, none have been able to account for the majority of the symptoms nor the diversity of cases. Genetic, environmental, viral, and lifestyle factors have been proposed as contributors to the susceptibility and triggering of the disease. Even though it has widely assumed that MS is primarily an autoimmune disorder, the possibility of a primary oligodendrogliopathy as the cause of MS has been proposed. Additionally, the possibility that MS is actually a group of diseases that share similar symptoms has emerged (Owens et al., 2011; Gourraud et al., 2012; Nakahara et al., 2012; Stys et al., 2012).

4.3 Proteomic screening of candidates for axoglia communication

Large-scale proteomic and transcriptomic analysis have proven to be powerful tools for the identification of myelin-associated proteins (Colello et al., 2002; Taylor et al., 2004; Jahn et al., 2009b), genes involved in oligodendrocyte differentiation (Nielsen et al., 2006; Cahoy et al., 2008; Baer et al., 2009), proteins relevant in myelin structural organization (Werner et al., 2007) or proteome changes after remyelination (Werner et al., 2010). We have performed an extensive proteomic analysis of myelin fractions aimed to identify proteins involved in axo-glia communication.

Except for the first layer, which is in direct contact with the axon, the majority of myelin is composed by a highly compacted, lipid-rich membrane layers. This facilitates the isolation of myelin domains in a sucrose gradient, based on their light density. We observed an enrichment of MAG and Neurofascin, characteristic of the periaxonal and paranodal/nodal regions respectively, at a slightly heavier fraction (0.9 M-1.0 M) than that usually used to isolate myelin (0.32-0.85 M) (Norton and Poduslo, 1973). The enrichment of non-compact proteins in the 0.9-1.0 M fraction is congruent with the myelin peak observed in *shiverer* mice at approximately 0.85-0.9 M sucrose (Bourre et al., 1980). As *shiverer* mice lack MBP and thus compact myelin, it indicates that non-compact myelin tends to float at that density.

We included myelin isolated on the postnatal day 14 (P14) in our proteomic analysis, since at this time-point myelination is still ongoing. Therefore, proteins important for initial axo-glia contact are assumed to be present, and compacted myelin represents a smaller fraction than in mature myelin. In addition, we successfully isolated myelin-associated glycoproteins using different lectin beads (ConA and WGA for mouse myelin, and lectin-lentil for human myelin). This combined analysis of myelin fractions resulted in a total of 1904 identified proteins. This database was taken as the starting point for the selection of novel candidates in axo-glia communication and myelination.

First, we selected candidates that were predicted to contain a signal peptide and a trans-membrane domain, as it would be expected that proteins involved in axo-glia communication are exposed at the cell surface in order to interact with adjacent cells. However, this

method can result in the exclusion of GPI-anchored proteins despite the fact that they are indeed exposed to the extracellular space. GPI-anchored proteins lack a transmembrane domain in their mature form but present a hydrophobic stretch, which is cleaved in the ER as a post-translational modification and replaced with glycosylphosphatidylinositol. Fatty acids from phosphatidyl-inositol group allow the anchoring of the protein to the exterior face of the cell membrane. A glycosphingolipids and cholesterol-enriched environment such as myelin favors the targeting of this type of proteins (Krämer et al., 1997).

In addition, as GPI-anchored proteins can act as cell-adhesion molecules or associate in *cis* to proteins that can trigger downstream cascades and generate responses in the cell, they should be considered potential candidates. Indeed, PSA-glycosylation of the glial GPI-anchored protein NCAM-120 inhibits myelin formation. Also, the axonal protein Contactin, which interacts with Caspr and Neurofascin-155 in the organization of the paranodes (Tait et al., 2000; Rios et al., 2000), is a GPI-anchored protein as well.

Although the presence of the hydrophobic stretch in GPI-anchored proteins in occasions resulted in the prediction of a transmembrane domain in our analysis, it was inconsistent. Even though all proteins from the IgLON family are GPI-anchored, Lsamp was predicted to have a transmembrane, Opcml was not, and Neurotrimin had incongruous results: while it was not predicted to have a transmembrane domain in the mouse samples, the human Neurotrimin isoform 2 did. Even though TMHMM and Phobius resulted useful in the prediction of transmembrane domains, GPI-anchored proteins would require additional prediction method to detect them consistently, as big-PI Predictor http://mende1.imp.ac.at/gpi/cgi-bin/gpi_pred.cgi (Eisenhaber et al., 1999).

