

C-terminal tyrosine residue
modifications modulate α -synuclein
toxicity in yeast as unicellular model for
Parkinson's disease

Dissertation

For the award of the degree

“Doctor rerum naturalium”

of the Georg-August-Universität Göttingen

within the doctoral program

“Molecular Physiology of the Brain” (CMPB)

of Georg-August University School of Science (GAUSS)

Submitted by

Alexandra Kleinknecht

from

Jawlenka (Kazakhstan)

Göttingen 2016

Thesis Committee:

Prof. Dr. Gerhard H. Braus (Department of Molecular Microbiology and Genetics, Institute for Microbiology and Genetics, Georg-August-Universität Göttingen)

Prof. Dr. Tiago F. Outeiro (Department of NeuroDegeneration and Restorative Research, University Medical Center Göttingen)

Prof. Dr. Blanche Schwappach (Department of Molecular Biology, University Medical Center Göttingen)

Members of the Examination Board:

1st Referee: Prof. Dr. Stefanie Pöggeler (Department of Genetics of Eukaryotic Microorganisms, Institute for Microbiology and Genetics, Georg-August-Universität Göttingen)

2nd Referee: Jun.-Prof. Dr. Kai Heimel (Department of Molecular Microbiology and Genetics, Institute for Microbiology and Genetics, Georg-August-Universität Göttingen)

3rd Referee: PD Dr. Michael Hoppert (Department of General Microbiology, Institute for Microbiology and Genetics, Georg-August-Universität Göttingen)

Date of oral examination: 30th June 2016

Declaration

Herewith I declare that the PhD Thesis entitled "**C-terminal tyrosine residue modifications modulate α -synuclein toxicity in yeast as unicellular model for Parkinson's disease**" has been written independently and with no other sources and aids than quoted.

Abstract

The presence of protein inclusions called Lewy bodies (LBs) that are mainly composed of misfolded and accumulated α -synuclein (α Syn) represents a hallmark of Parkinson's disease (PD). Oligomeric α Syn species are thought to play a central role in the neurodegeneration of PD. Elevated levels of oxidative or nitrative stresses have been implicated in α Syn-related toxicity. Phosphorylation of α Syn on serine 129 (S129) is prominently found in Lewy bodies and modulates autophagic aggregates clearance. The neighboring tyrosine residues Y125, Y133 and Y136 are phosphorylation and nitration sites. Overexpression of α Syn in the unicellular eukaryotic model *Saccharomyces cerevisiae* results in growth impairment and cytoplasmic protein inclusions resembling the aggregates observed within LBs. In this study, yeast was used as reference cell to study the contribution of tyrosine modifications on α Syn-related toxicity. Y133 is required for protective S129 phosphorylation and for S129-independent proteasome clearance. α Syn can be nitrated and forms stable dimers originating from covalent crosslinking of two tyrosine residues. LC-MS analysis of tyrosine residues involved in nitration and crosslinking revealed that the C-terminus, rather than the N-terminus of α Syn, is modified by nitration and di-tyrosine formation. The nitration level of wild-type α Syn was higher than the A30P mutant that is non-toxic in yeast. A30P formed more dimers than wild-type α Syn supporting dimer formation as a cellular detoxification pathway in yeast. In contrast to A30P, expression of α Syn significantly increased the accumulation of reactive oxygen species, which was independent from tyrosine modifications. Deletion of the yeast flavohemoglobin gene *YHB1* resulted in an increase of cellular nitrative stress and enhanced aggregation and cytotoxicity of A30P. Yhb1 protected yeast from A30P-induced mitochondrial fragmentation. Deletion of *YHB1* elevated the level of reactive nitrogen species in A30P expressing cells, which can be diminished by mutating the nitration sites. Protein analysis showed that Yhb1 affects nitration but not dimerization levels of A30P indicating that nitrated tyrosine residues, but not di-tyrosine crosslinked dimers, contribute to α Syn cytotoxicity and aggregation. Under nitrative stress, deletion of *YHB1* severely inhibited yeast growth in cells expressing wild-type and A30P α Syn. A30P was as toxic as wild-type α Syn indicating that increase in nitrative stress converts A30P to a toxic protein. Overexpression of neuroglobin, the human homolog of *YHB1*, protected against α Syn inclusion formation in mammalian cells. This study suggests that C-terminal Y133 plays a major role in α Syn aggregate clearance by supporting the protective S129 phosphorylation for autophagy and by promoting proteasome clearance. C-terminal tyrosine nitration increases pathogenicity and can be partially detoxified by α Syn di-tyrosine dimers. This novel complex interplay between S129 phosphorylation and C-terminal tyrosine modifications of α Syn likely participates in PD pathology.

Zusammenfassung

Morbus Parkinson ist durch Lewy Bodies als Protein-Einschlusskörper gekennzeichnet, die hauptsächlich aus dem Protein α -Synuclein (α Syn) bestehen. Dieses Protein hat zytotoxische Intermediate und erhöhter oxidativer sowie nitrosativer Stress sind an der Toxizität von α Syn beteiligt. Phosphorylierung von α Syn an Serin 129 (S129) wurde in Lewy Bodies gefunden und reguliert den Autophagie-abhängigen Aggregat-Abbau. Die benachbarten Tyrosin-Reste Y125, Y133 und Y136 sind Phosphorylierungs- und Nitrierungsstellen. Überexpression von α Syn in *Saccharomyces cerevisiae* als einzelluläres eukaryotisches Zell-Modell löst Wachstumsstörungen sowie die Fehlfaltung des Proteins mit darauffolgenden zytoplasmatischen Aggregationen aus, die an die in den Lewy Bodies beobachteten Aggregate erinnern. Mithilfe dieses Hefemodells für Morbus Parkinson wurde die Wirkung von Tyrosin-Modifikationen auf die von α Syn hervorgerufene Toxizität untersucht. Es konnte gezeigt werden, dass Y133 für die protektive Phosphorylierung von S129 und für den S129-abhängigen Proteasom-Abbau benötigt wird. α Syn kann nitriert werden und formt daraufhin stabile Dimere, die durch kovalente Verbindung von zwei Tyrosinen entstehen. LC-MS Analysen von Tyrosin-Resten, die bei der Nitrierung und Dimerisierung involviert sind, haben gezeigt, dass der C-Terminus von α Syn mehr als der N-Terminus durch Nitrierung und Di-Tyrosin-Bildung modifiziert wird. Der Grad an Nitrierung des normalen α Syn war höher als bei der A30P-Variante, die in Hefe nicht toxisch ist. Die A30P-Mutante bildete mehr Dimere im Vergleich zum α Syn Wildtyp, was darauf hindeutet, dass die Dimerisierung ein zellulärer Detoxifikationsmechanismus in Hefe sein könnte. Im Gegensatz zu der A30P-Mutante, erhöhte die Expression von α Syn unabhängig von der Tyrosin-Modifikation die Akkumulation von reaktiven Sauerstoffspezies. Die Deletion des Yeast Flavohemoglobin Gens, *YHB1*, führte zu einer Erhöhung von Nitrierungsstress sowie zum Anstieg von Aggregation und Zytotoxizität der A30P-Mutante. Yhb1 wirkte protektiv gegen A30P-induzierte Mitochondrien-Fragmentierung. Die Deletion von *YHB1* führte zum Anstieg von reaktiven Stickstoffspezies in Zellen, die A30P exprimieren, was durch den Austausch der Tyrosin-Reste verringert werden kann. Yhb1 beeinflusst den Nitrierungs-, aber nicht den Dimerisierungslevel von A30P. Es sind daher eher nitrierte Tyrosin-Reste als Di-Tyrosin-Verbindungen an der Zytotoxizität und Aggregation von α Syn beteiligt. Unter nitrativen Stress-Bedingungen, bei dem Peroxynitrit als Stickstoffmonoxid-Donor eingesetzt wurde, führte die Deletion von *YHB1* zur Wachstumshemmung von Wildtyp α Syn- und A30P-exprimierenden Zellen. Dabei war die A30P-Mutante gleichermaßen toxisch wie das normale α Syn. Der Anstieg von Nitrierungsstress verwandelt daher A30P vermutlich in ein toxisches Protein. Die Überexpression vom *NGB*, dem humanen Homolog von *YHB1*, wirkte protektiv gegen α Syn Aggregation in Säugetierzellen. Der C-terminale Y133 Rest spielt damit eine

wesentliche Rolle im α Syn-Aggregate-Abbau. Dieser Rest fördert die protektive S129-Phosphorylierung und damit den Autophagie-Abbau und stimuliert den Proteasom-Abbau. C-terminale Tyrosin-Nitrierung erhöht die Pathogenität und kann durch Di-Tyrosin-Dimere teilweise detoxifiziert werden. Diese neue komplexe Wechselwirkung zwischen der S129 Phosphorylierung und den C-terminalen Tyrosin-Modifikationen von α Syn ist wahrscheinlich an der Pathologie von Morbus Parkinson beteiligt.

1 Introduction

1.1 Parkinson's disease

1.1.1 Epidemiology

Parkinson's disease (PD) is the second most frequent neurodegenerative disorder after Alzheimer's disease. It causes a wide range of physical and mental impairments. Six million people are affected worldwide by PD with the prevalence of approximately 0.3 % of the population in industrialized countries (Dexter and Jenner, 2013). The cause of PD remains unknown although several risk factors such as environmental factors, aging and genetic susceptibility were identified to contribute to the onset of the pathogenic process. No curative therapies exist that slow the degenerative progression. PD therapies are usually restricted to systematic treatments. The average age of diagnoses is around 60 years. The prevalence increases to 1 % in the population older than 60 years and to 4 % older than 80. Hence, PD is considered as an age-related disease (de Lau and Breteler, 2006; de Rijk et al., 2000; Dexter and Jenner, 2013). Whereas in 95 % of PD patients an idiopathic background is diagnosed, approx. 5 % of patients are affected by inherited forms of PD. The familial cases of PD result in early-onset of disease and are caused by point missense mutations and multiplications of certain genes, e.g. *SNCA*, *Parkin*, *PINK1*, *LRRK2*, *DJ-1* and *ATP13A2* (Bonifati et al., 2003; Di Fonzo et al., 2007; Kitada et al., 1998; Polymeropoulos et al., 1997; Valente et al., 2001; Zimprich et al., 2004). In 1817, the British physician James Parkinson firstly described the core clinical features of the disorder in his historic publication "An Essay on the Shaking Palsy", which are today classified as common symptoms of PD (Parkinson, 2002). Characteristic clinical symptoms comprise akinesia (muscle rigidity), bradykinesia (slowness of movement), resting tremor and loss of postural reflexes. Furthermore, PD can also cause dysarthria, hypomimia, dysphagia, anosmia, insomnia and urinary incontinence (Galvin et al., 2001; Jankovic, 2008).

1.1.2 Pathophysiology and Etiology

Although many parts of the brain are affected by PD, its best known pathological hallmark is the selective loss of dopamine-producing neurons in the *substantia nigra* (SN), a core complex of melanin- and iron-containing neurons in the ventral midbrain involved in motor control (German et al., 1989; German et al., 1992). SN is a part of basal ganglia which regulates the dopamine maintenance of the striatum, the largest component of basal ganglia controlling complex regulatory circuits of voluntary movements. Although degeneration also occurs in other neuron types (Pillon et al., 1989), the mid-section of the *substantia nigra*,

zona compacta, is mostly affected by neurodegeneration. Loss of dopaminergic neurons is accompanied by the loss of neuromelanin neurons leading to depigmentation (Fearnley and Lees, 1991; Fedorow et al., 2005; Gibb and Lees, 1991). Degeneration of nigral dopaminergic neurons consequently results in dopamine depletion in the striatum leading to observed motoric and non-motoric dysfunctions of PD (Hornykiewicz, 2001; Obeso et al., 2002). The persistent reduction of dopamine misbalances other neurotransmitters including acetylcholine, glutamate or γ -aminobutyric acid (GABA), which can result in mental disorders such as emotional instability and depression (Giupponi et al., 2008). PD is also described to be associated with non-motoric and non-dopaminergic symptoms that extend beyond the nigrostriatal dopamine pathway and often occur years or even decades prior to the clinical diagnosis (Chaudhuri et al., 2006; Sung and Nicholas, 2013). At the time of symptom onset, approx. 50 % of dopamine-producing neurons are already degenerated (Fearnley and Lees, 1991). Degeneration of neurons coincides with the formation of intraneuronal proteinaceous inclusion bodies that can be observed in *post mortem* brain histology. Firstly, these inclusion bodies were described in 1912 by Friedrich Lewy and were later referred to as Lewy bodies (LBs). Together with the loss of dopaminergic neurons in the midbrain, LBs are defined as characteristic pathological hallmarks of PD (Gibb and Lees, 1988). LBs consist of various molecules including α -synuclein (α Syn), neurofilaments and ubiquitin (Baba et al., 1998; Spillantini et al., 1998; Spillantini et al., 1997). Similar pathologies are observed in other neurodegenerative diseases such as dementia with LBs, multiple lateral sclerosis and Alzheimer's disease, which are summarized as synucleinopathies (Hashimoto and Masliah, 1999; Spillantini et al., 1998; Spillantini and Goedert, 2000).

1.2 α -synuclein in Parkinson's disease

In 1997, Spillantini and colleagues discovered the small neuronal protein α Syn as the major constituent of LBs (Spillantini et al., 1997). In the same year, a missense mutation in the α Syn encoding gene was identified that causes autosomal dominant inherited form of PD resulting in earlier disease-onset than sporadic PD (Polymeropoulos et al., 1997). Since these findings, α Syn has been implicated as a key pathogenic factor in sporadic and familial form of PD. α Syn is a highly soluble protein of 140 amino acids, which is enriched in high concentration at presynaptic terminals (Maroteaux et al., 1988; Totterdell and Meredith, 2005). It is presumably involved in the regulation of SNARE-complex assembly of presynaptic vesicles and vesicle release of neurotransmitters (Abeliovich et al., 2000; Burre et al., 2010; Chandra et al., 2004; Lundblad et al., 2012). Moreover, several lines of evidence suggest a role in regulation of cell differentiation and phospholipid metabolism (Golovko et al., 2009; Oliveira et al., 2015). However, the physiological function of α Syn is still not

completely defined. The nuclear localization of α Syn is a matter of intense debate. Numerous studies have shown that α Syn is localized in the nucleus (Huang et al., 2011; Yu et al., 2007). It may impair histone acetylation and thereby promote neurotoxicity (Goers et al., 2003; Kontopoulos et al., 2006).

α Syn is composed of three distinct regions (Figure 1). The N-terminus comprises of six 11-amino acid repeats with a highly conserved hexamer motif (KTKEGV), which likely favours binding to phospholipid membranes (Jensen et al., 1998; Karube et al., 2008; Vamvaca et al., 2009). Interaction of α Syn to phospholipids promotes an unfolded-to-folded transition of the protein resulting in the formation of two long α -helices interacting with the lipid micelles of the membrane (Chandra et al., 2003; Davidson et al., 1998; Sharon et al., 2001). The hydrophobic middle part of α Syn is defined as non-amyloid- β component (NAC) and promotes formation of amyloid-like fibrils known as β -sheets (Giasson et al., 2001; Waxman et al., 2009). The acidic C-terminus, which is highly negatively charged, facilitates protein solubility and exhibits chaperone-like activity (Ahn et al., 2006; Souza et al., 2000b). α Syn can be targeted to nuclear compartments, which can be induced by oxidative stress (Specht et al., 2005; Xu et al., 2006).

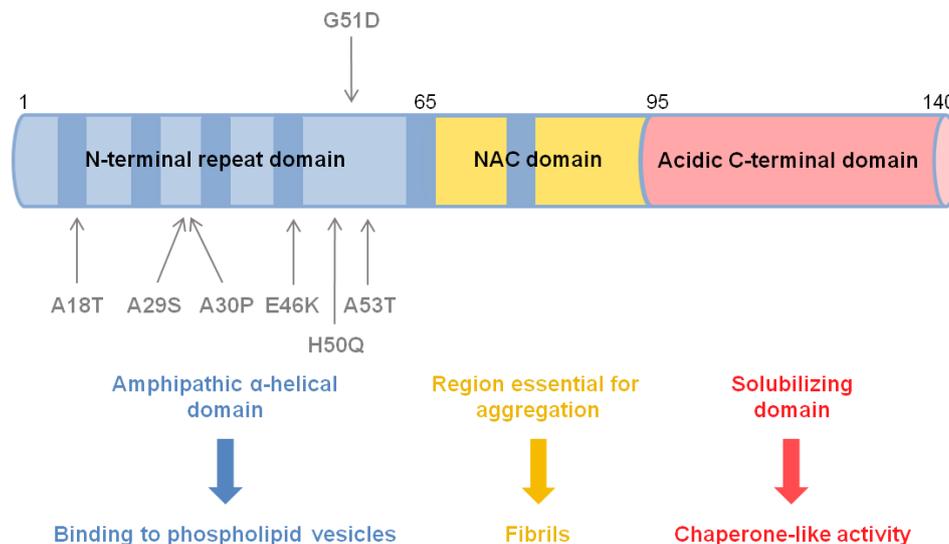

Figure 1. Schematic overview of human α Syn with the three distinct domains.

The six imperfect KTKEGV repeats are shown in dark blue. The N-terminus is indicated in blue, the non-amyloid- β component (NAC domain) in yellow and the acidic C-terminus in red. The N-terminus exhibits a binding affinity to phospholipids. The strong hydrophobic NAC domain promotes aggregate formation and the acidic C-terminus promotes solubility of α Syn. Grey arrows indicate the seven disease-associated mutation sites A18T, A29S, A30P, E46K, H50Q, G51D and A53T (for details and references, see Recchia et al., 2004; Sekiyama et al., 2014).

α Syn is encoded by the *SNCA* gene in the *PARK1* gene locus (Campion et al., 1995; Chen et al., 1995) and belongs to a protein family of soluble proteins including β -synuclein and γ -synuclein (Clayton and George, 1998; Jakes et al., 1994; Maroteaux and Scheller, 1991).

Seven independent point mutations in the *SNCA* gene locus as well as duplications or triplications of the wild-type α Syn locus have been described in familial inherited forms of PD (Figure 1; Appel-Cresswell et al., 2013; Athanassiadou et al., 1999; Kruger et al., 1998; Lesage et al., 2013; Polymeropoulos et al., 1997; Singleton et al., 2003; Zarranz et al., 2004). This makes α Syn a hallmark protein in the pathogenesis of PD and other synucleinopathies, which sparked an intense research to uncover the correlation between structural features of α Syn and its toxicity (Karpinar et al., 2009). All known missense mutations are confined to the N-terminal repeat region of α Syn. Numerous reports have shown that the mutated α Syn variants exhibit aberrant molecular properties and physical features (Sahay et al., 2015). They affect oligomerization, aggregation, formation of fibrillar structures and subcellular distribution of the α Syn protein through the cell (Conway et al., 1998; Conway et al., 2000; Goncalves and Outeiro, 2013; Greenbaum et al., 2005; Lazaro et al., 2014; Li et al., 2001). For instance, the substitution of an alanine to proline at position 30 of A30P mutant disrupts the α -helix and thereby reduces the affinity for binding phospholipid vesicles and shows increased propensities to aggregate (Jensen et al., 1998; Jo et al., 2002; Kruger et al., 1998; Li et al., 2001; Sahay et al., 2015).

1.3 α -synuclein aggregation and propagation

Parkinson's disease is characterized among others by pathological accumulation of misfolded α Syn proteins. These α Syn species are suggested to disrupt molecular mechanisms of specific cellular processes resulting in mitochondrial dysfunction, inhibition of protein degradation, ER-Golgi trafficking defects, disruption of vesicle-membrane fusion and impairment of histone acetylation (Chinta et al., 2010; Cooper et al., 2006; Devi et al., 2008; Emmanouilidou et al., 2010; Hsu et al., 2000; Kontopoulos et al., 2006; Martinez-Vicente et al., 2008; Snyder et al., 2003; Thayanidhi et al., 2010). α Syn aggregation was implicated in disruption of membranes, cytoskeleton changes and induction of oxidative stress (Chen et al., 2007; Junn and Mouradian, 2002; van Rooijen et al., 2009). α Syn was defined for a long time as a natively unfolded monomeric protein (Weinreb et al., 1996). This view was recently questioned by Bartels and colleagues showing α Syn as a helically folded tetramer that is resistant to amyloid-like aggregation (Bartels et al., 2011). Aggregation of α Syn is assumed to constitute the central pathological process in synucleinopathies. However, it is still not clear, which α Syn forms are the pathological species, how the aggregation pathway is initiated and whether LBs represent toxic or protective features. Accumulating evidence suggests oligomeric or protofibrillar forms of α Syn, rather than mature aggregates and fibrils, to be responsible for neurotoxicity (Choi et al., 2013; Conway et al., 2000; Karpinar et al., 2009; Winner et al., 2011). A wide range of factors can trigger α Syn misfolding and

accumulation, e.g. mitochondrial dysfunction, abnormal proteasome function, oxidative stress, metals and neurotoxins such as 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) (Hashimoto et al., 1999; Kowall et al., 2000; Lee et al., 2002; Uversky et al., 2001; Vila et al., 2000; Yamin et al., 2003a). The initiation of the α Syn aggregation pathway either starts in the cytoplasm or in association with the plasma membrane. In the cytoplasm, unfolded α Syn monomers interact to generate unstable dimers, which are further converted to oligomers, protofibrillar oligomers and mature amyloid fibrils. Further accumulation of amyloid fibrils results in deposits within LBs (Auluck et al., 2010). Up to a third of the cellular α Syn population in the cell is bound to synaptic membranes (Visanji et al., 2011). The N-terminal region of α Syn possesses a high binding affinity to phospholipids. The N-terminus binds to the membrane and triggers together with the central domain an unfolded-to-folded transition of α Syn resulting in the formation of two amphipathic α -helices that interact with the lipid micelles (Chandra et al., 2003; Lorenzen et al., 2014). At high concentrations, this conformational change subsequently leads to the formation of membrane-bound- β -sheet-rich structures that self-assemble to oligomers and fibrils (Zhu et al., 2003). α Syn does not accomplish its regular biological role in this composition but gains cytotoxic ability.

Recently, a novel concept of progressive interneuronal spreading of Lewy pathology emerged that might contribute to the development and progression of PD and other synucleinopathies (Braak et al., 2003). Braak and colleagues suggest a prion-like propagation of pathological α Syn forms by transmission from one neuron to another. Several lines of evidence support this idea showing that propagation of pathological α Syn between cells leads to subsequent initiation of “LB-like aggregates” in the acceptor cells as well as progressive neurodegeneration (Desplats et al., 2009; Luk et al., 2012a; Luk et al., 2012b; Masuda-Suzukake et al., 2013; Recasens et al., 2014; Sacino et al., 2014).

1.4 Posttranslational modifications of α -synuclein

Posttranslational modifications (PTMs) represent consistent markers of α Syn pathology within LBs (Anderson et al., 2006; Duda et al., 2000; Fujiwara et al., 2002; Giasson et al., 2000; Hasegawa et al., 2002; Paleologou et al., 2010). The precise contribution of different PTMs to the disease is still controversial. Several studies illustrated that PTMs influence the α Syn aggregation process and contribute to cellular neurotoxicity (Chen and Feany, 2005; Hodara et al., 2004; Norris et al., 2003; Oueslati et al., 2010). Major PTMs of α Syn include phosphorylation, ubiquitination, sumoylation, nitration, glycosylation or acetylation at multiple amino acid residues (Figure 2; Bartels et al., 2014; Dorval and Fraser, 2006; Duda et al., 2000; Fujiwara et al., 2002; Giasson et al., 2000; Guerrero et al., 2013; Hasegawa et al., 2002; Shimura et al., 2001).

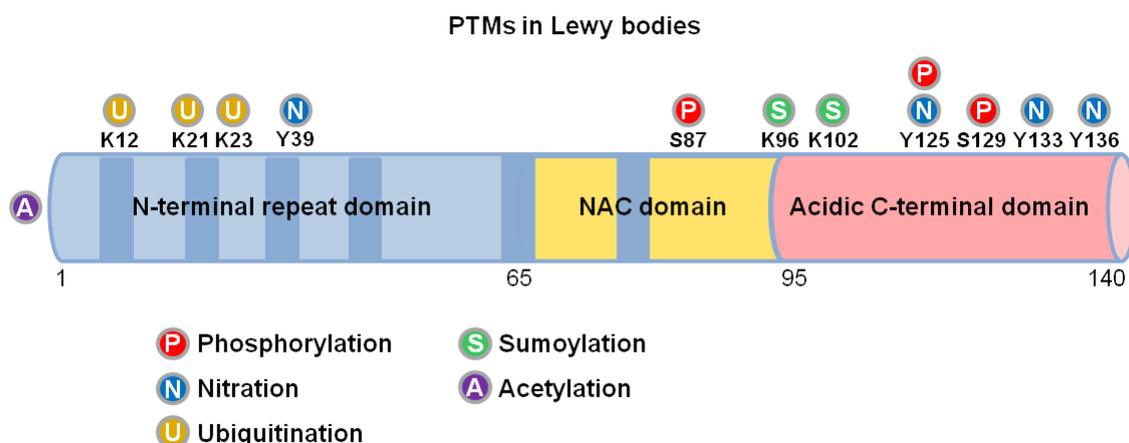

Figure 2. Posttranslational modifications of α Syn in Lewy bodies.

The locations of amino acid residues of the main disease-associated PTMs of α Syn (phosphorylation, nitration, ubiquitination, sumoylation and acetylation) identified in LBs are shown (for details and references, see Schmid et al., 2013).

PTMs such as phosphorylation, ubiquitination or sumoylation are primarily involved in modulating α Syn degradation by various proteolytic pathways. These PTMs are suggested to act as molecular switches that determine the preference of α Syn for a certain proteolytic process indicating their important role in balancing the protein level of α Syn. Since discovering posttranslationally modified α Syn in human cerebrospinal fluid and blood plasma (Borghetti et al., 2000; El-Agnaf et al., 2003; Foulds et al., 2011), PTMs are considered as potential targets for biomarkers.

1.4.1 Phosphorylation of α -synuclein

The predominant α Syn modification in LBs is phosphorylation at the residue serine 129 (S129). Approximately 90 % of α Syn found in LBs is phosphorylated at this residue, whereas only 4 % of the soluble monomeric α Syn is accordingly modified at physiological conditions (Anderson et al., 2006; Fujiwara et al., 2002). The molecular function of phosphorylation at S129 and its relevance in pathogenicity is still under debate (Tenreiro et al., 2014a). It was shown to play a role in regulation of α Syn localization, aggregation and toxicity. Studies in several mammalian models of PD have demonstrated a protective role of S129 phosphorylation on neuronal dysfunction (Gorbatyuk et al., 2008; Kuwahara et al., 2012). In contrast, neurotoxicity tests in rats revealed no protective effect of S129 phosphorylation on α Syn toxicity (McFarland et al., 2009). In a *Drosophila* model of PD, a pathogenic role of α Syn S129 phosphorylation was observed (Chen and Feany, 2005). There, increase in the phosphorylation status of α Syn correlates with enhanced neurotoxicity. A number of

heterologous studies in yeast support a suppressive effect of S129 phosphorylation on α Syn aggregation, vesicle trafficking and cytotoxicity (Sancenon et al., 2012; Zabrocki et al., 2008). This modification modulates clearance of α Syn inclusions in yeast cells (Tenreiro et al., 2014b). Phosphorylation at S129 suppressed the defects induced by impaired sumoylation such as increased number of cells with inclusions and reduced yeast growth (Shahpasandzadeh et al., 2014).

In human cells, several kinase families participate in S129 phosphorylation of α Syn, including Polo-like kinases (PLKs), G protein-coupled receptor kinases (GRKs), casein kinases (CKs) 1 and 2 and the leucine-rich repeat kinase 2 (LRRK2) (Oueslati et al., 2013; Pronin et al., 2000; Qing et al., 2009; Waxman and Giasson, 2008). GRK5-dependent phosphorylation of α Syn plays an important role in the pathogenesis of PD (Arawaka et al., 2006). The yeast Cdc5, ortholog of human PLK2, phosphorylates α Syn at the conserved S129 residue and rescues α Syn toxicity upon overexpression of the kinase (Gitler et al., 2009; Wang et al., 2012). Similar protective effects were provided by the yeast kinase Yck3, corresponding to human CK-1 (Zabrocki et al., 2008). Co-expression of PLK2 or GRK5 with α Syn in yeast significantly increased α Syn S129 phosphorylation (Shahpasandzadeh et al., 2014). Thereby, α Syn-induced cytotoxicity, which resulted from impairment of sumoylation, could be rescued by GRK5-mediated S129 phosphorylation. Recent studies in yeast revealed that expression of phosphorylation deficient variants, S129A or S129G, promotes α Syn-induced toxicity and inclusion formation (Tenreiro et al., 2014b). These findings support a protective function of S129 phosphorylation in yeast.

1.4.2 Nitration of α -synuclein

Nitrated α Syn represents another classical posttranslational modification found in LBs (Duda et al., 2000; Giasson et al., 2000). Nitration is a chemical process which incorporates a nitro group (NO_2) into proteins, lipids or nucleic acids via a radical-based mechanism. Tyrosine residues are the preferred nitration sites of proteins. Nitration changes the tyrosine residue into a negatively charged hydrophilic 3-nitrotyrosine (Figure 3). This modification modulates key properties of the amino acid including phenol group pK_a redox potential, hydrophobicity and volume, which leads to profound structural and functional changes (Radi, 2012). Tyrosine nitration is a marker for nitrative stress, which is mediated by reactive nitrogen species (RNS) such as peroxynitrite anion (ONOO^- , PON) or nitrogen dioxide ($^{\bullet}\text{NO}_2$) formed as secondary products of the small gaseous molecule nitric oxide ($^{\bullet}\text{NO}$) metabolism (Ischiropoulos, 1998; Radi, 2004; Schildknecht et al., 2013). $^{\bullet}\text{NO}$ is enzymatically generated from L-arginine by nitric oxide synthases.

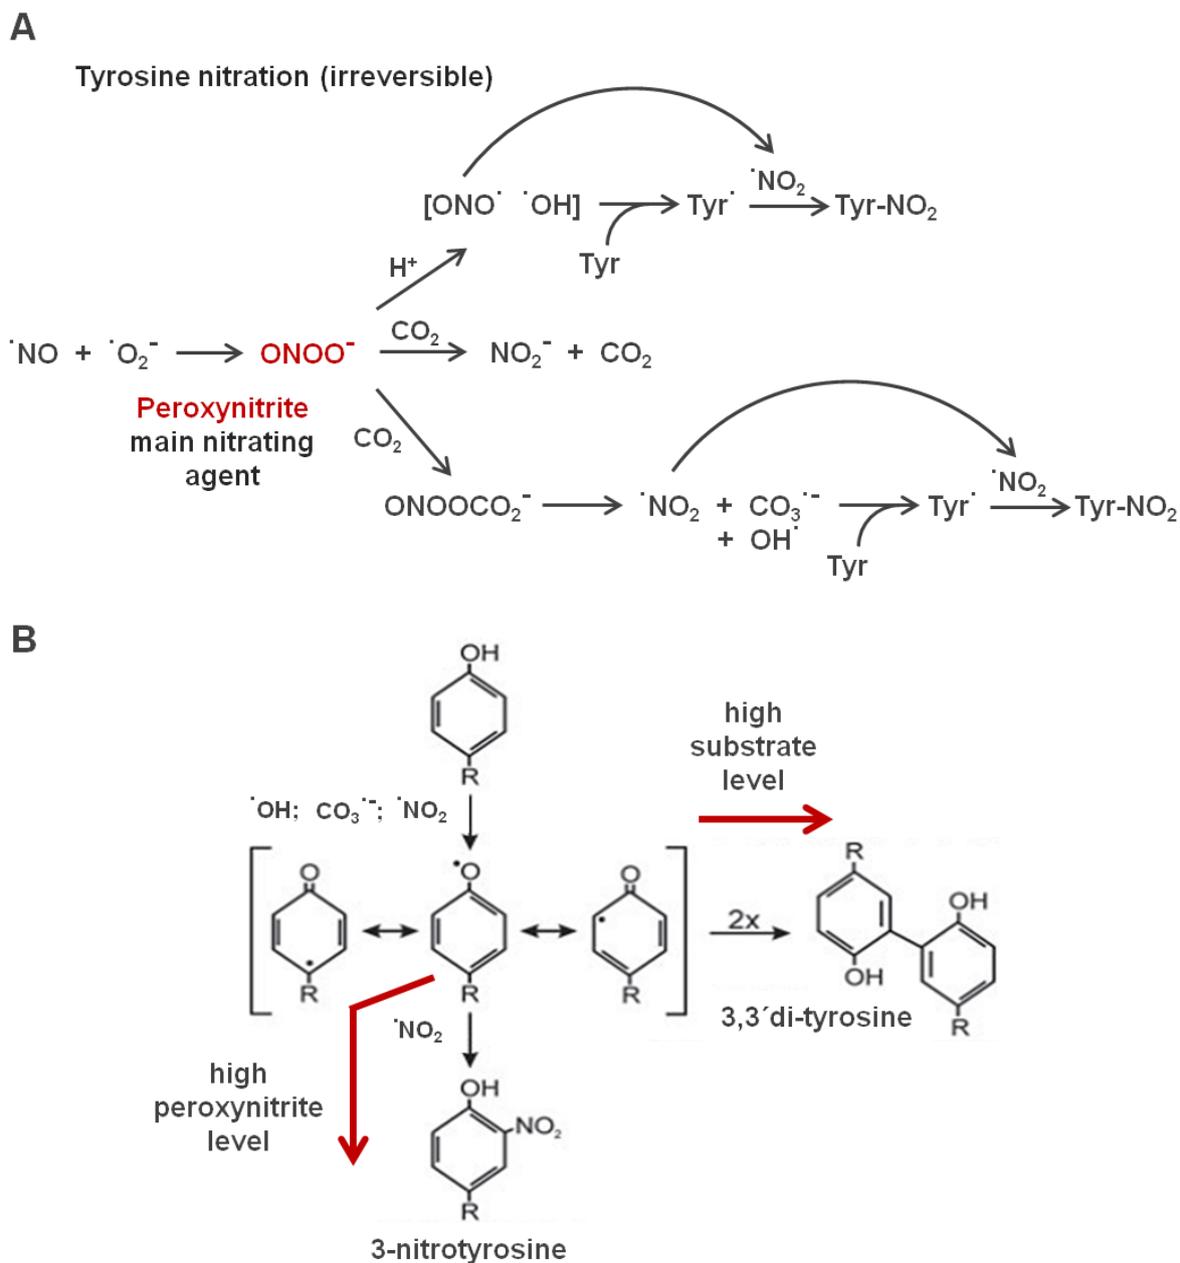

Figure 3. Tyrosine nitration and di-tyrosine formation.

(A) The free radicals nitric oxide ($\cdot\text{NO}$) and superoxide ($\cdot\text{O}_2^-$) react to generate peroxynitrite (ONOO^-). Under physiological pH conditions, 20–30 % of peroxynitrite is protonated to peroxynitrous acid (ONOOH). This strong oxidant is chemically unstable and dissociates readily into the highly reactive nitrogen dioxide ($\cdot\text{NO}_2$) and hydroxyl radicals ($\cdot\text{OH}$). $\cdot\text{NO}_2$ radicals represent the actual nitrating species, which can react with tyrosine residues to generate tyrosyl radicals. In the presence of high concentrations of carbon dioxide/bicarbonate (CO_2) in the cell, ONOO^- can also interact with CO_2 , which either results in the production of NO_2^- and CO_2 (two thirds of product) or $\cdot\text{NO}_2$ and $\text{CO}_3^{\cdot-}$ (one third of product). These radicals can interact with tyrosine residues to produce tyrosyl radicals. Further reaction with $\cdot\text{NO}_2$ results in the formation of 3-nitrotyrosine. (B) $\cdot\text{NO}_2$, $\text{CO}_3^{\cdot-}$ and $\cdot\text{OH}$ radicals react in radical-based mechanism with tyrosine residues and an unstable tyrosyl radical is formed. This tyrosyl radical either reacts with a $\cdot\text{NO}_2$ radical to form 3-nitrotyrosine or alternatively reacts with another tyrosyl residues, which results in the formation of a covalent 3,3'-di-tyrosine bond (modified from Schildknecht et al., 2013).

Nitric oxide can serve as an endogenous signalling molecule involved in the regulation of physiological processes, e.g. cardiovascular, immune and nervous system (Martinez-Ruiz and Lamas, 2009; Moncada, 1999; Schildknecht and Ullrich, 2009). NO-mediated signalling processes are summarized as “redox regulation” (Frein et al., 2005; Schildknecht and Ullrich, 2009).

α Syn possesses four tyrosine residues at position 39, 125, 133 and 136 that were identified as nitration sites (Sevcsik et al., 2011). *In vitro* studies demonstrated that all four tyrosine residues are also phosphorylation targets (Ahn et al., 2002; Ellis et al., 2001; Mahul-Mellier et al., 2014; Nakamura et al., 2001; Negro et al., 2002; Takahashi et al., 2002). *In vivo*, only Y39 and Y125 were identified as phosphorylation sites (Kiely et al., 2013; Mahul-Mellier et al., 2014). Y39 is located within the N-terminal KTKEGV repeat region and the other three tyrosine residues are located at the C-terminal end of α Syn in close neighbourhood to the protective S129 phosphorylation site. Exposure of α Syn to nitrative agents results in the formation of α Syn oligomers and higher molecular weight α Syn species that are resistant to strong denaturing conditions. This suggests that α Syn proteins are covalently crosslinked (Paxinou et al., 2001; Souza et al., 2000a; Takahashi et al., 2002; Uversky et al., 2005; Yamin et al., 2003b). This oligomerization can be abolished *in vitro* when α Syn lacks the four tyrosine residues at positions 39, 125, 133 and 136 (Norris et al., 2003).

Nitrating agents such as PON can nitrate tyrosine residues of α Syn to generate 3-nitrotyrosine (3-NT). Alternatively, highly stable 3,3'-di-tyrosine oligomers can be formed including dimers, trimers and higher oligomeric species (Hodara et al., 2004; Pfeiffer et al., 2000; Souza et al., 2000a). The majority of studies were performed *in vitro* after exposure of α Syn to nitrating agents leading to non-specific nitration at all tyrosine residues. It is still unclear, whether the nitration-modified α Syn intermediates are toxic and what are the functional consequences of these modifications. Even the precise positions or preferred combinations of the tyrosines involved in di-tyrosine formation *in vivo* are unknown yet.

1.5 Detoxification of nitric oxide by hemoglobins

Nitric oxide is a free radical which acts under normal conditions as signalling molecule in a diverse set of physiological processes (Martinez-Ruiz and Lamas, 2009; Schildknecht and Ullrich, 2009). High concentrations of nitric oxide harm the cell due to increased oxidative and nitrative stresses. Eukaryotes evolved many strategies for combating the damaging effects of nitric oxide. The use of detoxification enzymes is one valuable strategy to prevent the attack by nitric oxide. The flavohemoglobins are prominent among the detoxification enzymes. The heme of the hemoglobin domain binds \cdot NO and catalyses the conversion of

*NO to the more stable nitrous oxide (N₂O) via a NO dioxygenase reaction to detoxify the nitric oxide radical. In yeast, the gene *YHB1* (yeast flavohemoglobin) is involved in oxidative and nitrative stress responses (Cassanova et al., 2005). This gene encodes a nitric oxide oxidoreductase, which protects against nitration of cellular targets and against cell growth inhibition under aerobic and anaerobic conditions (Liu et al., 2000). Expression of *YHB1* is increased under aerobic conditions (Crawford et al., 1995; Zhao et al., 1996).

A BLAST search for human homologues of yeast *YHB1* revealed 49 % sequence similarity of the globin domain of Yhb1 to the human neuroglobin. Both Yhb1 and neuroglobin contain a globin domain and are members of the globin gene family. Neuroglobins are oxygen-binding proteins that are highly conserved among other vertebrates and are expressed in the central and peripheral nervous system. They provide protection against hypoxic induced cell injury in the brain, which is associated with ROS and RNS accumulation (Greenberg et al., 2008).

1.6 Degradation pathways of α -synuclein

One hypothesis of α Syn-induced toxicity includes gain of toxic function due to increased expression levels which is caused by the multiplication of the *SNCA* gene leading to enhanced amounts of misfolded or aggregated α Syn (Outeiro and Lindquist, 2003; Petroi et al., 2012; Singleton et al., 2003). This is further confirmed by findings which demonstrate that inhibition of degradation pathways resulting in inefficient protein clearance is sufficient to trigger neurotoxicity (Vilchez et al., 2014). The understanding of α Syn turnover machinery is an essential aspect to uncover the pathological mechanism of PD.

In eukaryotic cells, degradation of non-functional or potentially toxic proteins is primarily carried out by two pathways, the ubiquitin-proteasome or the autophagy-lysosome/vacuole system (Goldberg, 2003; Klionsky and Emr, 2000). Both pathways were suggested to contribute to α Syn degradation (Webb et al., 2003). The ubiquitin-proteasome pathway mostly degrades short-lived, soluble proteins (Goldberg, 2003). Numerous studies demonstrated that the 26S proteasome is important for α Syn degradation (Bennett et al., 1999; McLean et al., 2001; Tofaris et al., 2001). It is considered as the main degradation pathway for α Syn under normal conditions (Ebrahimi-Fakhari et al., 2011). The involvement of the 26S proteasome in α Syn toxicity is conserved in yeast (Chen et al., 2005; Outeiro and Lindquist, 2003; Sharma et al., 2006).