Following our proteomic analysis, we established a battery of functional assays to help elucidate the role of candidate proteins in the axoglial communication. In the present study, we used the IgLON family proteins Lsamp, Opcml and Ntm as candidates, and used Necl1, Necl4 and MCAM-Fc as controls. These methods are intended to be used also as future assay battery for other novel candidates in axo-glial communication. IgLON proteins have previously been described to be expressed in neurons and mediate neurite outgrowth regulation (Gil et al., 1998; Lodge et al., 2000; Reed et al., 2004). However, they have been suggested to have additional roles in recognition and cell adhesion (McNamee

et al., 2002). As they have previously been shown to be expressed in neurons, we focused on developing functional assays to determine the response on oligodendrocytes.

We evaluated the effect of our candidate proteins on the intrinsic behavior and development of oligodendrocytes by analyzing changes in proliferation, migration and differentiation patterns. We did not observe any significant changes in these processes induced by IgLON proteins. Adhesion and myelination assays were performed to evaluate the effect of the candidates on the interaction between oligodendrocytes and neurons. While we did not observe a significant effect on the adhesion of oligodendrocytes, we observed a reduction in myelination in samples where Ntm-Fc was added to the media.

The addition of a soluble fusion protein can inhibit intercellular communication blocking binding sites or it could trigger a response in the cell it binds to. The reduction in myelination efficiency could be explained in different ways: either the soluble protein blocks binding sites involved in myelination initiation (interaction interference), it induces oligodendrocytes to not myelinated but rather enter the default sheet formation (effect on oligodendrocytes), or it exerts an effect on axonal organization that hinders myelination to occur (effect on axons). This type of assay has been useful to elucidate the role of Necl4 in myelination in the PNS (Spiegel et al., 2007) and L1 in CNS myelination (Laursen et al., 2009). Our results propose Ntm as an interesting candidate in axo-glia interaction and further analysis remain to be done to elucidate the mechanism and specific role of the protein. Assays inducing neuronal downregulation of the proteins would facilitate understanding their role.

Myelin is a highly compacted structure, and it has been found that proteins with a cytoplasmic domain larger than 30 aminoacids are excluded from the compact, MBP-positive sheets in oligodendrocytes *in vitro*; PLP tagged with intracellular EGFP is also restricted from entering compact myelin *in vivo* (Aggarwal et al., 2011). GPI-anchored glycoproteins can theoretically freely diffuse along myelin compacted and non-compacted areas, allowing the incorporation of glycoproteins along myelin. This could facilitate the establishment of intercellular contact sites or theoretically, inter-lamellar adhesion. Even though the exogenous expression of full length constructs showed that the IgLON proteins distribute throughout compact, MBP-positive areas in primary oligodendrocytes, the actual expression and distribution patterns remain to be elucidated. The interaction

molecule(s) expressed in oligodendrocytes, which could be, but is not limited to, a member of the IgLON family itself, remains to be identified.

It is important to highlight that the exploratory approach of this study implies the selection of proteins that are not yet fully described, or even known. Therefore, the availability of functional antibodies can be limited and has been one of the principal difficulties encountered. The characterization of the expression profile of a candidate allows to identify the type of cell, the moment in development where the protein is expressed, and facilitates the selection of relevant functional assays. However, the development and acquisition of antibodies for a large number of proteins during a screening process is not feasible.

For this reason, we established a binding assay as a screening method and a set of functional tests that can be applied universally to any candidate protein as long as it has a known aminoacid sequence, using tags as Fc and myc, which allow the detection and purification of the protein. Therefore a battery of tests presented in this study is a useful method to evaluate potential candidates previous to antibody generation (when commercially unavailable), and *in vivo* gene silencing. In addition, the proteomic database generated by the analysis of myelin fractionation and glycoprotein isolation provides a valuable source of novel candidates of axo-glial communication and myelination in the CNS.

Chapter 5

Summary and conclusions

In demyelinating diseases like multiple sclerosis (MS), myelin is damaged but can be replaced by a thinner myelin sheath. Remyelination restores saltatory conduction and is thought to contribute to the functional recovery in MS. However, even if remyelination is extensive, most patients enter a progressive phase with continuous accumulation of neurological deficits (SPMS), questioning the role of myelin on the long-term survival of axons.

Two toxin-based demyelinating models, which do not involve an autoimmune response or blood-brain barrier disruption, were used to study the effect of demyelination on axonal integrity. To study the short-term impact of demyelination, histological analysis was performed in samples from a mouse model where myelinating oligodendrocytes are ablated by the expression of diphtheria toxin receptor in mature oligodendrocytes and systemic diphtheria toxin injection. We observed, in accordance to studies using similar models, that the animals became severely ill, and that demyelination of the corpus callosum was accompanied by microglia activation and axonal damage. We showed that the use of systemic oligodendrocyte ablation through the targeted effect of diphtheria toxin is an effective and highly specific model of demyelination. However, due to its clinical severeness it was not possible to observe remyelination and recovery of the animals. Therefore, this model is very useful in studying the most acute stages of demyelination and could be used to develop strategies to minimize the extent of axonal damage and cytotoxic inflammatory response resulting from oligodendrocyte death and myelin loss.