The ubiquitin-proteasome pathway shows only a minor contribution in yeast compared to the autophagy-vacuole system for degradation of α Syn aggregates (Petroi et al., 2012). Generally, the autophagy-lysosome/vacuole system is suggested to degrade longer-lived macromolecules such as large oligomeric and aggregated species (Klionsky and Emr, 2000;

Lee et al., 2004). It takes care of misfolded proteins under pathological conditions when the ubiquitin-proteasome system is impaired as during α Syn-induced toxicity (Ebrahimi-Fakhari et al., 2011; Lee et al., 2004). Numerous studies demonstrated a contribution of the autophagy-lysosome/vacuole system to α Syn degradation. The autophagy-stimulating drug rapamycin promotes α Syn clearance (Webb et al., 2003) and causes reduction of α Syn aggregates (Zabrocki et al., 2005).

PTMs serve as molecular switches that determine the preference of α Syn degradation for a certain proteolytic pathway. It was shown that de-ubiquitinated α Syn is preferentially degraded by autophagy system, whereas mono-ubiquitinated α Syn favours the proteasome (Rott et al., 2011). S129-phosphorylated α Syn is targeted to the 26S proteasome in an ubiquitin-independent manner (Machiya et al., 2010). In yeast, increased phosphorylation of α Syn mediated by PLK2 leads to aggregate clearance by the autophagy-vacuole system and suppressed cytotoxicity (Oueslati et al., 2013). Further studies in yeast revealed that sumoylation preferentially directs α Syn aggregates towards autophagy (Shahpasandzadeh et al., 2014). Impaired α Syn sumoylation results in growth inhibition and increased aggregate formation. Phosphorylation at S129 suppresses this defect by shifting the fate of α Syn to increased ubiquitination and proteasome degradation (Shahpasandzadeh et al., 2014).

1.7 *Saccharomyces cerevisiae* as model for Parkinson's disease

The budding yeast *Saccharomyces cerevisiae* is a simple eukaryotic model system which is used to uncover the correlation between structural features of α Syn and its toxicity. Although a homologue of the *SNCA* gene is not present in the yeast genome (Lavedan, 1998), it provides a unique tool to study the molecular basis of PD *in vivo* (Franssens et al., 2010). Protein quality control systems are highly conserved between yeast and humans manifesting yeast as valuable model system for studying protein misfolding and cellular pathways associated with neurodegenerative diseases (Botstein et al., 1997; Tenreiro et al., 2013). Due to its high susceptibility to genetic manipulations, the short generation time of ~90 minutes and a wide range of genetic tools available, yeast is ideally convenient to study the function of genes implicated in human disease (Mager and Winderickx, 2005).

The yeast genome is well characterized. It consists of 16 chromosomes and contains 6217 genes (Goffeau et al., 1996). 44 % of the yeast genes reveal significant sequence similarities to human genes (Hughes, 2002). Yeast and humans share significant cellular pathways that regulate key aspects of eukaryotic cell biology, including cell cycle, vesicular transport and programmed cell death (Bonifacino and Glick, 2004; Botstein et al., 1997; Brodsky and Skach, 2011; Hartwell, 2002; Munoz et al., 2012).

Heterologous expression of different forms of human α Syn in yeast cells recapitulates central features of PD, including dose-dependent toxicity and aggregation (Outeiro and Lindquist, 2003; Petroi et al., 2012). In yeast, aggregation of α Syn causes vesicle traffic defects, proteasome dysfunction and damage to cellular membranes (Cooper et al., 2006; Gitler et al., 2008; Outeiro and Lindquist, 2003; Soper et al., 2008). Aggregation of α Syn induces mitochondrial dysfunction and the formation of reactive oxygen and nitrogen species in yeast cells (Flower et al., 2005; Hsu et al., 2000; Junn and Mouradian, 2002; Outeiro and Lindquist, 2003; Parihar et al., 2008; Parihar et al., 2009; Su et al., 2010; Witt and Flower, 2006), which is similar to mammalian cells.

To probe the toxicity of α Syn in yeast, transgenic yeast cells were engineered carrying human α Syn (Outeiro and Lindquist, 2003; Petroi et al., 2012). Thereby, α Syn was C-terminally fused to GFP via KLID linker. The fusion construct is integrated into the genome or is externally present on a plasmid under the control of galactose-inducible promoter (*GAL1*-promoter). The benefit of the *GAL1*-promoter is that it can be switched on and off by supplementing galactose into the medium as an inducer of expression. This allows investigating the situation in the presence or absence of the gene of interest.

When expressing a single copy of the gene in yeast, α Syn associates with plasma membrane in a highly selective manner and has no obvious effect on yeast viability (Figure 4). Expression of two *GAL1*-driven copies causes formation of cytoplasmic inclusions and expression of three copies results in yeast growth impairment and strong increase in aggregate formation. Thus, α Syn toxicity increases in a copy number-dependent manner, similar to a familial form of PD linked with allele multiplication of the wild-type *SNCA* locus driven by its own human promoter (Chartier-Harlin et al., 2004; Hardy et al., 2006; Singleton et al., 2003). Three *GAL1*-driven copies of wild-type α Syn and two copies of A53T were determined as thresholds for cytotoxicity and aggregation in yeast (Petroi et al., 2012). Similar to wild-type and A53T α Syn, expression of E46K mutant results in significant growth inhibition and formation of inclusions (Lazaro et al., 2014).

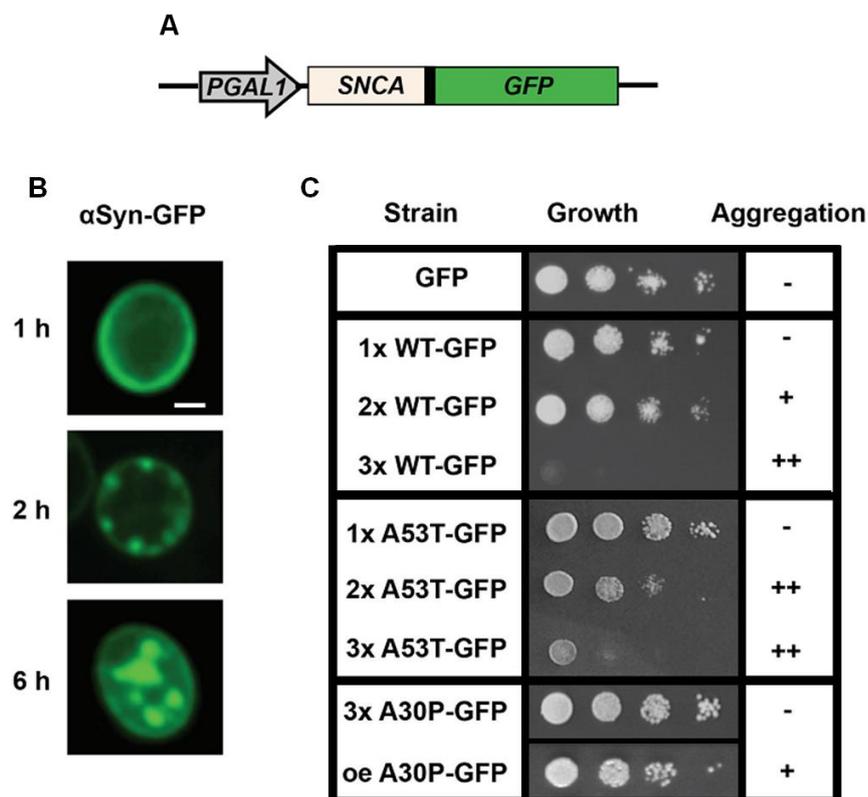

Figure 4. Localization of α Syn in yeast and its impact on growth.

(A) GFP-fused human α Syn (SNCA) is expressed from the galactose-inducible yeast *GAL1*-promoter (*PGAL1*). GFP was C-terminally fused to α Syn via KLID linker. (B) Fluorescence microscopy of time-dependent aggregate formation of α Syn, expressed from a high-copy plasmid (2 μ). After one hour (h) induction of α Syn expression, the protein is localized at the plasma membrane. Two hours of α Syn expression results in nucleation of α Syn at the plasma membrane and formation of small membrane-localised aggregates. After six hours of α Syn expression, large cytoplasmic aggregates are formed. Scale bar = 1 μ m. (C) Growth behaviour of yeast cells expressing increasing copy numbers of *GAL1*-driven wild-type α Syn fused to GFP (WT-GFP) and two different familial mutants of α Syn. Growth analysis indicates decreased growth with increasing copy number of wild-type and A53T α Syn but not A30P; oe, overexpression (Popova et al., 2015).

An unusual feature of the yeast system, which is different from PD and other models, is that the A30P variant only forms inclusions when highly expressed and fails to display a growth inhibition in yeast, because aggregation of A30P is only transient (Dixon et al., 2005; Petroi et al., 2012). Expression of A30P α Syn has different toxicity properties in yeast compared to human cells. Whereas wild-type and A53T α Syn are delivered to the plasma membrane, A30P is located in the cytoplasm. Three integrated copies of A30P α Syn do not impair yeast growth. Only overexpression from a high-copy number plasmid results in formation of fluorescent foci, similar to the foci obtained by the other variants. However, the impact of A30P overexpression on yeast growth is not considerable in comparison with wild-type and A53T variants (Petroi et al., 2012).

1.8 Aims of the study

A pathological hallmark of PD is the accumulation of posttranslationally modified α Syn aggregates in susceptible neurons in the form of LBs. PTMs of α Syn are important triggers for aggregation and cytotoxicity properties. Nitrative stress leading to α Syn nitration is implicated in the pathogenesis of the disease. Four tyrosine residues of α Syn were identified as nitration sites. α Syn nitration results in the formation of 3-NT or alternatively in the formation of covalently crosslinked di-tyrosine dimers. It is still not resolved whether the nitration-modified α Syn intermediates are toxic or what is the functional consequence of these modifications. The precise positions or preferred combinations of the tyrosines involved in di-tyrosine formation *in vivo* are also still elusive. Moreover, the interplay between nitration and other PTMs such as phosphorylation at the protective S129 residue was never sufficiently addressed.

In this study, the budding yeast was used as reference cell to study the impact of nitration on α Syn aggregation and α Syn-mediated toxicity. The toxic wild-type α Syn and the A30P mutant that is not toxic in yeast were compared. In the first part of the thesis, nitration, phosphorylation and dimerization sites were determined *in vivo* using LC-MS. *In vitro* nitrated α Syn after PON-exposure was used to examine the effect of nitration on α Syn dimer and oligomer formation. α Syn tyrosine mutants inhibited in modification were explored by growth and aggregation tests to address the question, whether nitration is involved in α Syn aggregation and toxicity. A yeast strain was used that lacks *YHB1*, a gene involved in nitrative stress response, to investigate α Syn-induced cytotoxicity under increased intracellular nitrative stress. Tyrosine and S129 mutants impaired in modifications were analyzed by growth, aggregation and immunoblot analysis using a phospho-S129 antibody in order to elucidate, whether there is an interplay between nitration and phosphorylation at S129. In the last part of the thesis, it was examined how tyrosine modifications affect autophagy or proteasome-mediated clearance of α Syn aggregates.

2 Materials and Methods

2.1 Materials

2.1.1 Companies of chemicals, molecular biological substances and equipment

Chemicals for the preparation of buffers, solutions and media were obtained from the companies **Carl Roth GmbH & CO. KG** (Karlsruhe, Germany), **Invitrogen** (Carlsbad, USA), **Roche** (Basel, Switzerland), **Sigma-Aldrich** (St. Louis, USA), **AppliChem GmbH** (Darmstadt, Germany), **Becton Dickinson** (Franklin Lakes, USA) and **Merck KGaA** (Darmstadt, Germany). Agarose was used from **Biozyme Scientific GmbH** (Hessisch Oldendorf, Germany). Bradford solution “Roti®-Quant” for the determination of protein concentration was used from **Carl Roth GmbH & CO. KG** (Karlsruhe, Germany).

Restriction enzymes and polymerases were purchased from **Thermo Fisher Scientific** (Waltham, USA). For RNA degradation, RNase A from **Roche** (Basel, Switzerland) was used. Proteases, trypsin and Asp-N, were purchased from **Serva Electrophoresis GmbH** (Heidelberg, Germany) and **Sigma-Aldrich** (St. Louis, USA). Primary antibodies were purchased from **Abcam** (Cambridge, UK), **JaICA** (Shizuoka, Japan), **Upstate Biotechnology Inc** (Lake Placid, USA), **Wako Pure Chemical Industries Ltd** (Osaka, Japan), **Santa Cruz Biotechnology Inc** (Dallas, USA), **AnaSpec Inc** (Fremont, USA) and **Thermo Fisher Scientific** (Waltham, USA). Secondary antibodies were purchased from **Invitrogen** (Carlsbad, USA) and **Jackson ImmunoResearch Laboratories** (West Grove, USA). Synthetic oligonucleotides were purchased from **Sigma-Aldrich** (St. Louis, USA). For cloning, the GeneArt® Seamless Cloning and Assembly Enzyme Mix from **Invitrogen** (Carlsbad, USA) was used. Substitution of amino acids was performed with the QuikChange II Site-Directed Mutagenesis Kit from **Agilent Technologies** (Santa Clara, USA). As DNA-size and protein-weight standards the DNA-marker “GeneRuler 1kb DNA ladder” and the protein-marker “PageRuler Prestained Protein Ladder” were used from **Thermo Fisher Scientific** (Waltham, USA). *Saccharomyces cerevisiae* wild-type and deletion strains were purchased from **EUROSCARF** (Frankfurt, Germany). Mammalian expression vector pcDNA3.1 was obtained from **Invitrogen** (Carlsbad, USA).

Solutions were filtered to sterility using Filtropur S 0.2 and S 0.45 filters from **Sarstedt AG & Co** (Nümbrecht, Germany). For plasmid DNA purification from *Escherichia coli* and DNA extraction from agarose gels the kits “QIAGEN Plasmid Mini Prep Kit” and “QIAquick Gel Extraction Kit” from **QIAGEN** (Hilden, Germany) were used. DNA concentrations were measured using the “NanoDrop ND-1000 photospectrometer” from **Peqlab Biotechnologie GmbH** (Erlangen, Germany). PCR reactions were performed using the “MWG Biotech Inc Primus 96 Thermal Cycler” from **MWG-Biotech** (Ebersberg, Germany). Gel electrophoresis

was done in the “Mini-Sub Cell GT” chamber using the “Powerpac 300” power supply from **Bio-Rad Laboratories** (Hercules, USA). SDS-PAGE and protein immunoblotting were performed using the “Mini-PROTEAN® 3 Cell”, “Mini Trans-Blot® Electrophoretic Cell” and the “Powerpac 300” power supply from **Bio-Rad Laboratories** (Hercules, USA). For protein transfer, the nitrocellulose membrane “Amersham™ Protran™ 0.45 µm NC” from **GE Healthcare** (Little Chalfont, UK) and the “Amersham™ Hybond-P™ 0.45 µm PVDF” from **GE Healthcare** (Little Chalfont, UK) were used. Chemiluminescence was detected using the “Amersham™ Hyperfilm™ ECL” from **GE Healthcare** (Little Chalfont, UK). Exposing Hyperfilms™ for immunoblot techniques occurred with the “Optimax X-ray Film Processor” from **PROTEC GmbH & Co. KG** (Oberstenfeld, Germany). Optical density was measured by T80 UV/VIS spectrometer from **PG Instruments Ltd** (Lutterworth, UK) or alternatively by the microplate reader “Infinite® M200” from **Tecan Group** (Männedorf, Switzerland). Centrifugations were performed with the centrifuge “Biofuge pico” from the company **Heracus** (Hanau, Germany), “Centrifuge 5804R” from **Eppendorf AG** (Hamburg, Germany), “Centrifuge 4K15” from **Sigma Laborzentrifugen GmbH** (Osterode am Harz, Germany) or “Sorvall RC-3B Plus Refrigerated Centrifuge” from **Thermo Fisher Scientific** (Waltham, USA). Incubation of agar plates at 37 °C was performed in the incubator “BD 53/E2” from **BINDER GmbH** (Tuttlingen, Germany) and incubation at 30 °C was performed in the incubator “BE 400” from **Memmert GmbH + Co. KG** (Schwabach, Germany). Other instrumentation, manufacturers or certain variations are named in the further work.

2.1.2 Strains, plasmids and oligonucleotides

The *Saccharomyces cerevisiae* strains, plasmids and oligonucleotides used in this study are listed in Table 1 to 3. *Escherichia coli* strain DH5α [$\Delta 80dlacZ \Delta M15$, *recA1*, *endA1*, *gyrA96*, *thi-1*, *hsdR17* (*rK-*, *mK+*), *supE44*, *relA1*, *deoR*, $\Delta(lacZYA-argF)$ U169] was used for general cloning procedures and purification of plasmid DNA (Meselson and Yuan, 1968; Woodcock et al., 1989). Human α Syn cDNA sequence and the corresponding A30P sequence were expressed from yeast high expression vector pME2795 (2µ) under the *GAL1*-promoter and *CYC1* terminator as described previously (Petroi et al., 2012). *YHB1* sequence was amplified on genomic DNA from *Saccharomyces cerevisiae* and cloned into pME2788 low expression vector (*CEN/ARS*) or pME2792 high expression vector (2µ) preceded by *GAL1*-promoter and *CYC1* terminator (Mumberg et al., 1994). *NGB* was amplified on cDNA sequence and cloned into pME2788 low expression vector (*CEN/ARS*). Additionally, *NGB* was cloned into the mammalian high expression vector pcDNA3.1 (Invitrogen), which is preceded by *CMV* promoter. The 4(Y/F) α Syn mutant constructs were generated by site-directed mutagenesis using QuikChange II Site-Directed Mutagenesis Kit (Agilent Technologies). Plasmids

pME3763, pME3764, pME4095 and pME4101 were used as templates to substitute successively the four tyrosines (Y39, Y125, Y133, and Y136) by phenylalanine. Plasmids pME3763, pME3764 and pME4095 were used as templates to substitute serine 129 to alanine. For growth and microscopy studies, α Syn variants were used that are C-terminally tagged with GFP via the KLID linker (Petroi et al., 2012). For Ni²⁺-NTA affinity chromatography, α Syn and A30P were C-terminally fused to His₆-tag using pME3760 and pME3761 as templates. All constructs were verified by DNA sequencing. As negative control, the empty vector pME2788, pME2792 and pME2795, or the GFP expressing vector pME3759 was used.

Table 1. Yeast strains

AspN (100 mM NH ₄ HCO ₃ [pH 8.5])	1:100	37 °C		Sigma-Aldrich

2.1.4 Media

If not indicated otherwise, buffers and media were dissolved in H₂O and autoclaved for 20 minutes at 121 °C and 2 bar. Thermally unstable substances were dissolved and filtered to sterility using Filtropur S 0.2 filters (Sarstedt AG & Co). For cultivation of bacterial and yeast strains the following media were used.

Table 5. Media

Ingredients	Agar-plates	Liquid medium
LB medium (<i>Escherichia coli</i>)		
Bacto-Tryptone	10 g	10 g
Yeast extract	5 g	5 g
NaCl	10 g	10 g
Agar	20 g	
H ₂ O	ad 1000 mL	ad 1000 mL
SC medium (<i>Saccharomyces cerevisiae</i>)		
YNB-aa-as (yeast nitrogen base w/o AA and AS)	0.9 g	1.5 g
Ammonium sulfate	3.0 g	5.0 g
200 mM Inositol	0.6 mL	1.0 mL
Amino acid powder mix	1.2 g	2.0 g
Glucose/Galactose	12 g	
Raffinose/Galactose		20 g
Agar	9 g	
H ₂ O	ad 600 mL	ad 1000 mL

Ingredients	Agar-plates	Liquid medium
YEPD medium (<i>Saccharomyces cerevisiae</i>)		
Bacto-Peptide	6 g	6 g
Yeast extract	3 g	3 g
Glucose/Galactose	6 g	6 g
Agar	6 g	
H ₂ O	ad 300 mL	ad 300 mL
MV medium (<i>Saccharomyces cerevisiae</i>) [pH 7.2]		
YNB-aa-as (yeast nitrogen base w/o AA and AS)	1.45 g	
Ammonium sulfate	5.52 g	
Succinic acid	10 g

adjust pH with 10 mM KOH		
Amino acid mix (-His, -Leu, -Trp, -Ura)		
Adenine (Ade), L-Alanine (Ala), L-Arginine (Arg), L-Asparagine (Asn), L-Aspartic acid (Asp), L-Cysteine (Cys), L-Glutamine (Gln), L-Glutamic acid (Glu), Glycine (Gly), L-Isoleucine (Ile), L-Lysine (Lys), L-Methionine (Met), L-Phenylalanine (Phe), L-Proline (Pro), L-Serine (Ser), L-Threonine (Thr), L-Tyrosine (Tyr), L-Valine (Val), para-Aminobenzoic acid (Paba)	2 g (each)	
	0.2 g	

2.1.5 Antibiotics

For antibiotic selection, stock solutions of all antibiotics used in this study were prepared. Autoclaved media had to cool down to approx. 50 °C before the antibiotic stock solutions were added. The final concentrations for all antibiotics are listed below.

Table 6. Antibiotics

Antibiotic	stock solution	storage temperature	final concentration
Ampicillin	100 mg/mL	-20 °C	100 µg/mL
G418	100 mg/mL	-20 °C	200 µg/mL

2.1.6 Antibodies

Table 7. Primary antibodies

Antibody	Animal	Type	Dilution	Source
anti-3-nitrotyrosine	mouse	monoclonal	1:1400	Abcam
anti-di-tyrosine	mouse	monoclonal	1:1000	JalCA
anti-nitroY39 α Syn	mouse	monoclonal	1:1000	Upstate Biotechnology Inc
anti-phosphoY133 α Syn	rabbit	polyclonal	1:1000	Abcam
anti-phosphoY125 α Syn	rabbit	polyclonal	1:1000	Abcam
anti-phosphoS129 α Syn	mouse	monoclonal	1:2500	Wako Pure Chemical Industries Ltd
anti- α Syn	rabbit	polyclonal	1:2500	Santa Cruz Biotechnology Inc
anti- α Syn	mouse	monoclonal	1:2000	AnaSpec Inc
anti-GAPDH	mouse	monoclonal	1:5000	Thermo Fisher Scientific

Table 8. Secondary antibodies

Antibody	Type	Dilution	Source
HRP-conjugated Goat anti-Rabbit IgG (H+L)	polyclonal	1:2000 1:5000	Invitrogen
Peroxidase-conjugated AffiniPure Goat anti- Mouse IgG (H+L)	polyclonal	1:2000 1:5000	Jackson ImmunoResearch Laboratories

2.2 Methods

2.2.1 Cultivation of cells

2.2.1.1 Cultivation of *Escherichia coli*

Escherichia coli strains were grown in 5 mL Lysogeny Broth (LB) medium (1 % (w/v) bacto-tryptone, 0.5 % (w/v) yeast extract, 1 % (w/v) NaCl, for solid medium: 2 % (w/v) agar) on a rotation shaker (Infors AG) at 37 °C overnight (Bertani, 1951). In this study, the *Escherichia coli* strain DH5 α was used for general cloning procedures and purification of plasmid DNA. To select the colonies harboring the plasmid of interest, 100 μ g/mL of ampicillin (Carl Roth GmbH & CO. KG) was added to LB medium. Solid LB media contained 2 % agar (Carl Roth GmbH & CO. KG).

2.2.1.2 Cultivation of *Saccharomyces cerevisiae*

Saccharomyces cerevisiae strains were cultivated in 10 mL YEPD medium (2 % (w/v) bacto-peptone, 1 % (w/v) yeast extract, 2 % (w/v) glucose, for solid medium: 2 % (w/v) agar) at

30 °C on a rotation shaker (Fröbel Labortechnik GmbH) overnight. On solid YEPD medium *Saccharomyces cerevisiae* strains were cultivated at 30 °C for two to three days. In this study, strains BY4741 (EUROSCARF) and $\Delta yhb1$ (5887-EUROSCARF) were used. For cultivation of the $\Delta yhb1$ strain, 200 µg/mL G418 (Geneticin® Selective Antibiotic, Thermo Fisher Scientific) was added to YEPD medium. After transformation, plasmid carrying strains were selected in Synthetic Complete (SC) medium (0,15 % (w/v) YNB-aa-as (yeast nitrogen base w/o AA and AS), 0.5 % (w/v) ammonium sulfate, 0.2 mM inositol, 0.2 % (w/v) amino acid powder mix, for liquid medium: 2 % (w/v) raffinose, for solid medium: 2 % (w/v) glucose, 1.5 % (w/v) agar) supplemented with appropriate amino acids (Guthrie and Fink, 1991). Transformants harboring α Syn constructs were selected in SC medium lacking uracil (SC-Ura). For growth of cells co-expressing α Syn with *YHB1* or *NGB*, SC medium lacking uracil and histidine (SC-Ura-His) was used. As carbon source SC medium contained either 2 % raffinose / 2 % glucose for growth without α Syn induction or 2 % galactose to induce the *GAL1*-promoter of α Syn. Expression of α Syn was induced for five hours by shifting overnight cultures from 2 % raffinose- to 2 % galactose-containing medium at an OD₆₀₀ of 0.1. Cell growth was controlled by measuring the optical density at 600 nm using the T80 UV/VIS spectrometer (PG Instruments Ltd).

2.2.1.3 Cell storage

For long-term storage *Escherichia coli* and *Saccharomyces cerevisiae* strains were stored at -80 °C in 1.8 mL CryoPure Tubes (Sarstedt AG & Co). To prevent freezing damage, *Escherichia coli* cells were mixed with 50 % (v/v) glycerol (Carl Roth GmbH & CO. KG). For storage of *Saccharomyces cerevisiae*, cells were mixed with 15 % (v/v) glycerol.

2.2.2 Nucleic acid methods

2.2.2.1 Purification of DNA

Linear DNA fragments were purified using the QIAquick Gel Extraction Kit (QIAGEN) according to the manufacturer's instructions. QIAquick Kits contain a silica membrane assembly which binds DNA in high-salt buffer and allows elution of the DNA with water. The purification procedure removes primers, nucleotides, enzymes, mineral oil, salts, agarose, ethidium bromide, and other impurities from DNA samples. To elute DNA from the columns, 30 µL dH₂O was used. The concentration of purified DNA was determined by a NanoDrop ND-1000 spectrophotometer (Peqlab Biotechnologie GmbH). Purified DNA was stored at -20 °C or used for further procedures.

2.2.2.2 Isolation of plasmid DNA from *Escherichia coli*

Escherichia coli colonies containing a plasmid harboring the gene of interest were grown in 5 mL LB medium supplemented with 100 µg/mL of ampicillin at 37 °C overnight. Cells were collected by centrifugation at 13 000 rpm for one minute in a benchtop centrifuge (Biofuge pico, Heraeus) and plasmid DNA was isolated using the QIAprep Spin Miniprep Kit (QIAGEN) according to the manufacturer's advice. For elution of DNA from the columns, 30 µL dH₂O was used. After purification, DNA concentration was determined by a NanoDrop ND-1000 spectrophotometer (Peqlab Biotechnologie GmbH). Purified plasmid DNA was stored at -20 °C or used for further procedures.

2.2.2.3 Isolation of genomic DNA from *Saccharomyces cerevisiae*

Isolation of yeast genomic DNA was performed according to standard procedures (Hoffman and Winston, 1987). *Saccharomyces cerevisiae* cells were grown in 10 mL YEPD medium at 30 °C overnight. After harvesting the cells by centrifugation at 3000 rpm for three minutes, the cell suspension was washed in 1 mL TE buffer (10 mM Tris-HCl [pH 8.0], 1 mM EDTA [pH 8.0]). Afterwards, 200 µL breaking buffer (2 % (v/v) triton X-100, 1 % (w/v) SDS, 100 mM NaCl, 10 mM Tris-HCl [pH8.0], 1 mM EDTA [pH8.0]) together with 200 µL of phenol:chloroform:isoamyl-alcohol (25:24:1) and 0.25-0.5 mm glass beads were added to the cell precipitates. Cells were broken by mechanical agitation at 4 °C for 10 minutes using a vortex mixer (Vortex-Genie 2, Scientific Industries Inc) and centrifuged at 13 000 rpm at 4 °C for five minutes. For DNA precipitation, the supernatant was collected and mixed with 1 mL cold ethanol (96 %). After short centrifugation, the precipitates were incubated with 400 µL TE buffer and 3 µL RNase (10 mg/mL, Roche) to a final concentration of 75 µg/mL at 37 °C for 50 minutes. Thereafter, 1 mL cold ethanol (96 % (v/v)) was added and the samples were centrifuged at 13 000 rpm for five minutes. After discarding the supernatant, the DNA precipitate was additionally centrifuged at 13 000 rpm for 30 seconds and dried at room temperature. Finally, genomic DNA was dissolved in 50 µL TE buffer and verified by agarose gel electrophoresis.

2.2.2.4 DNA agarose gel electrophoresis

Analytical and preparative separation of DNA fragments was performed using DNA agarose gel electrophoresis (Lee et al., 2012). During this procedure, lower molecular weight nucleic acids migrate faster through the gel than larger fragments. Thereby, DNA size can be estimated. For DNA agarose gel electrophoresis, 1 % agarose gel (1 % (w/v) agarose, 0.001 mg/mL ethidium bromide) was prepared in TAE buffer (40 mM Tris base, 20 mM acetic

acid, 1 mM EDTA). For subsequent visualization of DNA, the gel was supplemented with ethidium bromide to a final concentration of 0.001 mg/mL. The samples were mixed with 6x DNA loading dye (10 % (v/v) ficoll typ 400, 0.25 % (w/v) bromophenol blue, 0.25 % (w/v) xylene cyanol ff, 200 mM EDTA [pH 8.0]) and separated until the bromophenol blue band reached the last third of the gel. As size standard, the GeneRuler 1kb DNA ladder (250 to 10 000 bp, Thermo Fisher Scientific) was loaded onto the gel. The separation was performed in a Mini-Sub Cell GT chamber (Bio-Rad Laboratories) using Bio-Rad Powerpac 300 power supply (Bio-Rad Laboratories) in an electric field at 90 V in TAE buffer. Afterwards, UV light with 254 nm was applied to detect the DNA and a photograph was taken using a gel documentation imager (Gel iX20 Imager Windows Version, Intas Science Imaging Instruments GmbH).

2.2.2.5 DNA isolation from agarose gels

For purification of DNA fragments from a DNA mixture, the fragments were separated according to their length by agarose gel electrophoresis. Then, the desired fragment was excised from the gel and purified using the QIAquick Gel extraction Kit (QIAGEN). This purification method depends on the ability of DNA to bind to silica membranes. After elution of DNA fragments in 30 μ L dH₂O from the column, the fragments were stored at -20 °C or used for further procedures.

2.2.2.6 Polymerase chain reaction (PCR)

PCR is a technique to amplify specific DNA *in vitro*, which allows the amplification of DNA fragments with partly known sequences (Saiki et al., 1988). The polymerase chain reaction is based on two specific oligonucleotides which anneal to the 5' ends of DNA fragment of interest. Next, the DNA polymerase binds to the oligonucleotides and synthesizes the complementary strand. The oligonucleotides used for PCR reactions were purchased from Sigma-Aldrich (St. Louis, USA) and are listed in Table 3. For cloning reactions the high fidelity DNA polymerase *Phusion* High-Fidelity DNA Polymerase (Thermo Fisher Scientific) was required which exhibits a 3' \rightarrow 5' exonuclease activity. Due to its proof reading function, an accurate oligonucleotide extension reaction with very low error rate can be obtained. Temperature of annealing depends on the melting temperature of used oligonucleotides. Usually, the annealing temperature is 5 °C below the melting temperature. Chromosomal DNA or plasmid DNA was used as template DNA. The polymerase chain reaction was performed in a Thermo cycler (MWG Biotech Inc Primus 96 Thermal Cycler, MWG-Biotech). An example for a *Phusion* reaction mix and PCR program is listed in Table 9 and 10.

Table 9. Reaction mix for *Phusion* DNA polymerase

Component	50 μ L Reaction	Final concentration
5x HF buffer	10 μ L	1 x
dNTP mix	1 μ L	200 μ M each
Primer 1	1 μ L	0.2 μ M
Primer 2	1 μ L	0.2 μ M
Template DNA	x μ L	300-500 ng
DMSO	1.5 μ L	3 %
<i>Phusion</i> DNA polymerase	0.5 μ L	0.02 U/ μ L

Table 10. PCR program for *Phusion* DNA polymerase

Cycle step	Temperature	Time	Cycles
Denaturation	98 °C	3 min	1
Denaturation	98 °C	30 sec	30
Annealing	T _m -5 °C	30 sec	30
Elongation	72 °C	15-30 sec/kb	30
Final extension	72 °C	10 min	1
Pause	4 °C	∞	1

If the amplified DNA fragments were required for analytical PCR reaction, the thermostable *Taq* polymerase (Thermo Fisher Scientific) was applied. This DNA polymerase lacks a proof reading function leading to higher error prone oligonucleotides extension. For analytical PCR reaction, the transformants were used as DNA template. Thereby, clones can be tested for the correct integration of DNA fragments into a vector. The colonies to be analyzed were picked from a plate and resuspended in 25 μ L PCR reaction mix. Positive colonies were isolated using the QIAprep Spin Miniprep Kit (QIAGEN) and used for subsequent investigation in yeast. An example for a *Taq* reaction mix and PCR program is listed in Table 11 and 12.

Table 11. Reaction mix for *Taq* DNA polymerase

Component	25 μ L Reaction	Final concentration
10x <i>Taq</i> DNA polymerase buffer	2.5 μ L	1 x
dNTP mix	1 μ L	200 μ M each
Primer 1	1 μ L	0.4 μ M
Primer 2	1 μ L	0.4 μ M
<i>Taq</i> DNA polymerase	1 μ L	0.04 U/ μ L
Mg ₂ SO ₄	3 μ L	3 mM

Table 12. PCR program for *Taq* DNA polymerase

Cycle step	Temperature	Time	Cycles
Denaturation	95 °C	3 min	1
Denaturation	95 °C	30 sec	30
Annealing	T _m -5 °C	30 sec	30
Elongation	72 °C	1 min/kb	30
Final extension	72 °C	10 min	1
Pause	4 °C	∞	1

2.2.2.7 Digestion of DNA

Restriction enzymes purchased from Thermo Fisher Scientific were used to digest DNA molecules according to the manufacturer's instructions. Restriction enzymes cut DNA fragments at specific recognition sequences. PCR amplified DNA fragments and plasmid DNA were digested with the appropriate restriction enzymes. Usually, 10 U enzyme was used per 3-6 µg DNA. Final volume of 30 µL reaction mixture was incubated in corresponding reaction buffer at 37 °C for two to four hours. Afterwards, digested DNA fragments were purified from the digestion mixture using the QIAquick Gel extraction Kit (QIAGEN).

2.2.2.8 Ligation of DNA

T4 DNA ligase (Thermo Fisher Scientific) was used for ligation of linearized vector and the respective insert. In presence of ATP, it catalysis the formation of phosphodiester bond between 3'-OH and a 5'-PO₄ ends of nucleic acids. For ligation, 100 or 300 ng of the prepared vector DNA and a threefold number of insert DNA was used. Ligation was carried out in T4 ligase buffer (Thermo Fisher Scientific) using 2 µL T4 DNA ligase (2 U) in a final volume of 20 µL at 16 °C overnight. Subsequently, 1 µL of ligation mix was used for transformation into *Escherichia coli* DH5α strains and incubated on selective LB plates containing 100 µg/mL ampicillin at 37 °C overnight. Alternatively to T4 DNA ligation, the GeneArt® Seamless Cloning and Assembly Enzyme Mix (Invitrogen) was used to assemble DNA fragments. For assembly reaction, 100 ng linearized vector DNA was mixed with 200 ng insert DNA and 4 µL of 5x reaction buffer. After adjusting the total volume of 20 µL with dH₂O, 1 µL of 10x enzyme mix was added to the reaction mixture and incubated at room temperature for 30 minutes. Finally, 8 µL of ligation mix was transformed into *Escherichia coli* DH5α strains and incubated on selective LB plates containing 100 µg/mL ampicillin at 37 °C overnight. In order to verify successful integration of the insert into the vector, plasmid DNA

was isolated using the QIAprep Spin Miniprep Kit (QIAGEN) and sequenced as described in section 2.2.2.10.

2.2.2.9 Quick change site-directed mutagenesis

The quick change site-directed mutagenesis system was used to modify amino acids in proteins. This method is based on PCR amplification allowing introduction of multiple mutations, deletions and insertions into genes *in vitro* (Wang and Malcolm, 1999). Thereby, one pair of complementary oligonucleotide primer containing the mutation of interest introduces the mutation during a PCR amplification process. The mutagenic oligonucleotide primers used in this method were designed individually according to the desired mutation. Both 5'-phosphorylated mutagenic primers should be 25 to 45 bases in length with melting temperature above or equal to 78 °C. The desired mutagenic section should be located at the middle of the primer and flanked on both sides by stretches of 10 to 20 bases complementary to the template DNA. Importantly, the amplification of target DNA was carried out using the thermostable high fidelity *PfuTurbo Cx* hotstart DNA polymerase (Agilent Technologies), which replicates target DNA without displacing the mutagenic primers. For this study, plasmid DNA containing the gene of interest was used as template DNA. An example for a quick change site-directed mutagenesis reaction mix and PCR program is listed in Table 13 and 14.

Table 13. Reaction mix for *PfuTurbo Cx* hotstart DNA polymerase

Component	50 μ L Reaction	Final concentration
10x <i>PfuTurbo Cx</i> reaction buffer	5 μ L	1 x
methylated plasmid DNA	x μ L	300-500 ng
mutagenic primer 1	1 μ L	0.2 μ M
mutagenic primer 2	1 μ L	0.2 μ M
dNTP mix	1 μ L	200 μ M each
DMSO	1.5 μ L	3 %
<i>PfuTurbo Cx</i> hotstart DNA polymerase	1 μ L	0.05 U/ μ L

Table 14. PCR program for *PfuTurbo Cx* hotstart DNA polymerase

Cycle step	Temperature	Time	Cycles
Denaturation	95 °C	5 min	1
Denaturation	95 °C	30 sec	20
Annealing	60 °C	1 min	20
Elongation	68 °C	60 sec/kb	20
Final extension	68 °C	10 min	1
Pause	4 °C	∞	1

Afterwards, the PCR product was purified by the QIAquick Gel extraction Kit (QIAGEN). In order to remove parental DNA template and to select for mutation-containing synthesized DNA, 2 μ L of *DpnI* endonuclease (20 U) and 2 μ L Tango buffer (Thermo Fisher Scientific) was directly added to 16 μ L mutagenesis reaction and incubated at 37 °C for two hours. This restriction enzyme specifically digests methylated DNA. DNA isolated from *Escherichia coli* strains is commonly methylated, therefore, the synthesized DNA is susceptible to *DpnI* digestion. As control for effective elimination of parental DNA template reaction, one reaction mix was simultaneously incubated lacking *DpnI* restriction enzyme. Subsequently, 15 μ L of digested reaction mix was transformed into *Escherichia coli* DH5 α strains and incubated on selective LB plates containing 100 μ g/mL ampicillin at 37 °C overnight. In order to verify mutated genes, plasmid DNA was isolated using the QIAprep Spin Miniprep Kit (QIAGEN) and sequenced as described in section 2.2.2.10.

2.2.2.10 Sequencing of DNA

All DNA constructs used for this work were verified by the Göttingen Genomics Laboratory (G2L, Göttingen, Germany) or the SeqLab-Microsynth GmbH (Göttingen, Germany) using the Sanger Cycle Sequencing method (Sanger et al., 1992). For each G2L sequencing reaction 300 ng plasmid DNA purified by the QIAprep Spin Miniprep Kit (QIAGEN) was mixed with 1 μ L of respective sequencing primer (5 pmol) and adjusted to a final volume of 5 μ L. Annealing temperature was chosen between 53 °C and 60 °C according to the length and nucleotide composition of sequencing primer. For each DNA sample sequenced by the SeqLab test laboratory 1200 ng plasmid DNA in a volume of 12 μ L was mixed with 3 μ L of respective sequencing primer (30 pmol). The received sequences were analyzed using the Chromas 2.3.0.0 software (Technelysium Pty Ltd) and the multiple sequence align tool MultAlin (Corpet, 1988). Yeast chromosomal sequences were obtained from the SGD (*Saccharomyces* genome database) website (www.yeastgenome.org) (Cherry et al., 2012).

2.2.3 Transfer of DNA

2.2.3.1 Transformation of plasmid DNA into *Escherichia coli*

Plasmid DNA was transformed into *Escherichia coli* performing the heat shock method (Inoue et al., 1990). For transformation, 100 μ L competent DH5 α *Escherichia coli* cells were thawed for 20 minutes on ice and mixed with 0.5 μ g of the desired plasmid DNA or 10 μ L of ligation reaction. To allow annealing of plasmid DNA to the cell envelope of *Escherichia coli* cells, the mixture was incubated for 10 minutes on ice. Afterwards, the cells were heated at 42 °C for 90 seconds and stored on ice for five minutes. Thereby, the cells take up the

plasmid DNA. After transformation, cells were supplemented with 1 mL LB medium and recovered at 37 °C for 45 minutes. Finally, 100 µL cell suspension was transferred to LB plates containing the respective antibiotics to select for transformants containing the desired plasmid DNA. For sufficient transformation yield, remaining cell suspension was centrifuged at 13 000 rpm in a benchtop centrifuge (Biofuge pico, Heraeus) for one minute and the supernatant was decanted. The precipitate was resuspended in 100 µL LB medium and plated on another LB plate. After incubation overnight at 37 °C, the colonies were analyzed by PCR and sequencing as described in section 2.2.2.6 and 2.2.2.10.