In addition, to analyse the consequence of demyelination in the long-term, we used the cuprizone model of de- and remyelination. We aimed at establishing an animal model that mimics aspects of progressive MS, which is characterized by late-onset progressive neurological deficits, often in the absence of active inflammation. This model induces demyelination most prominently in the corpus callosum and superior cerebellar peduncle, does not involve the infiltration of the immune system through the blood-brain barrier, and is associated with extensive remyelination and recovery. We observed that after one or two demyelinating events, animals recovered to an extent that they became undistinguishable from age-matched controls. However, they presented late-onset motor impairment, showing that functional recovery was not permanent and latent consequences become detectable in the long-term. Single and repeated cuprizone-induced demyelinating events have shown similar long-term functional motor readouts.

These functional deficits were accompanied by a substantial loss of axons in the corpus callosum and extensive, but incomplete remyelination. These findings suggest that there is a yet unknown trigger of axonal dysfunction at late stages of remyelination. Both unmyelinated and myelinated axons exhibit acute damage evidenced with APP accumulation. This is a non-inflammatory model of demyelination with ongoing axonal damage in both acute and chronic stages, making it especially useful for testing neuroprotective treatment strategies. The use of models in which de- and remyelination are restricted to defined/reproducible areas of the CNS can facilitate the study of axonal preservation and functional recovery after remyelination.

Finally, we successfully generated an extensive list of 1904 proteins potentially associated to myelin axo-glia contact sites and a set of functional assays to choose and evaluate the role of candidate proteins in oligodendrocyte life-cycle and myelin formation *in vitro*. We have identified a family of proteins (IgLON) as potential candidates that appear to interact with both neurons and oligodendrocytes, with the presence of soluble neurotrimin having a negative effect on myelination efficiency *in vitro*. Further exploration of their role *in vivo* is necessary to elucidate their function in myelination in the CNS.

Chapter 6

Appendix: Complete myelin proteomics list

6.0.1 Complete list of proteins identified in myelin samples analysed with LC-MS/MS.

In summary, we isolated different fractions of myelin from C57/BL6 mice (1-5) or human brain samples (6) and analyzed them with mass spectrometry:

1. Myelin isolated from postnatal day 14 brain homogenate in a discontinuous sucrose gradient (“P14 (myelin)”), 0.32M/0.85M interphase (Norton and Poduslo, 1973).
2. Purified myelin solubilised with 1% Triton X-100 overnight and bound to ConA beads (“ConA myelin”).
3. Purified myelin bound to WGA beads (“WGA myelin”).
4. Myelin isolated from brain homogenate subjected to an initial hyposmotic shock with water and then subjected to a continuous gradient, fraction 0.9-1 M sucrose (“Continuous (myelin)”).
5. Myelin isolated from brain homogenate subjected to an initial discontinuous gradients and collected from 0.32-1.2 M interphase (crude myelin) and subsequently subjected to a continuous sucrose gradient. Collected from Fraction 3, or 0.9-1 M sucrose (“Continuous (brain)”).
6. Glycoprotein from human myelin preparation, subjected to a lentil-lectin column (Mathey et al., 2007), kindly provided by Edgar Meinel, Max Planck Institute of Neurobiology, Munich (“Human Myelin”).

The complete list of proteins identified based on unique peptide count is included. The electronic version of the list as a spreadsheet is found at the folder `\\em-filer\ag-simons\Manrique\proteomics` at the server of the Max Planck Institute of experimental medicine, Göttingen.

EDUCATION

- PhD** **Georg-August University Goettingen**, Neuroscience. *2009-expected November 2012*
Dissertation: "Neurodegeneration in toxin-mediated demyelinating animal models of MS"
Committee: Dr. Mikael Simons (advisor), Dr. Wolfgang Brück, Dr. Till Marquardt
- MS** **Georg-August University Goettingen**, Neuroscience. *2007-2009*
Thesis: "Proteomic analysis of myelin in aging and demyelinating disease"
Committee: Dr. Mikael Simons (advisor), Dr. Wolfgang Brück, Dr. Till Marquardt
- BS** **Pontificia Universidad Javeriana**, Biology *2002-2007*
GPA: 4.24 (out of 5).