2.2.3.2 Transformation of plasmid DNA into *Saccharomyces cerevisiae*

Transformation of plasmid DNA into *Saccharomyces cerevisiae* cells was performed by the LiAc/SS Carrier DNA/PEG method (Ito et al., 1983). In this technique, alkali cations treated yeast cells take up plasmid DNA after heat pulse in the presence of polyethylene glycol. For transformation, 800 µL of an overnight culture grown in 10 mL YEPD medium at 30 °C was used to inoculate 10 mL YEPD medium and incubated at 30 °C on a rotation shaker (Fröbel Labortechnik GmbH) for five hours. Afterwards, the total cell culture was harvested by centrifugation at 3000 rpm for three minutes using the centrifuge 5804R (Eppendorf AG). The cell precipitate was repeatedly washed with 10 mL, 5 mL and 2 mL of LiOAc/TE buffer (100 mM LiOAc, 1 mM Tris-HCL [pH 8.0], 0.1 mM EDTA [pH 8.0]) and dissolved in 400 µL LiOAc/TE buffer. From now on, the yeast cells are competent for transformation. 50 µL of cell suspension was mixed with 5 µL SS carrier DNA (single stranded salmon sperm DNA), 800 µL of 50 % polyethylene glycol 4000 (PEG 4000, Carl Roth GmbH & CO. KG) dissolved in LiOAc/TE buffer and 2.5 µL plasmid DNA. After incubation of the transformation mixture at 30 °C for 30 minutes, cells were exposed to heat shock at 42 °C for 25 minutes. After centrifugation at 13 000 rpm for one minute, the cell precipitate was resuspended in 1 mL YEPD medium and incubated at 30 °C for one hour. Subsequently, cells were collected by centrifugation at 13 000 for one minute, the supernatant was discarded and the remaining cell suspension was transferred on solid SC medium which lacks the appropriate amino acid to select for colonies carrying the plasmid with corresponding auxotrophic marker. After two to three days cultivation at 30 °C, colonies were restreaked on new solid SC medium to select for colonies carrying the desired plasmid.

2.2.4 Protein methods

2.2.4.1 Production of crude extracts of yeast cells

The strains to be analyzed were grown in 10 mL SC medium containing the respective amino acids and 2 % raffinose at 30 °C overnight. For induction of the *GAL1*-promoter, the overnight culture was centrifuged at 3000 rpm for three minutes and the cell precipitate was used to inoculate 10 mL SC medium containing 2 % galactose. The cultures were rotative grown at 30 °C for five hours. Afterwards, the samples were stored for 10 minutes on ice and centrifuged at 3000 rpm for one minute at 4 °C. The cell precipitate was then washed with 1 mL TE buffer (10 mM Tris-HCl [pH 8.0], 1 mM EDTA [pH 8.0]) and dissolved in 200 μ L buffer R (50 mM Tris-HCl [pH 7.5], 1 mM EDTA [pH 8.0], 50 mM DTT, 6 μ L/mL protease inhibitor (1 Cocktail Tablet in 1 mL dH₂O), 100 μ L/mL phosphatase inhibitor (1 Cocktail Tablet in 1 mL dH₂O), 1 mM NaF, 8 mM β -glycerol phosphate, 0.5 mM Na₃VO₄). Additionally, the same amount of 0.25-0.5 mm glass beads was added to the mixture. In order to break the cells, the samples were vigorously shaken at 4 °C using a vortex mixer (Vortex-Genie 2, Scientific Industries Inc) for 10 minutes. Subsequently, the suspension was centrifuged at 13 000 rpm for one minute at 4 °C and the crude cell extract was obtained by collecting the supernatant. After determination of the protein concentration by the Bradford assay (Bradford, 1976), the protein samples were resuspended in 6x sample buffer (250 mM Tris-HCl [pH 6.8], 15 % (v/v) β -mercaptoethanol, 7 % (w/v) SDS, 30 % (v/v) glycerol, 0.3 % (w/v) bromophenol blue) and boiled at 95 °C for 10 minutes. In order to analyze the isolated protein extracts, the samples were loaded onto a SDS polyacrylamide gel and separated by electrophoresis as described in section 2.2.4.5.

2.2.4.2 Determination of protein concentration

The protein content of a sample was determined by the Bradford protein concentration assay which is based on the proportional binding of Coomassie dye to proteins (Bradford, 1976). Thereby, the protein concentration is quantified by comparison to that of a series of known protein standards. In this study, BSA (Albumin Fraktion V, AppliChem GmbH) was used as protein reference. In order to exhibit a linear calibration line, 2 μ L, 5 μ L, 10 μ L, 15 μ L, 20 μ L and 40 μ L of 1 mg/mL BSA solutions were added to 990 μ L of 1:5 diluted Bradford reagent (Roti®-Quant, Carl Roth GmbH & CO. KG) and incubated for five minutes at room temperature. Subsequently, extinction was measured at 595 nm using a light absorption photometer (T80 UV/VIS spectrometer, PG Instruments Ltd). The same procedure was performed with 10 μ L of the protein sample of interest in 990 μ L of 1:5 diluted Bradford reagent. On the basis of the linear calibration line, the protein concentration was calculated.

Alternatively, protein concentration was determined using a microplate reader (Infinite® M200, Tecan Group). Here, 200 μL of 1:5 diluted Bradford reagent was mixed with 5 μL of 1:10 or 1:100 diluted protein sample and measured at 595 nm after five minutes incubation. For standard curve, 0 μL , 1 μL , 2 μL , 5 μL , 10 μL and 20 μL of 1 mg/mL BSA solution was used with 200 μL of 1:5 diluted Bradford reagent. All samples were prepared in triplicates.

2.2.4.3 Ni²⁺-NTA affinity chromatography

Purification of HIS₆-tagged recombinant proteins expressed in *Saccharomyces cerevisiae* was performed using the Ni²⁺-NTA affinity chromatography (Porath et al., 1975). This technique is based on the high binding affinity of nickel ions to histidine residues. Thereby, immobilized nickel ions of nickel-nitrilotriacetic acid beads (Ni²⁺-NTA) located on a highly crosslinked agarose matrix bind to HIS-tagged proteins and retain them until elution by competition with imidazole. At first, a HIS₆-tag was fused to the C-terminus of the protein of interest and cloned into the desired plasmid. After verification of effective cloning, the constructs were transformed into yeast strains of interest and selected on selective SC medium. Cells cultured overnight in 200 mL selective SC liquid medium supplemented with 2 % glucose were collected by centrifugation at 4000 rpm for 20 minutes using the centrifuge 5804R (Eppendorf AG) and washed with 5 mL dH₂O. The total cell precipitate was used to inoculate 1.5 L YEPD medium containing 2 % galactose. After 12 hours induction of αSyn expression at 30 °C, cells were harvested by centrifugation at 4000 rpm for 20 minutes at 4 °C in the Sorvall RC-3B Plus Refrigerated Centrifuge (Thermo Fisher Scientific) and lysed by 25 mL 1.85 M NaOH containing 7.5 % β -mercaptoethanol on ice for 10 minutes. To precipitate the protein crude extract, 25 mL 50 % trichloroacetic acid (TCA, Carl Roth GmbH & CO. KG) were added to the cell lysate and incubated on ice for 30 minutes. After centrifugation at 4000 rpm for 15 minutes at 4 °C, the precipitate was washed with 25 mL of 100 % acetone and resuspended in 25 mL buffer A (6 M guanidine HCl, 100 mM sodium phosphate buffer [pH 8.0], 10 mM Tris-HCl [pH 8.0]). Then, the mixture was rotated at 25 °C for at least one hour and again centrifuged as described above. The collected supernatant was calibrated by 1 M Tris [pH 8.5] to pH 7.0 and supplemented with imidazole (AppliChem GmbH) to reach the total concentration of 20 mM. For column preparation, 1 mL of Ni²⁺-NTA agarose (Qiagen) was added into a Poly-Prep® Chromatography Column (Bio-Rad Laboratories). After equilibration with 5 mL of buffer A containing 20 mM imidazole, the protein crude extracts were applied to the columns. Afterwards, the columns were washed with 10 mL buffer A containing 20 mM imidazole and equilibrated with 5 mL buffer B (8 M urea, 100 mM sodium phosphate buffer [pH 6.3], 10 mM Tris-HCl [pH 6.3]). Elution of the HIS₆-tagged protein was carried out using four times 1 mL of 200 mM imidazole resolved in

buffer B. Thereby, imidazole rings bind to the nickel ions and disrupt the binding of histidine residues. The protein content of the elution fractions was determined by Bradford protein concentration assay. Afterwards, the protein samples were resuspended in 6x sample buffer and boiled for 10 minutes at 95 °C. The protein samples were stored at -80 °C or subjected to immunoblot analysis (2.2.4.6). To reuse the columns, they were first washed with 20 mL dH₂O followed by 10 mL 0.2 M NaOH and another washing step with 20 mL dH₂O. After equilibration of the columns by 5 mL buffer A, they were stored in ethanol (20 % (v/v)).

2.2.4.4 Trichloroacetic acid protein precipitation

2,2,2-trichloroacetic acid (TCA) is widely used for precipitating soluble proteins from an aqueous solution. TCA triggers protein precipitation by inducing hydrophobic aggregation (Sivaraman et al., 1997). For TCA protein precipitation, 100 % TCA solution (500 g TCA in 350 mL dH₂O) was added to the protein sample with a ratio of 1:4 and incubated at 4 °C for 10 minutes. After centrifugation at 13 000 rpm for five minutes at 4 °C, the supernatant was discarded and the protein precipitate was washed with cold acetone. Next, the protein precipitate was centrifuged at 13 000 rpm for five minutes at 4 °C and the washing step was repeated. The precipitate was dried at 95 °C for five minutes and dissolved in 2x sample buffer. After heating the protein precipitates at 95 °C for 10 minutes, the samples were stored at -80 °C or used for further procedures.

2.2.4.5 Discontinuous SDS-polyacrylamide gel electrophoresis (SDS-PAGE)

SDS-PAGE is an electrophoretic technique which is used to separate proteins by their molecular mass (Laemmli, 1970). The charge of proteins as well as the three dimensional fold is superimposed by the addition of SDS which denatures the proteins and mediates a strong negative charge. Due to this effect, the proteins are separated by mass and not by charge. The vertical SDS gel used for protein separation is composed of a stacking and a separation gel. The stacking gel contains 5 % polyacrylamide and allows fast migration of the proteins until the separation gel containing 12 % polyacrylamide is reached. This concentration is suitable for separation of proteins of medium size. First, the separation gel (2.5 mL 1.5 M Tris-HCl / 0.4 % (w/v) SDS [pH 8.8], 3.5 mL dH₂O, 4 mL acrylamide solution [30 % acrylamide, 0.8 % bisacrylamide], 30 µL APS [10 % (w/v)], 15 µL TEMED) was poured and covered with isopropanol. After the separation gel was completely polymerized, the isopropanol was removed and the stacking gel (1.5 mL 500 mM Tris-HCl / 0.4 % (w/v) SDS [pH 6.8], 3.9 mL dH₂O, 0.6 mL acrylamide solution [30 % acrylamide, 0.8 % bisacrylamide], 40 µL APS [10 % (w/v)], 20 µL TEMED) was poured on top of the separation gel. According

to the volume of the samples, 1 mm or 1.5 mm 10-well comb was inserted into the stacking gel. Before the protein samples were loaded onto the gel, they were mixed with 6x sample buffer and denatured at 95 °C for 10 minutes. Electrophoresis was performed in running buffer (25 mM Tris base, 250 mM glycine, 0.1 % (w/v) SDS) using the Mini-PROTEAN® 3 Cell and the Bio-Rad Powerpac 300 power supply (Bio-Rad Laboratories) at 100 V until the samples reached the separation gel. Thereafter, the electric current was raised to 200 V and electrophoresis was performed until the blue band of the 6x sample buffer ran out of the gel. PageRuler Prestained Protein Ladder (10 to 180 kDa, Thermo Fisher Scientific) was used as size standard to monitor separation of the proteins.

2.2.4.6 Protein immunoblotting

The protein immunoblotting technique is used to identify individual proteins in a protein mixture by specific recognition of antigens by antibodies on a carrier membrane. The proteins were first separated by discontinuous SDS-polyacrylamide gel electrophoresis and afterwards transferred electrophoretically on a nitrocellulose membrane (Amersham™ Protran™ 0.45 µm NC, GE Healthcare) or polyvinylidene difluoride (PVDF) membrane (Amersham™ Hybond-P™ 0.45 µm PVDF, GE Healthcare), respectively (Towbin et al., 1979). The transfer was performed in transfer buffer (25 mM Tris base, 192 mM glycine, 0.02 % (w/v) SDS) with 20 % methanol using a Mini Trans-Blot® Electrophoretic Cell (Bio-Rad Laboratories). Due to the prior treatment with SDS, the proteins have a strong negative charge. By applying an electric current of 100 V to the blotting device for 1.5 hours, the proteins migrate towards the anode, which allows the transfer to the membrane. A schematic assembly of an immunoblot transfer stack is shown in Figure 5.

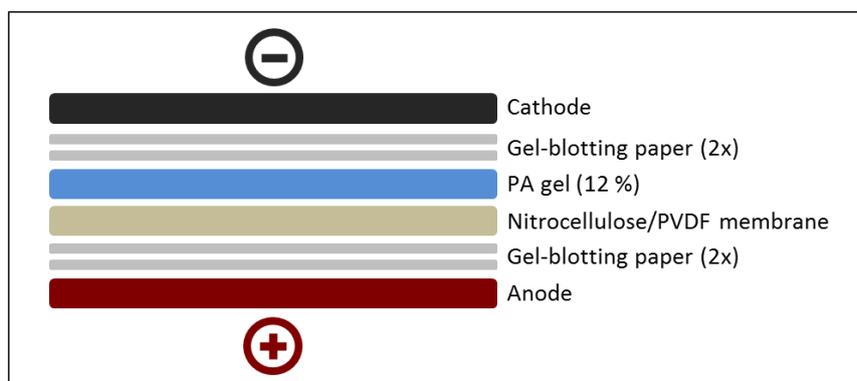

Figure 5. Schematic assembly of an immunoblot device.

For immunoblotting using tank transfer system, the polyacrylamide gel and the nitrocellulose membrane are placed between two layers of gel-blotting papers (Schleicher and Schuell BioScience GmbH) that have to be soaked in transfer buffer before the stack is assembled. The electric current moves from the cathode to the anode. In this way, proteins are transferred from the polyacrylamide gel to the membrane.

As soon as the proteins were transferred to the membrane, they could be visualized with specific antibodies. In order to achieve this, membrane was shaken after blotting in TBST buffer (10 mM Tris-HCl [pH 8.0], 150 mM NaCl, 0.05 % (v/v) tween-20) containing 5 % milk powder for at least one hour. Thereby, the free binding sites of the membrane are blocked to avoid binding of the antibody directly to the membrane. Next, a primary antibody, diluted in TBST buffer with 5 % milk powder, was incubated with the membrane overnight. Primary and secondary antibodies that were used in this study are listed in Table 7 and 8. Subsequently, the membrane was washed with TBST buffer three times for 20 minutes. The second antibody, which specifically binds to the first antibody and is conjugated to horseradish peroxidase, was diluted 1:2000 or 1:5000 in TBST buffer with 5 % (w/v) milk powder and incubated with the membrane for one hour. After removing the unbound antibody by washing the membrane as described before, the proteins were detected using the Enhanced Chemiluminescence (ECL) technology. For that an ECL solution was prepared by mixing ECL solution 1 (1 mL 1 M Tris [pH 8.5], 9 mL dH₂O, 45 µL paracoumaric acid [400 mM in DMSO], 100 µL luminol [250 mM in DMSO]) with ECL solution 2 (1 mL 1 M Tris [pH 8.5], 9 mL dH₂O, 6.2 µL H₂O₂). The ECL solution was immediately casted onto the membrane and incubated for two minutes. Hereby, the enzymatic reaction of the horseradish peroxidase was started. This enzyme catalyzes the transfer of electrons from H₂O₂ to the luminol substrate which is thereby converted to a light releasing substance. The membrane was then covered in foil and exposed in the dark to Amersham™ Hyperfilm™- ECL (GE Healthcare) in time periods of several seconds and minutes leading to chemiluminescence signals visualized on the film. For the hybridization of the anti-nitrotyrosine antibody, the proteins were transferred to a PVDF membrane. Before electrophoretic blotting, the PVDF membrane had to be activated by methanol for 15 seconds. The following procedure was performed as described above. Detected bands were quantified using the Java-based image processing software ImageJ (Wayne Rasband, National Institutes of Health). To remove the antibodies, the membrane was incubated in 10 mL stripping solution (50 mM Tris-HCl [pH 7.0], 2 % (w/v) SDS, 50 mM DTT) at 60 °C for 30 minutes. Afterwards, the membrane was washed in TBST buffer for five minutes and the free binding sites of the membrane were blocked by incubating the membrane in TBST buffer containing 5 % (w/v) milk powder for at least one hour.

2.2.4.7 Staining of proteins with Coomassie brilliant blue R-250

Coomassie brilliant blue R-250 (Serva Electrophoresis GmbH) was used to stain unspecific protein bands on SDS gel (Fairbanks et al., 1971) based on its capability to attach to basic side chains of amino acids. Detection limit of Coomassie dye amounts of 100 ng per protein

band. Therefore, proteins separated on SDS gel were fixated for two hours in the fixation solution (40 % (v/v) ethanol, 10 % (v/v) acetic acid) and washed in H₂O for one minute. The gel was then incubated overnight with Coomassie stain solution (50 % (v/v) methanol, 10 % (v/v) acetic acid, 0.2 % (w/v) Coomassie brilliant blue R-250) and again rinsed in water. To remove background, the gel was incubated in Coomassie destain solution (50 % (v/v) methanol, 10 % (v/v) acetic acid) for at least 30 minutes and washed three times in water for one minute.

2.2.4.8 Silver staining

A more sensitive technique to visualize protein bands on an SDS gel is the silver staining (Blum et al., 1987). In this method, silver ions bind to glutamic acid-, aspartic acid-, and cysteine residues of the proteins which are then reduced to elementary silver by formaldehyde resulting in a dark staining of the protein bands. Detection limit of silver stain is at 1-10 ng per band. The proteins separated on SDS gel were first incubated in fixing solution (40 % (v/v) ethanol, 10 % (v/v) acetic acid) for at least two hours or overnight and then washed three times for 20 minutes in 30 % ethanol. After incubation in 0.02 % sodium thiosulfate for one minute the gel was rinsed three times for 20 seconds with H₂O and incubated in 0.2 % silver-nitrate solution for 20 minutes. The gel was again washed two times with H₂O for 20 seconds and the developing solution (3 % (w/v) sodium carbonate, 0.05 % (v/v) formaldehyde [37 % (v/v)], 0.0004 % (w/v) sodium thiosulfate) was applied on the gel. As soon as the protein bands are visible (~ five minutes), the gel was washed twice with H₂O for one minutes and the reaction was stopped by incubating the gel in 0.5 % glycine for five minutes. Finally, the gel was washed in H₂O for 30 minutes. All procedure steps were performed under shaking.

2.2.4.9 *In vitro* protein nitration with peroxyntirite

In vitro nitration of proteins was carried of using the highly reactive nitrating agent peroxyntirite (PON, Cayman Chemical). Because of its oxidizing ability, the peroxyntirite anion can participate directly in electron oxidation reactions with biomolecules (Lymar and Hurst, 1998). In proteins, tyrosine residues can be nitrated by PON that may alter protein function. For nitration, 20 µL of purified protein was filled into a 50 µL reaction tube. 1 µL of PON was placed into the lid of the reaction tube. Because the reactivity of PON is highly pH-dependent, 1 µL of 0.3 M HCl was additionally placed into the lid. To induce the reaction, the tube was immediately vortexed for approx. 10 seconds. Subsequently, the nitrated protein was subjected to immunoblot analysis.

2.2.5 Liquid chromatography-mass spectrometry

2.2.5.1 In-gel protein digestion with trypsin

Digesting and recovering proteins from stained protein bands excised from polyacrylamide gel were performed using trypsin restriction (Shevchenko et al., 1996). This protein hydrolase cleaves the peptide chain at specific sites. Its property is used to identify proteins by analyzing the resultant peptides using Liquid chromatography-mass spectrometry (LC-MS). In order to prepare proteins of interest for LC-MS, they were separated by 12 % SDS-PAGE and stained with Coomassie dye as described in section 2.2.4.5 and 2.2.4.7. To improve the recovery rate of the samples and to prevent contamination with silicon, detergents and plastic softening agents, low-bind cups (Protein Lobind Tubes, Eppendorf AG) and vinyl gloves were used in all procedure steps. Excised polyacrylamide gel slices of Coomassie stained proteins were digested with the proteases according to the protocol of Shevchenko and supplier's instructions. After excising the target bands from the polyacrylamide gel, 50 μ L acetonitrile were added to the gel fractions and incubated for 10 minutes at room temperature. Next, the supernatant was removed and the polyacrylamide gel slices were dried using a vacuum concentrator (Savant SPD111V SpeedVac concentrator, Thermo Fisher Scientific) at 50 °C for 10 minutes. Then, the samples were incubated with 150 μ L 100 mM ammonium bicarbonate containing 10 mM DTT at 56 °C for one hour. After spinning down the condense water by centrifugation at 13 000 rpm for one minute and decanting the supernatant, the polyacrylamide gel fractions were incubated with 150 μ L 100 mM ammonium bicarbonate containing 55 mM iodoacetamide at room temperature in the dark for 45 minutes. The supernatant was again removed and the samples were incubated with 150 μ L 100 mM ammonium bicarbonate for 10 minutes. Afterwards, the ammonium bicarbonate was changed against 150 μ L acetonitrile and the samples were shaken for 10 minutes. The supernatant was again extracted and the samples were covered with 150 μ L ammonium bicarbonate for 10 minutes. After additional incubation of the gel fractions with acetonitrile as described above, the samples were subjected to a drying step in the vacuum concentrator at 50 °C for 10 minutes. After that, the polyacrylamide gel slices were covered by approx. 50 μ L trypsin digestion buffer (Serva Trypsin (Serva Electrophoresis GmbH) in 25 mM ammonium bicarbonate (1:2.5)) and digested on ice for 45 minutes. Subsequently, the trypsin containing solution was discarded, the samples were covered by approx. 50 μ L of 25 mM ammonium bicarbonate [pH 8.0] and incubated at 37 °C overnight. After centrifugation at 13 000 rpm for one minute, the supernatant was collected and the gel slices were incubated in 50 μ L 20 mM ammonium bicarbonate for 10 minutes. After centrifugation as described before, the supernatant was again gathered and the gel slices were incubated for 20 minutes in 50 μ L 50 % acetonitrile containing 5 % formic acid. The samples were

centrifuged at 13 000 rpm for one minute and the supernatant was again collected. Acetonitrile/formic acid extraction was repeated twice. Finally, the united supernatant was humidified using the vacuum concentrator at 50 °C and stored at room temperature.

2.2.5.2 In-solution protein digestion with Asp-N

Trypsin digested α Syn peptides were additionally digested by Asp-N to obtain appropriate peptides for LC-MS. For double digestion, α Syn peptides were digested by trypsin as described in section 2.2.5.1. Afterwards, humidified peptides were dissolved in 30 μ L 100 mM ammonium bicarbonate [pH 8.0] and incubated with Asp-N (1:100, Sigma-Aldrich) at 37 °C overnight. Finally, the peptides were humidified using the vacuum concentrator at 50 °C and stored at room temperature.

2.2.5.3 C18 StageTip purification

Before performing analysis by LC-MS, the peptide mixture was purified by the C18 StageTip purification method using self-made C18 stop-and-go-extraction tips (C18 StageTips) (Rappsilber et al., 2007). During this procedure, peptides are enriched and purified from urea, salts and other contaminants through binding to reversed-phase material (C18) and eluted in organic solution. StageTips were prepared by placing a small portion of C18 material in a pipette tip. For equilibration, 100 μ L methanol containing 0.1 % (v/v) formic acid was added into the StageTips and centrifuged at 13 000 rpm for two minutes. After discarding the flow through, 100 μ L of 70 % (v/v) acetonitrile containing 0.1 % (v/v) formic acid was added and centrifuged at 13 000 rpm for two minutes. After the flow through was discarded, the 100 μ L dH₂O containing 0.1 % (v/v) formic acid was added and centrifuged at 13 000 rpm for two minutes. The flow through was discarded and the StageTip equilibration was completed by repeating the last step. Humidified peptides were resolved in 20 μ L of 2 % (v/v) acetonitrile containing 0.1 % (v/v) formic acid and incubated in an ultrasonic bath (Bandelin Sonorex™ Digital 10 P ultrasonic bath, Bandelin electronic GmbH & Co. KG) at 35 °C at maximum power for three minutes. The peptide mixtures were loaded onto the StageTips, centrifuged at 1000 rpm for five seconds and incubated for five minutes at room temperature. Afterwards, the peptide samples were centrifuged at 4000 rpm for five minutes and the flow through was reloaded onto the StageTips and centrifuged at 4000 rpm for five minutes. Next, the flow through was discarded and the columns were washed twice with 100 μ L dH₂O containing 0.1 % (v/v) formic acid by centrifugation at 10 000 rpm for two minutes. After the StageTips were transferred into a low-bind cup, 60 μ L acetonitrile containing 0.1 % (v/v) formic acid was added and incubated for five minutes at room

temperature. Finally, the StageTips were centrifuged for five minutes at 4000 rpm and the peptides were humidified using the vacuum concentrator at 50 °C. In order to prepare the resultant protein fragments for mass spectrometry, peptides were resolved in 20 µL of 2 % (v/v) acetonitrile containing 0.1 % (v/v) formic acid and incubated in an ultrasonic bath at 35 °C at maximum power for three minutes. Mass spectrometry was performed by Dr. Oliver Valerius (Department of Molecular Microbiology and Genetics, Georg-August-Universität Göttingen) using Orbitrap Velos Pro (Thermo Fisher Scientific).

2.2.5.4 Mass spectrometry analysis of α -synuclein

The single digestions as well as the double digested tryptic/AspN peptides were analyzed by LC-MS. Peptides of 1-5 µL sample solution were trapped and washed with 0.07 % (v/v) trifluoroacetic acid containing 2.6 % (v/v) acetonitrile on an Acclaim® PepMap 100 column (100 µm x 2 cm, C18, 3 µm, 100 Å, P/N164535, Thermo Fisher Scientific) at a flow rate of 25 µL/min for five minutes. Analytical peptide separation by reverse phase chromatography was performed on an Acclaim® PepMap RSLC column (75 µm x 25 cm, C18, 3 µm, 100 Å, P/N164534, Thermo Fisher Scientific) running a 40 minutes gradient from 100 % solvent A (0.1 % (v/v) formic acid) to 65 % solvent B (80 % (v/v) acetonitrile, 0.1 % (v/v) formic acid) and further to 95 % solvent B within one minute at flow rates of 300 nL/min (Fisher Chemicals). Chromatographically eluting peptides were on-line ionized by nano-electrospray (nESI) using the Nanospray Flex Ion Source (Thermo Fisher Scientific) at 2.4 kV and continuously transferred into the mass spectrometer. Full scans within m/z of 300-1850 were recorded with the Orbitrap-FT analyzer at a resolution of 30 000 with parallel data-dependent top 10 MS²-fragmentation in the LTQ Velos Pro linear ion trap. LC-MS method programming and data acquisition was performed with the software Xcalibur 2.2 (Thermo Fisher Scientific). MS/MS² data processing for protein analysis and PTM identification was done with the Proteome Discoverer 1.4 (PD, Thermo Fisher Scientific) software using the SequestHT search engine (Thermo Fisher Scientific) and *Saccharomyces cerevisiae* protein database extended by the most common contaminants with the following criteria: peptide mass tolerance 10 ppm, MS/MS ion mass tolerance 0.8 Da, and up to two missed cleavages allowed. Only high confident peptides with a false discovery rate less than 0.01 were considered.

2.2.5.5 Identification of crosslinked peptides

The MS data of crosslinked peptides were analyzed with StavroX2.3.4.5 (Gotze et al., 2012). MS data in the Mascot generic file (mgf) format containing all MS/MS data of precursor ions

were loaded into the program. The following parameters were used for the StavroX analysis: (i) cleavage sites: C-terminal: K, R; N-terminal: D; (ii) number of missed cleavages = 2; (iii) variable modifications: oxidation of methionine; nitration of tyrosine; cysteine-to-cysteine acetamide; (iv) mass of crosslinker: -H₂; (v) crosslinks only between two tyrosines; (vi) precision precursor comparison = 10 ppm. The false-positive rate was evaluated by decoy analysis using the reversed protein sequence. The frequency of occurrence of candidates from the data analysis and decoy analysis was compared for each sample. Only scores with decoy frequencies below 8 % of the data frequency were considered as possible crosslinks. The data were filtered for unique scans and each scan was considered only once with its highest score. Since multiple tyrosine residues are located on one and the same peptide, different combinations of crosslinked peptides with equal masses were possible. For each scan, the crosslinked tyrosine dimers were assigned according to the score calculated by the program based on the fragment ions series.

2.2.6 Phenotypical characterization

2.2.6.1 Spotting assay

Growth of yeast strains on solid medium was analyzed by performing spotting assay. Cells were grown in selective SC medium supplemented with 2 % raffinose at 30 °C overnight. After normalizing the cells to equal densities (OD₆₀₀ of 0.1), 10-fold dilutions series were prepared (10⁻¹, 10⁻², 10⁻³, 10⁻⁴) and spotted in a volume of 10 µL on selective SC agar plates supplemented with either 2 % glucose or 2 % galactose. The growth intensity was documented after two to three days incubation at 30 °C.

2.2.6.2 Fluorescence microscopy

For fluorescence microscopy cells were pre-grown in selective SC medium containing 2 % raffinose at 30 °C overnight and inoculated in 2 % galactose-containing SC medium to an OD₆₀₀ of 0.1. αSyn expression was induced for five hours. 300 µL of the cells were subjected to fluorescence microscopy. Fluorescent images were obtained with 63x magnification using a Zeiss Axio Observer. Z1 microscope (Zeiss) equipped with a CSU-X1 A1 confocal scanner unit (Yokogawa), QuantEM:512SC digital camera (Photometrics) and SlideBook 6.0 software package (Intelligent Imaging Innovations GmbH). Depending on the fluorescent agent, ssGFP or sdRFP filter were applied. To quantify aggregation of αSyn, at least 300 cells were counted per strain and experiment and the number of cells displaying αSyn aggregation was referred to the total number of counted cells.

2.2.6.3 Mitochondrial staining

To study mitochondrial morphology within live cells, the red-fluorescent dye MitoTracker® Red CMXRos-Special Packaging (Invitrogen) was used. MitoTracker Red accumulates in mitochondria depending on membrane potential. Cells were pre-grown in selective SC medium containing 2 % raffinose and inoculated in 2 % galactose-containing SC medium to an OD₆₀₀ of 0.1. α Syn expression was induced for five hours. To label mitochondria, the cells were incubated for 45 minutes in the presence of 50 nM MitoTracker Red, washed once with fresh medium and imaged.

2.2.6.4 Detection of reactive oxygen and nitrogen species

Reactive oxygen species (ROS) in yeast cells were visualized by microscopy using dihydrorhodamine 123 (DHR123, Cayman Chemical). The nonfluorescent ROS indicator passively diffuses across cell membranes where it is oxidized to the highly fluorescent product rhodamine 123 (Crow, 1997). It has an excitation and emission wavelengths of 500 and 536 nm, respectively. In order to test yeast for production of ROS, cells were pre-grown in selective SC medium containing 2 % raffinose at 30 °C overnight and inoculated in 2 % galactose-containing medium to an OD₆₀₀ of 0.1. α Syn expression was induced for six hours. After washing the cells in 1 mL dH₂O, DHR123 was added to a final concentration of 5 μ g/mL to 300 μ L cells resuspended in dH₂O and incubated in the dark at 30 °C for 1.5 hours. After washing, cells were re-suspended in dH₂O and microscopy was performed using RFP filter. To test yeast for reactive nitrogen species (RNS) production, the sensitive fluorescent indicator DAF-2 diacetate (Genaxxon BioScience GmbH) was used (Kojima et al., 1998). Upon entry into the cell, DAF-2 diacetate is transformed into DAF-2 by cellular esterases, which reacts with nitric oxide in the presence of oxygen to yield the highly fluorescent triazolofluorescein. It has an excitation and emission wavelengths of 485 and 538 nm, respectively. Cells pre-grown overnight in 2 % raffinose-containing SC medium were transferred to 2 % galactose-containing SC medium at OD₆₀₀ of 0.1. After six hours induction of α Syn expression, cells were washed and diluted in PBS buffer [pH 7.5] (137 mM NaCl, 8 mM Na₂HPO₄, 2 mM NaH₂PO₄) to OD₆₀₀ of 0.1. DAF-2 diacetate was added to a final concentration of 25 μ g/mL and cells were incubated in the dark at 30 °C for one hour. Before microscopy, the cells were washed in PBS buffer [pH 7.5] and RNS were visualized using GFP filter.

2.2.6.5 Flow cytometry

For quantification of ROS and RNS stained by DHR123 and DAF-2 diacetate in yeast cells, flow cytometry was performed. This technique simultaneously measures and analyzes multiple physical characteristics of single particles, such as cells that flow in a fluid stream through a beam of light (Fulwyler, 1965). Cells were grown and treated with DHR123 or DAF-2 diacetate as described in section 2.2.6.4. Before measuring, cells were resuspended in 50 mM trisodium citrate buffer pH 7.0. Flow cytometry analysis was performed on a BD FACSCANTO II (Becton Dickinson). 100 000 events were counted for each experiment. Data analysis was performed using the BD FACSDIVA™ software (Becton Dickinson). Representative examples were repeated at least three times.

2.2.6.6 Cell integrity assay

Yeast cell membrane integrity was analyzed with propidium iodide (PI) staining. After five hours induction of α Syn expression in 2 % galactose-containing SC medium, yeast cells with an OD₆₀₀ of 0.3 were washed in 500 μ L PBS and incubated with 12.5 μ g/mL PI in 500 μ L PBS for 30 minutes. As a positive control, cells were boiled for 10 minutes at 95 °C. Flow cytometry analysis was performed as described in section 2.2.6.5.

2.2.6.7 Growth analysis in liquid culture

For growth tests in liquid cultures, cells were pre-grown in 2 % raffinose-containing selective SC medium at 30 °C overnight and inoculated in 2 % galactose-containing SC medium to equal densities of OD₆₀₀ of 0.1. Optical density measurements of 200 μ L cell cultures were performed in triplicates in 96-well plates for 48 hours using a microplate reader (Infinite® M200, Tecan Group). Growth analyses under nitrate stress conditions were performed using 600 μ M or 1 mM DETA-NONOate (Cayman Chemical) as NO donor. This compound releases NO radicals and thereby induces nitrate stress in the cells. For DETA-NONOate use, the induction 2 % galactose-containing SC medium was adjusted to pH 7.4 by 200 mM NaOH to avoid a fast release of the compound. Incubation without DETA-NONOate served as control.

2.2.6.8 Promoter shut-off assay

To study the ability of yeast cells to degrade α Syn, promoter shut-off analyses were performed. Yeast cells were pre-grown in selective SC medium containing 2 % raffinose overnight and shifted to 2 % galactose-containing selective SC medium to induce α Syn

expression for four hours. Afterwards, cells were transferred to selective SC medium containing 2 % glucose to shut-off the promoter. Four hours after promoter shut-off, cells were visualized by fluorescence microscopy and the reduction of number of cells displaying α Syn inclusions was recorded. To study the lysosome/vacuole degradation pathway (autophagy), 1 mM phenylmethanesulfonyl fluoride (PMSF, Carl Roth GmbH & CO. KG) dissolved in ethanol was applied to the cell suspension (Lee and Goldberg, 1996). As control, equal volume of ethanol was applied to the cells. For impairment of the proteasomal degradation system, Carbobenzoxyl-leucinylleucinyll-leucinal (MG132, Selleck Chemicals) dissolved in dimethyl sulfoxide (DMSO) was added to the cell suspension in a final concentration of 75 μ M. In parallel, equal volume of DMSO was applied to the cells as a control. For drug treatment with MG132, induction-medium containing galactose and shut-off-medium containing glucose was supplemented with 0.003 % (w/v) SDS and 0.1 % (w/v) proline (Liu et al., 2007).

2.2.6.9 Agar diffusion assay

To analyze the sensitivity of *Saccharomyces cerevisiae* strains to reactive oxygen species, agar diffusion assay was performed using hydrogen peroxide (H_2O_2). H_2O_2 is reduced to hydroxyl radical ($OH\cdot$), which is one of the strongest oxidants in nature leading to oxidative stress. For testing sensitivity to oxidative stress, cells were grown in selective SC medium containing 2 % raffinose at 30 °C overnight and harvested by centrifugation at 3000 rpm for three minutes using the centrifuge 5804R (Eppendorf AG). After washing the cells in 1 mL dH_2O , optical densities were normalized to OD_{600} of 1 in 1 mL dH_2O . 100 μ L of cell suspension was resuspended in 10 mL liquid top agar (0.5 % (w/v)) and transferred on solid MV medium [pH 7.2] supplemented with 2 % galactose. Small Whatman paper disks were soaked with 10 μ L 30 % H_2O_2 and placed in the middle of the agar plate. The size of the inhibition area was measured after two to three days incubation at 30 °C.

2.2.6.10 Oxygen consumption rate assay

Oxygen consumption rate (OCR) is an indicator of mitochondrial respiration, which was assessed using the XF24 Extracellular Flux Analyzer (Seahorse Bioscience). This device measures the oxygen concentration in the medium and concludes the oxygen consumption rate (OCR). Cells were pre-grown in selective SC medium containing 2 % raffinose at 30 °C overnight and inoculated in 2 % galactose-containing medium to an OD_{600} of 0.1. α Syn expression was induced for six hours. For the assay, cells were seeded in galactose-containing selective SC medium with OD_{600} of 0.075. OCR was assessed at basal conditions,

as well as after sequential addition of 2 μ M FCCP (protonophore), 20 μ M oligomycin A (ATP synthase inhibitor) and 50 μ M antimycin A (complex III inhibitor). Basal OCR was obtained after subtraction of non-mitochondrial respiration (difference between initial OCR and antimycin A OCR response). Bioenergetic parameters were calculated upon normalizing OCR values to the baseline. Measuring of OCR was performed in the Department of Neurodegeneration and Restorative Research of the University Medical Center Göttingen (Göttingen, Germany).

2.2.7 Cell culture methods

All experiments carried out in mammalian cell culture were performed by Diana F. Lázaro in the Department of Neurodegeneration and Restorative Research of the University Medical Center Göttingen (Göttingen, Germany).

2.2.7.1 Transfection of H4 cells

H4 neuroglioma cells were used to analyze aggregation propensity of α Syn in mammalian cells. H4 cells are tumor cells of human neuroglia. H4 cells were plated 24 hours prior to transfection in 12-well plates (Costar). Cells were transfected with FuGENE®6 Transfection Reagent (Promega) using equal amounts of plasmid DNA encoding for α Syn, synphilin-1 (McLean et al., 2001) and Neuroglobin-mCherry or pcDNA3.1 (Invitrogen), according to the manufacturer's instructions.

2.2.7.2 Immunocytochemistry

For visualization of α Syn in H4 cells, immunocytochemistry was performed. This technique is based on the principle of specific binding of antibodies to antigens and is used to detect antigens in biological tissues. 48 hours after transfection, cells were washed with PBS and fixed with 4 % paraformaldehyde for 10 minutes at room temperature. After washing with PBS, cells were permeabilized with 0.5 % Triton X-100/PBS (Sigma-Aldrich) for 20 minutes at room temperature and blocked in 1.5 % normal goat serum (PAA)/PBS for one hour. Cells were incubated with a mouse anti- α Syn antibody (1:1000, BD Transduction Laboratory) overnight and then with a secondary antibody (Alexa Fluor 488 donkey anti-mouse IgG) for two hours at room temperature. Finally, cells were stained with Hoechst 33258 (1:5000 in PBS, Invitrogen) for five minutes and maintained in PBS prior to epifluorescence microscopy.

2.2.7.3 Quantification of α -synuclein inclusions in H4 cells

Transfected cells were scored based on the α Syn inclusion pattern and classified into: cells without inclusions, less than ten inclusions (<10 inclusions), and more than ten inclusions (\geq 10 inclusions), as described (Lazaro et al., 2014). The total number of transfected cells was expressed in percentage, as the average from three independent experiments.