RESEARCH EXPERIENCE

- PhD (in progress)** *April 2009-present*
"Glial-mediated axonal support in animal models of multiple sclerosis"
Department of Cellular Neuroscience. Max Planck Institute for Experimental Medicine, Göttingen. Advisor: Dr. Mikael Simons.
- Master Thesis** *October 2008-March 2009*
"Proteomic analysis of myelin in aging and demyelinating disease".
Department of Cellular Neuroscience. Max Planck Institute for Experimental Medicine, Göttingen. Advisor: Dr. Mikael Simons.
- Graduate School Lab Rotation** *May- June 2008*
"Expression of MHC class I in the brain of common marmoset (*Callithrix jacchus*)".
Clinical Neurobiology Laboratory, German Primate Center, Göttingen. Advisor: Dr Eberhard Fuchs.
- Graduate School Lab Rotation** *March-April 2008*
"Proteolipids interactions in Pelizaeus-Merzbacher disease". Department of Neurogenetics
Max Planck Institute for Experimental Medicine, Göttingen. Advisor: Dr. Hauke Werner.
- Graduate School Lab Rotation** *January-March 2008*
"Assessment of Beta-Synuclein-induced Experimental Autoimmune Encephalomyelitis in CD8-deficient Lewis rats". Department of Neuropathology, Göttingen Georg-August-Universität. Advisor: Dr. Christine Stadelmann.
- Undergraduate Thesis Project** *September 2006 -May 2007*
"Genetic structure and connectivity of *Palythoa caribaeorum* populations in the Colombia Caribbean using nuclear rDNA markers". Population Genetics and Evolutionary Biology Laboratory, Javeriana University. Advisor: Dr. Alberto Acosta.
- Internship** *January - May 2006*
"Standardization of heterologue rDNA nuclear and microsatellite markers PCR protocol for *Palythoa caribaeorum*". Population Genetics and Evolutionary Biology Laboratory, Javeriana University. Coordinated by Dr. Alberto Acosta and Dr. Manuel Ruiz-Garcia.

HONORS AND AWARDS

PhD Excellence Stipend *2009-Present*

Awarded by the Göttingen Graduate School for Neurosciences and Molecular Neurosciences (GGNB), Georg-August University Goettingen (4 awarded per semester).

MSc Stipend *2007 – 2008*

Excellence Foundation for the Promotion of the Max Planck Society, International Master's/PhD/MD-PhD IMPRS Neuroscience Program (15-20 awarded per year).

3rd best national score, Biology undergraduate studies examination ECAES Colombia 2006.

Acknowledgement granted on August 4th, 2006 by the Javeriana University.

11th best national score in the examination for university entrance (ICFES), Colombia, 2001

Diploma granted on November 29th, 2001 by the Education Ministry to the best 50 scores.

TEACHING EXPERIENCE

Mentoring *May-June 2011*

Designed and mentored a 2-month lab rotation student. Department of Cellular Neuroscience, Max Planck Institute for Experimental Medicine, Göttingen, Germany.

Teaching Assistant *January-June 2005*

Genetics undergraduate course. Department of Biology, Javeriana University, Colombia.

PUBLICATIONS

Manrique-Hoyos, N., T. Jürgens, M. Grønborg, M. Kreutzfeldt, M. Schedensack, T. Kuhlmann, C. Schrick, W. Brück, H. Urlaub, M. Simons and D. Merkler. 2012. Late motor decline after accomplished remyelination: Impact for progressive multiple sclerosis. *Ann Neurol.* 71: 227 – 244.

Ghosh A*, **N. Manrique-Hoyos***, A. Voigt, J. Schulz, M. Kreutzfeldt, D. Merkler and M. Simons. 2011. Targeted Ablation of Oligodendrocytes Triggers Axonal Damage. *PLoS ONE* 6(7): e22735.

Hsu, C., Y. Morohashi, S. Yoshimura, **N. Manrique-Hoyos**, S. Jung, M. Lauterbach, M. Bakhti, M. Groenborg, W. Möbius, J. Rhee, F. Barr and M. Simons. 2010. Regulation of exosome secretion by Rab35 and its GTPase-activating proteins TBC1D10A-C. *J. Cell Biol.* 189(2): 223-32.

PRESENTATIONS

Seminars

- Progress reports at IMPRS Neuroscience retreat, and at the departments of Neurogenetics and Cellular Neuroscience, MPI of Experimental Medicine, Goettingen. 2008-present.
- EMBO Young Investigator Programme PhD workshop, Heidelberg, Germany. 2010.

Poster presentation

- 26th Congress of the European Committee for Treatment and Research in Multiple Sclerosis (ECTRIMS), Goteburg, Sweden. 2010.
- Neurizons 2011: From Molecules to Mind, Goettingen, Germany. 2011
- EMBO Young Investigator Programme PhD workshop, Heidelberg, Germany. 2010.
- Glia in Health & Disease Meeting. Cold Spring Harbor Laboratory, NY. 2012.

PROFESSIONAL SERVICE

International Scientific Conference Co-Organizer *2011*

International symposium “Neurizons 2011: From Molecules to Mind”.
May 25th- 28th, 2011. Goettingen, Germany. Over 250 participants, responsibilities included public relations, logistics, invitation and introduction of international speakers.