2.2.7.4 Lactate dehydrogenase assay

The lactate dehydrogenase (LDH) cytotoxicity assay (Roche Diagnostics) was performed according to the manufacturer's instructions. Growth media from cells were applied in triplicates in a 96-well plate in a ratio 1:1 with the reaction mixture. The measurements were performed in a TECAN Infinite 200 Pro plate reader (Tecan Group) at 490 nm. The percentage of toxicity was calculated as indicated by the manufacturer.

2.2.8 Statistical analysis

Data were analyzed using GraphPad Prism 5 Software (San Diego, USA) and were presented as mean \pm SEM of at least three independent experiments. The significance of differences was calculated using Student's t-test, one-way ANOVA test with Bonferroni's multiple comparison test or Dunnett's multiple comparison test. P value < 0.05 was considered to indicate a significant difference.

3 Results

Misfolded oligomeric α Syn species have been hypothesized to be involved in the neurodegeneration process of PD and other synucleinopathies. In this study, ability of an eukaryotic cell to overcome misfolded and accumulated α Syn species was explored. Moreover, the impact of oxidative stresses on these molecular processes was addressed. Therefore, α Syn was heterologously expressed in *Saccharomyces cerevisiae* cells and the influence of nitration on α Syn-mediated cytotoxicity was examined. Thereby, aggregation propensity, growth impact, ROS/RNS accumulation, protein and mitochondrial analysis served as instruments to question, whether nitration affects α Syn-induced cytotoxicity. Moreover, it was investigated, whether there is an interplay between nitration and phosphorylation of α Syn on S129 as the predominant posttranslational modification found in LBs.

3.1 α -synuclein forms dimers *in vivo* in yeast cells

Exposure of α Syn to nitrating agents causes tyrosine nitration *in vitro* and leads to formation of covalently crosslinked α Syn dimers and inclusions (Hodara et al., 2004; Norris et al., 2003; Paxinou et al., 2001; Souza et al., 2000a; Takahashi et al., 2002). High levels of α Syn with C-terminal HIS₆-tags were heterologously expressed in yeast cells to uncover how nitration influences *in vivo* α Syn toxicity and aggregate formation. The first approach was to examine, whether α Syn and A30P form dimers *in vivo* without additional exposure of the cells to nitrating or oxidative agents. α Syn and A30P expression was driven by the *GAL1*-promoter, which was repressed in the presence of glucose and induced when shifted to 2 % galactose-containing medium for 12 hours. High copy number expression of the HIS₆-tagged α Syn resulted in growth inhibition, whereas high expression of the A30P mutant resulted in a similar growth rate as the yeast control without any α Syn (Figure 6A). Similar results were previously reported with untagged or GFP-tagged α Syn and corroborate that the HIS₆-tag does not interfere with the behavior of α Syn in yeast (Outeiro and Lindquist, 2003; Petroi et al., 2012).

Next, α Syn proteins were enriched by Ni²⁺ pull-down under denaturing conditions in the presence of urea. Immunoblotting with anti- α Syn antibody revealed distinct bands, corresponding to monomeric (~17 kDa), dimeric (~35 kDa) and higher molecular weight α Syn species (oligomers), detected from *in vivo* samples (Figure 6B). This supports that α Syn and the A30P mutant form dimers and oligomers *in vivo* even without additional exposure of the cells to nitrating or oxidative agents.

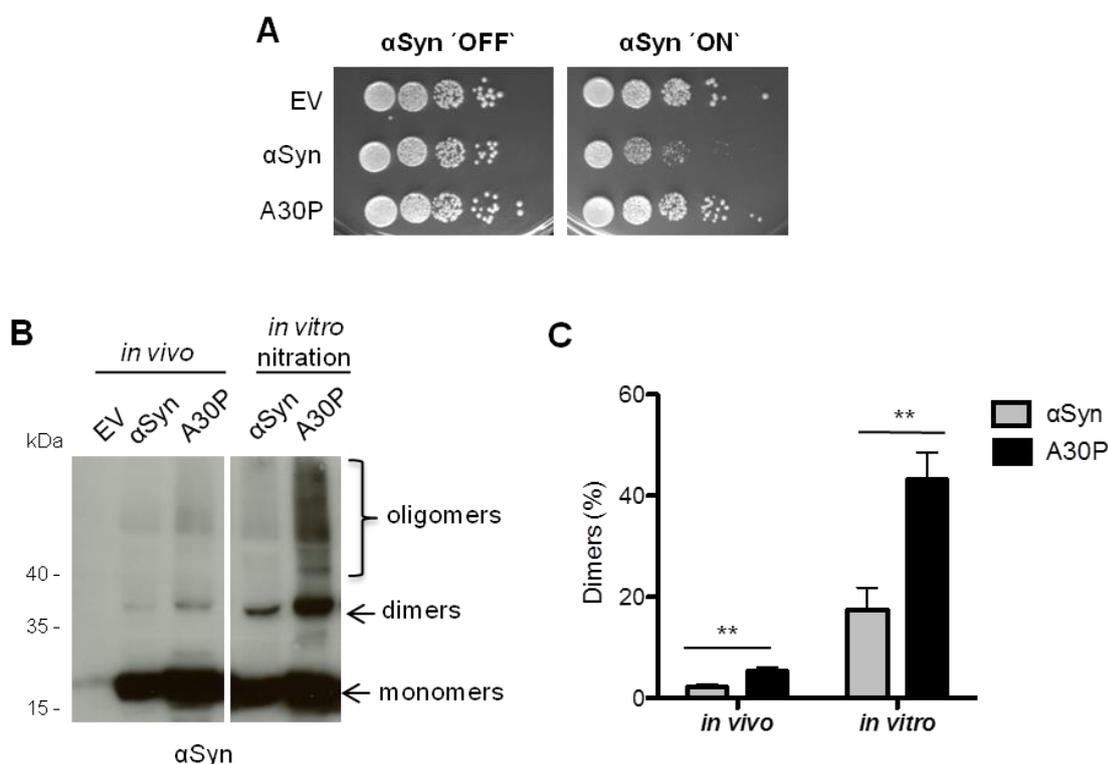

Figure 6. αSyn forms dimers *in vivo* in yeast.

(A) Spotting analysis of yeast cells expressing C-terminally HIS₆-tagged αSyn and A30P αSyn on a high copy vector (2μ) driven by the inducible *GAL1*-promoter on non-inducing ('OFF': glucose) and inducing ('ON': galactose) SC-Ura medium after three days. Control cells expressed only the empty vector pME2795 (EV). (B) Immunoblotting of αSyn and A30P enriched from cell extracts by Ni²⁺ pull-down with anti-αSyn antibody. *In vitro* nitration was carried out with 15 μg of αSyn extracts using 1 μL peroxyntirite (PON) in the presence of 1 μL 0.3 M HCl. (C) Quantification of dimers. Densitometric analysis of the immunodetection of αSyn and A30P dimers *in vivo* and in PON-treated samples. The amount of dimers is presented as percent of the total amount of αSyn detected per lane (monomer + dimer). Significance of differences was calculated with t-test (**, *p* < 0.01, *n*=4).

Dimer and oligomer formation of αSyn *in vivo* was further analyzed by comparison to additional *in vitro* nitration (Souza et al., 2000a). PON (ONOO⁻) was applied as nitrating agent for αSyn tyrosine residues because it leads to the formation of stable αSyn oligomers. PON is formed by the reaction of superoxide (O₂⁻) with the free radical nitric oxide (NO) and represents a major nitrating agent that causes tissue injury in several neurological disorders (Beckman, 1994; Beckman, 1996). αSyn and A30P proteins were expressed in yeast, pulled-down using Ni²⁺-NTA and exposed to PON. Immunoblotting of the *in vitro* nitrated proteins revealed that the abundance of dimers and oligomers is significantly increased with the same pattern as for *in vivo* isolated αSyn species (Figure 6B). The major distinct band corresponds to the αSyn dimer species. Quantification of the dimer band intensities of *in vivo* isolated probes showed that A30P forms approximately twice as many dimers relative to monomers as wild-type αSyn (Figure 6C). *In vitro* nitration of αSyn and A30P increased the total amount

of dimers. However, the dimer to monomer ratios between α Syn and A30P were not changed when the *in vivo* samples were enhanced by additional *in vitro* nitration (Figure 6C). This result suggests that the high molecular weight variants of α Syn, which can be isolated from yeast cells and which withstand strong denaturing conditions during the pull-down (8 M Urea, 2 % SDS), represent covalently crosslinked α Syn species. These data support the formation of α Syn dimers in living cells. A remarkable result is that the toxicity of α Syn, which correlates to a high protein aggregation rate (Petroi et al., 2012), results in a reduced amount of α Syn dimer relative to monomer. In contrast, the non-toxic A30P mutant that does not inhibit cellular growth (Figure 6A), and has a reduced aggregation rate (Petroi et al., 2012), produces twice as many dimers relative to monomers in comparison to wild-type α Syn. This suggests that α Syn dimer formation is a molecular mechanism which can be used by the cell as salvage pathway for detoxification.

3.2 The C-terminus of α -synuclein is preferentially modified by nitration and di-tyrosine formation

Liquid chromatography-mass spectrometry (LC-MS) analysis was performed to study α Syn and A30P nitration sites *in vivo*. Single trypsin or AspN digestions were employed and the resulting peptides were analyzed by LC-MS. In addition to single digestions, a combined proteolytic approach by double digestion of the proteins with trypsin and AspN was employed that enabled 100 % sequence coverage. The modifications of the tyrosine residues identified from fragment spectra are summarized in Table 15.

Table 15. Determination of nitrated peptides from α Syn and A30P.

	<i>in vivo</i>				<i>in vitro</i> (PON)			
	Y39	Y125	Y133	Y136	Y39	Y125	Y133	Y136
αSyn monomers		3-NT	3-NT	3-NT	3-NT	3-NT	3-NT	3-NT
αSyn dimers					3-NT			
A30P monomers		3-NT			3-NT	3-NT	3-NT	
A30P dimers					3-NT	3-NT	3-NT	

α Syn and A30P were enriched by Ni^{2+} pull-down from yeast crude extracts and separated by SDS-PAGE. Monomeric and dimeric α Syn stained with Coomassie were excised from the gel and digested with trypsin and AspN. Untreated (*in vivo*) and subsequent peroxyxynitrite (PON) treated (*in vitro*) α Syn and A30P protein samples were analyzed with LC-MS for tyrosine nitration. 3-NT (3-nitrotyrosine) indicates identified nitration sites, supported by at least two peptides and two independent experiments.

As a positive control, α Syn was used, where nitration was enhanced after the pull-down by additional PON exposure. MS data revealed nitration of wild-type α Syn at all three C-terminal tyrosines (Y125, Y133, Y136). Nitration of A30P was restricted to Y125 and absent at Y133

or Y136. Nitration of the additional tyrosine residue Y39 in the N-terminal domain of α Syn could not be identified from any *in vivo* samples by LS-MS. Additional PON exposure, however, resulted in Y39 nitration in all samples. This suggests that Y39 is not a primary *in vivo* nitration target within cells. Additional PON-exposure after pull-down also revealed that the α Syn dimers can be potentially nitrated *in vitro*. The increased *in vitro* PON-mediated nitration of the A30P in comparison to wild-type could be due to the higher amounts of the dimer in this mutant strain. Beyond nitration, also phosphorylation of α Syn as well as of A30P at S129, Y125 or Y133 was identified but not at Y39 or Y136 (Table 16).

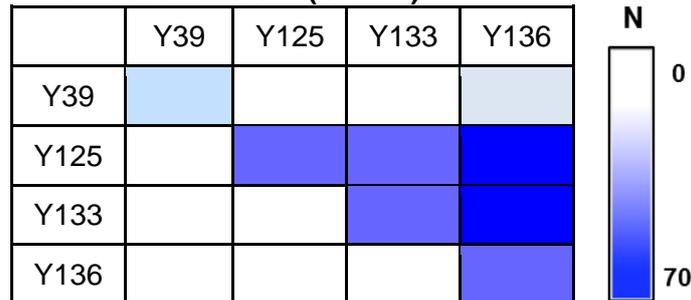

Table 16. Phospho-peptides identified by MS/MS.

Position	Modification	PTM Score α Syn	PTM Score A30P	Sequence Motif
Y39	Phospho	0	1.5	KEGVLyVGSKT
Y125	Phospho	9.7	8	PDNEAyEMPSE
S129	Phospho	100	100	AYEMPseEGYQ
Y133	Phospho	99.8	100	PSEEGyQDYEP
Y136	Phospho	0	0	EGYQDyEPEA

Posttranslational modification (PTM) scores were calculated with phosphoRS algorithm and represent the probability for phosphorylation modification. The corresponding amino acid is indicated by a small letter code in the sequence motif. Number of peptide sequence matches: α Syn = 332; A30P = 414.

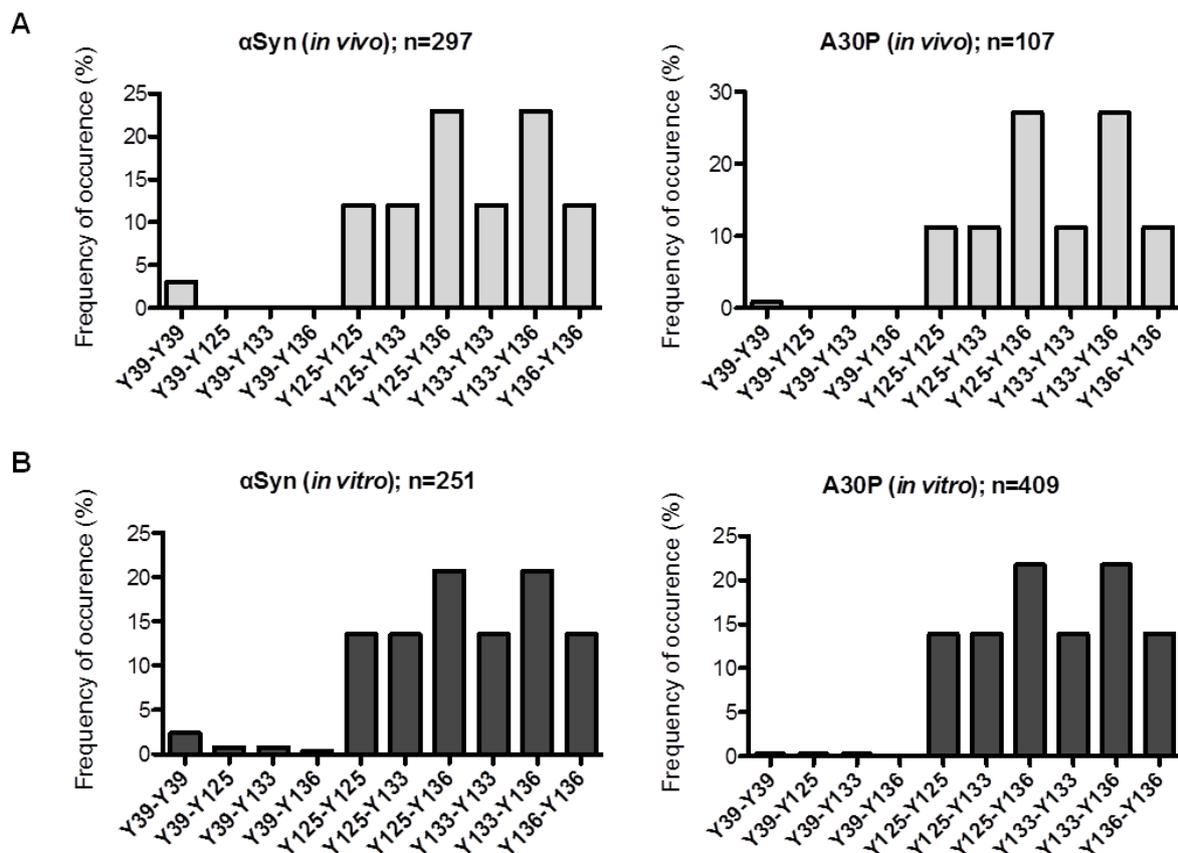

The probabilities for possible phosphorylation sites were calculated with the phosphoRS algorithm (Taus et al., 2011). Phosphorylation of Y125 was identified with only low probability scores (Table 16). In contrast, S129 and Y133 were almost completely co-phosphorylated with scores of 100 % for S129 and 99 % for Y133, respectively.

The LC-MS spectra of α Syn and A30P migrating in SDS-PAGE with the size of the dimer band were analyzed to assess whether di-tyrosines cause dimer formation of α Syn or A30P. The presence of di-tyrosine peptide crosslinks was validated using StavroX2.3.4.5 software (Gotze et al., 2012). This software compares the masses of all potential crosslinked peptides with the precursor ion masses, calculates b- and y-type ions for all possible crosslinks and compares them to MS2 data of the precursor ion. Different combinations of crosslinked peptides with an identical mass are possible when multiple tyrosine residues are located on one and the same peptide. The crosslinked tyrosine pairs were assigned according to the scores calculated by StavroX based on the fragment ion series of the MS2 spectra. The MS data analysis verified that α Syn dimers are crosslinked by tyrosine residues. The detected combinations of crosslinked tyrosines are depicted in Table 17. The results indicate a strong preference for crosslinking of defined combinations of tyrosines (Table 17, Figure 7, 8).

Table 17. Number of verified crosslinks (*in vivo*).

Determination of crosslinked peptides from α Syn and A30P. Exemplary heat map diagram of the number (N) of identified di-tyrosine crosslinked peptides of the non-treated α Syn samples.

The most frequent combinations for either wild-type α Syn or A30P are Y125-Y136 and Y133-Y136 dimers which are all located in the C-terminus. Only the C-terminal tyrosine residues can mutually interact. Only a small fraction of Y39-Y39 dimers were found and there are no tyrosine dimers between the N-terminal Y39 and the C-terminal tyrosines of α Syn or A30P.

**Figure 7. Analysis of di-tyrosine dimers from α Syn.**

(A) Distribution of all identified di-tyrosine peptides for untreated (*in vivo*) α Syn (left diagram) and A30P (right diagram) protein samples. Identified combinations of crosslinked peptides are presented as percentage of n (n = total number of MS2 spectra verified as crosslinked peptides). (B) Distribution of all identified di-tyrosine peptides for peroxyntirite (PON) treated (*in vitro*) α Syn (left diagram) and A30P (right diagram) protein samples.

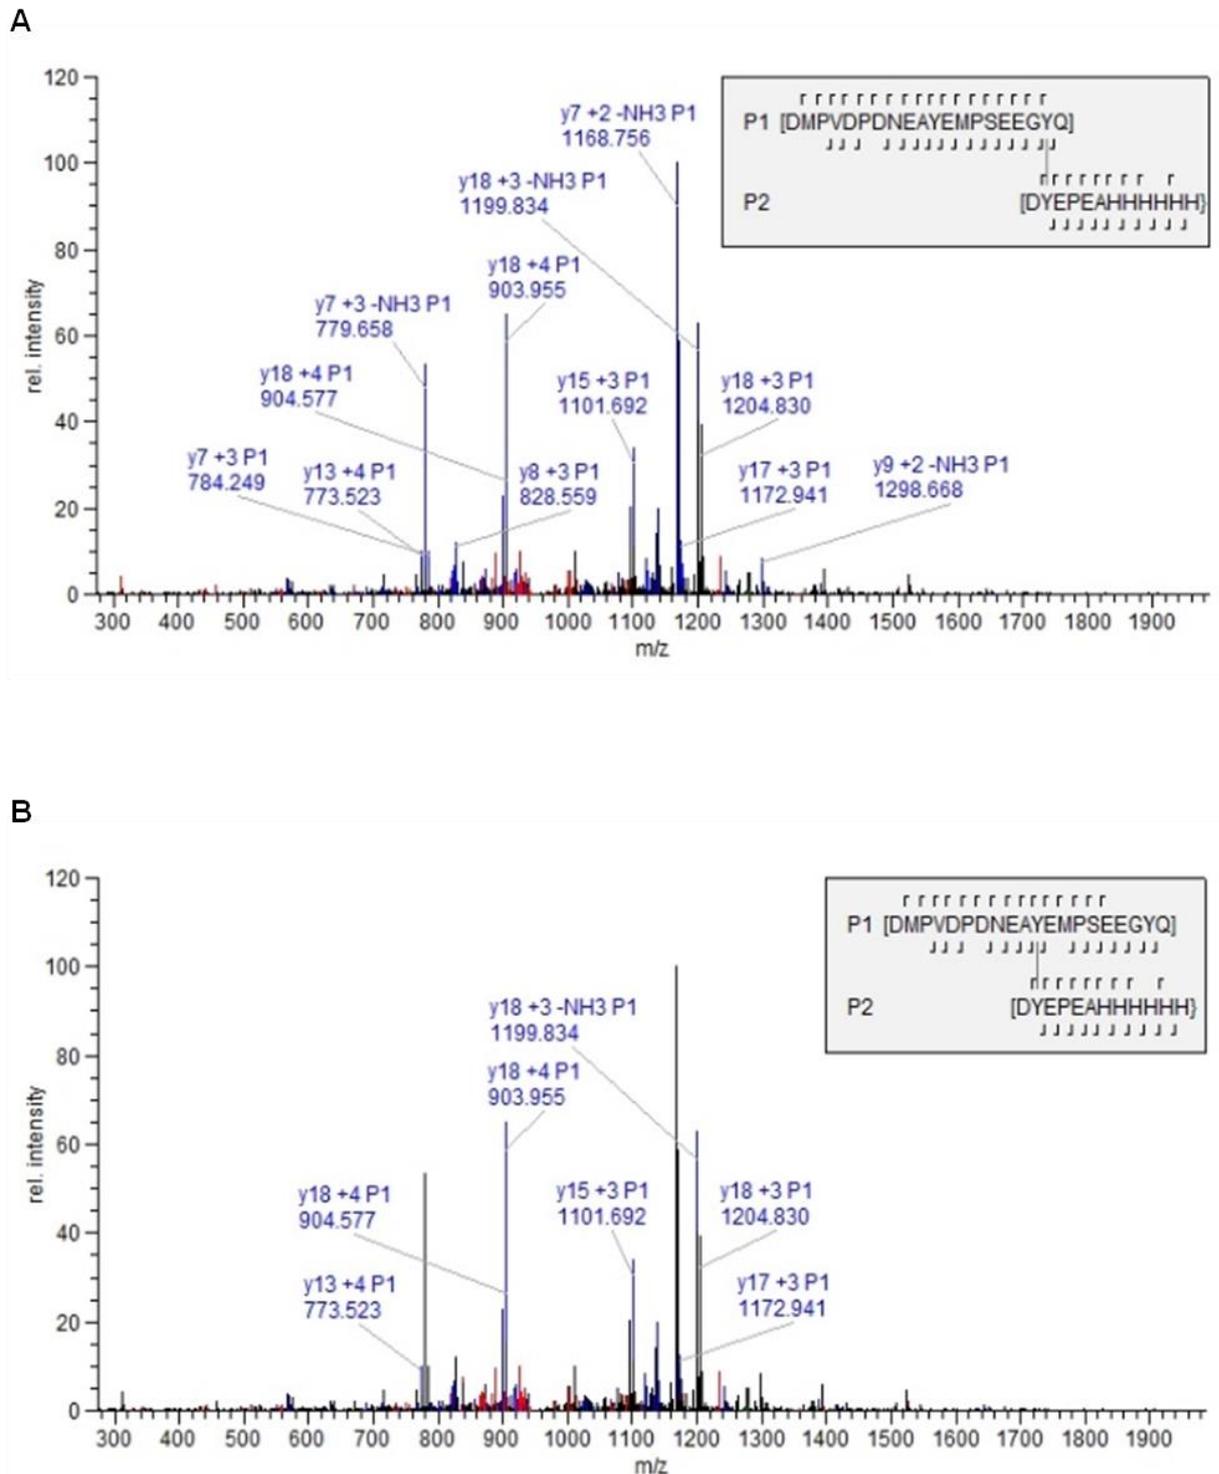

Figure 8. MS2 analysis of crosslinked peptides.

(A) Exemplary fragment ion MS2 spectrum of the crosslink between Y133 and Y136 of α Syn dimers. y-ions of the crosslinked peptides are represented in blue, while b-ions are represented in red. Fragmentation sites are indicated in the amino acid sequence. (B) Exemplary fragment ion MS2 spectrum of the crosslink between Y125 and Y136 of A30P dimers.

These data suggest that the C-terminus of α Syn or A30P has an increased susceptibility for nitration and di-tyrosine formation compared to the N-terminus. Only Y125 is a major nitration site of A30P. In contrast, all three C-terminal tyrosines Y125, Y133 and Y136 of the wild-type α Syn are putative targets for nitration. Y133 is an additional strong and Y125 a weak phosphorylation site, respectively. Dimer formation through di-tyrosine follows a specific pattern for both tested α Syn proteins with predominant forms including Y136 interacting either with Y125 (Y125-Y136) or with Y133 (Y133-136).

3.3 Tyrosine residues contribute to α -synuclein cytotoxicity and aggregate formation

The codons for the four tyrosine sites of α Syn and A30P (Y39, Y125, Y133 and Y136) were replaced in the corresponding genes by phenylalanine codons (4(Y/F)) to analyze the role of the tyrosine residues on α Syn dimer formation, cytotoxicity or aggregation. Fusion genes with GFP- or HIS₆-tags were constructed and expressed. Here, it was assessed whether the quadruple Y to F replacements influence the dimerization of α Syn and A30P. Expression of α Syn and A30P as well as their 4(Y/F) mutants was induced for 12 hours. Tagged proteins were enriched by Ni²⁺ pull-down under denaturing conditions. Immunoblotting using α Syn antibodies as well as antibodies that specifically recognize di-tyrosines revealed that 4(Y/F) mutants of α Syn or A30P had lost the potential to form dimers *in vivo* (Figure 9A).

Additional *in vitro* nitration with PON did also not result in any dimer or oligomer formation and served as control (Figure 9A). Immunoblotting analysis was carried out to determine *in vivo* nitrated α Syn using 3-nitrotyrosine specific antibodies (Figure 9B). The results demonstrated that the 4(Y/F) variants of wild-type α Syn or A30P did not result in any nitration signal even after additional PON treatment. This is in contrast to wild-type α Syn with its four original tyrosine residues as control, where nitration is present *in vivo* and can be further increased by additional PON treatment.

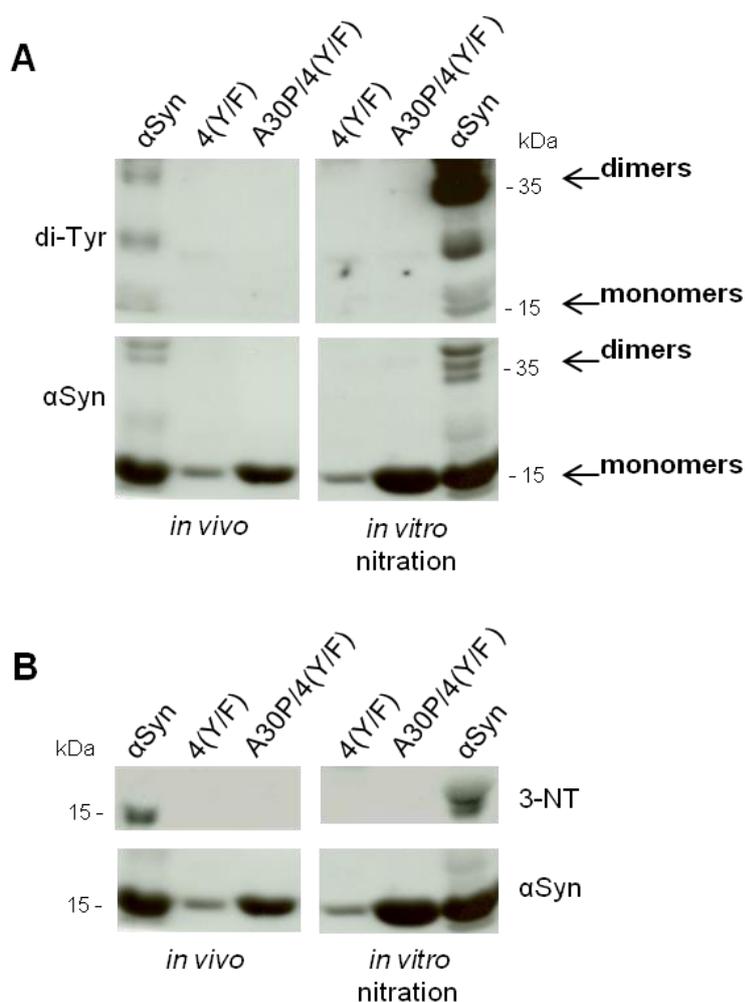

Figure 9. Mutation of tyrosines of α Syn prevents dimerization and nitration of α Syn.

(A) Expression of α Syn, A30P, 4(Y/F) and A30P/4(Y/F) α Syn was induced for 12 hours in galactose-containing medium and the proteins were enriched by Ni^{2+} pull-down from yeast cell extracts. For *in vitro* nitration, 1 μL peroxyxynitrite (PON) was mixed with 15 μg of α Syn extracts in the presence of 1 μL 0.3 M HCl. Immunoblotting with di-tyrosine antibody reveals a major band at about 36 kDa, corresponding to dimers. Additional bands with lower molecular weights are probably due to intramolecular di-tyrosine crosslinking. The same membrane was stripped and re-probed with α Syn antibody. (B) Immunoblotting using 3-nitrotyrosine antibody (3-NT). Phenylalanine codon substitutions eliminate immunoreactivity. The same membrane was stripped and re-probed with α Syn antibody.

The growth impact of wild-type α Syn or the A30P variant were compared with that of the additional 4(Y/F) substitutions by spotting analysis and in liquid medium, respectively (Figure 10). Substitutions of the four tyrosine residues in wild-type α Syn significantly improved growth on solid medium, whereas A30P α Syn growth was similar with tyrosine or instead with phenylalanine residues (Figure 10A). Growth in liquid medium resulted in similar effects, revealing significantly reduced growth inhibition of the 4(Y/F) mutant strain in comparison to wild-type α Syn (Figure 10B), whereas A30P and its A30P/4(Y/F) derivative were growing similarly (Figure 10C).

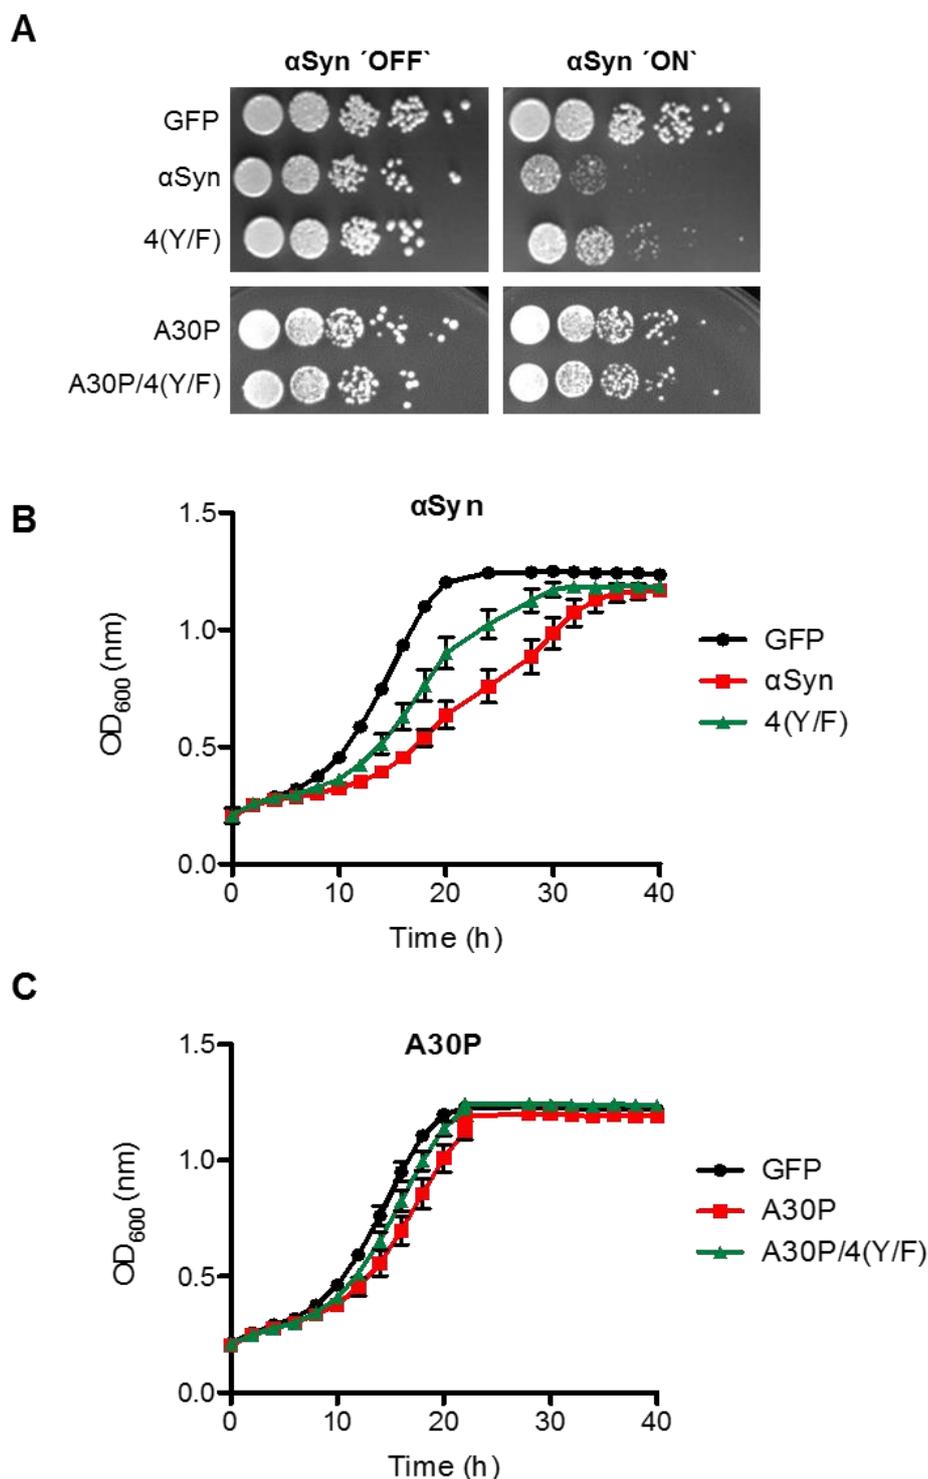

Figure 10. Blocking of α Syn tyrosine nitration decreases cytotoxicity.

(A) Spotting analysis of yeast cells expressing *GAL1*-driven α Syn, A30P, 4(Y/F), A30P/4(Y/F) α Syn and GFP (control). Yeast cells were spotted in 10-fold dilutions on SC-Ura plates containing glucose (α Syn 'OFF') or galactose (α Syn 'ON'). (B) Cell growth analysis of yeast cells expressing α Syn, 4(Y/F) and GFP (control) in galactose-containing SC-Ura medium for 40 hours. Error bars represent standard deviations of three independent experiments. (C) Cell growth analysis of yeast cells expressing A30P, A30P/4(Y/F) α Syn and GFP (control), in galactose-containing SC-Ura medium for 40 hours. Error bars represent standard deviations of three independent experiments.

It was assessed, whether the decrease in wild-type α Syn toxicity was related to the formation of α Syn inclusions (Figure 11A, B). No change in inclusion formation could be monitored when A30P was compared to A30P/4(Y/F). However, yeast cells expressing the 4(Y/F) α Syn variant formed less inclusions in comparison to wild-type α Syn (Figure 11A, B). Immunoblotting with α Syn antibody revealed that the protein levels of the different α Syn variants were similar (Figure 11C), excluding that reduction of aggregates results from lower α Syn expression levels.

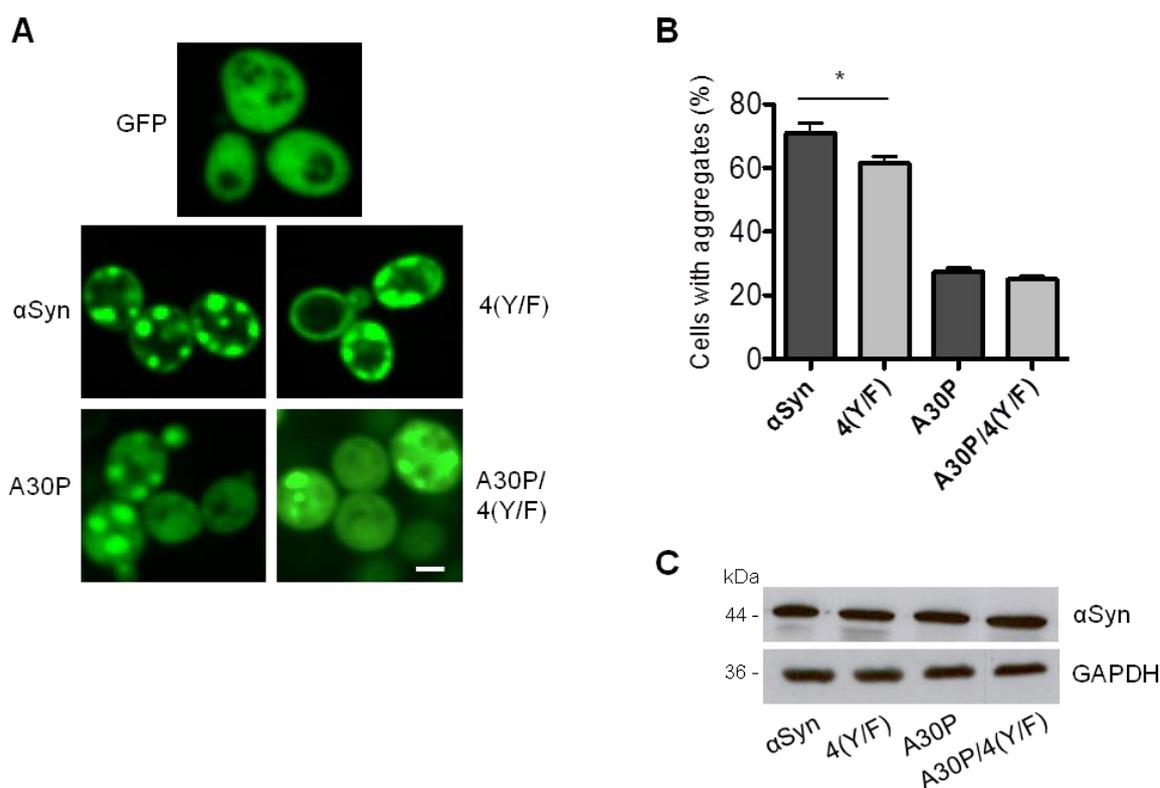

Figure 11. Blocking of α Syn tyrosine nitration decreases aggregation.

(A) Fluorescence microscopy of yeast cells, expressing indicated α Syn-GFP variants after six hours of induction in galactose-containing medium. Scale bar: 1 μ m. (B) Quantification of the percentage of cells displaying aggregates after six hours induction in galactose-containing medium. Significance of differences was calculated with t-test (*, $p < 0.05$, $n=6$). (C) Immunoblotting of protein crude extracts of GFP-tagged α Syn, 4(Y/F), A30P and A30P/4(Y/F) α Syn after six hours induction in galactose-containing medium. GAPDH antibody was used as loading control.

Taken together, only tyrosine replacements by phenylalanine in case of wild-type α Syn but not in case of an additional A30P substitution reduce α Syn-induced toxicity and inclusion formation. Accordingly, there is only growth improvement in the absence of an A30P substitution that correlates with decrease of intracellular accumulations of α Syn fluorescent foci. This supports that tyrosine residues that are responsible for nitration of α Syn contribute

to the cytotoxic effect and inclusion formation of α Syn in yeast. This tyrosine-dependent effect is significantly less pronounced in the presence of an A30P codon mutation suggesting that A30P suppresses the tyrosine effect, which can be observed in wild-type α Syn. The presence of tyrosine residues in wild-type α Syn favor nitration and di-tyrosine crosslinking but offer only a minor contribution to inclusion formation.

3.4 The nitric oxide oxidoreductase Yhb1 reduces A30P aggregation and toxicity

The effect of nitrative stress on the toxicity and aggregation of wild-type and A30P mutant α Syn was examined. A yeast strain carrying a deletion in the yeast flavohemoglobin gene (*YHB1*), responsible for stress signaling, was used for enhancement of nitrative stress. Yhb1 is a nitric oxide oxidoreductase, which protects against nitration of cellular targets and against cell growth inhibition under aerobic or anaerobic conditions (Liu et al., 2000). Deletion of *YHB1* abolishes the nitric oxide (NO) consuming activity of yeast cells (Liu et al., 2000). The compound DETA-NONOate causes nitrative stress by acting as a NO donor.

The absence of the flavohemoglobin results in a growth impairment of the hypersensitive *yhb1* deletion strain in comparison to wild-type under NO nitrative stress conditions (Figure 12A). The genes encoding wild-type or A30P α Syn, or GFP as a control, were expressed in $\Delta yhb1$ or the isogenic wild-type background. Cell growth was compared in the absence of nitrative stress by spotting assays (Figure 12B). Wild-type α Syn was as well cytotoxic in the presence or absence of *YHB1*. This was different for A30P, where no cytotoxicity was observed in the presence of *YHB1*. However, expression of A30P in $\Delta yhb1$ cells inhibited cell growth. This effect was verified by low copy plasmid expression of *YHB1*. Cells rescued with *YHB1* showed the same growth phenotype as the original A30P or the GFP control in the *YHB1* background (Figure 12B).

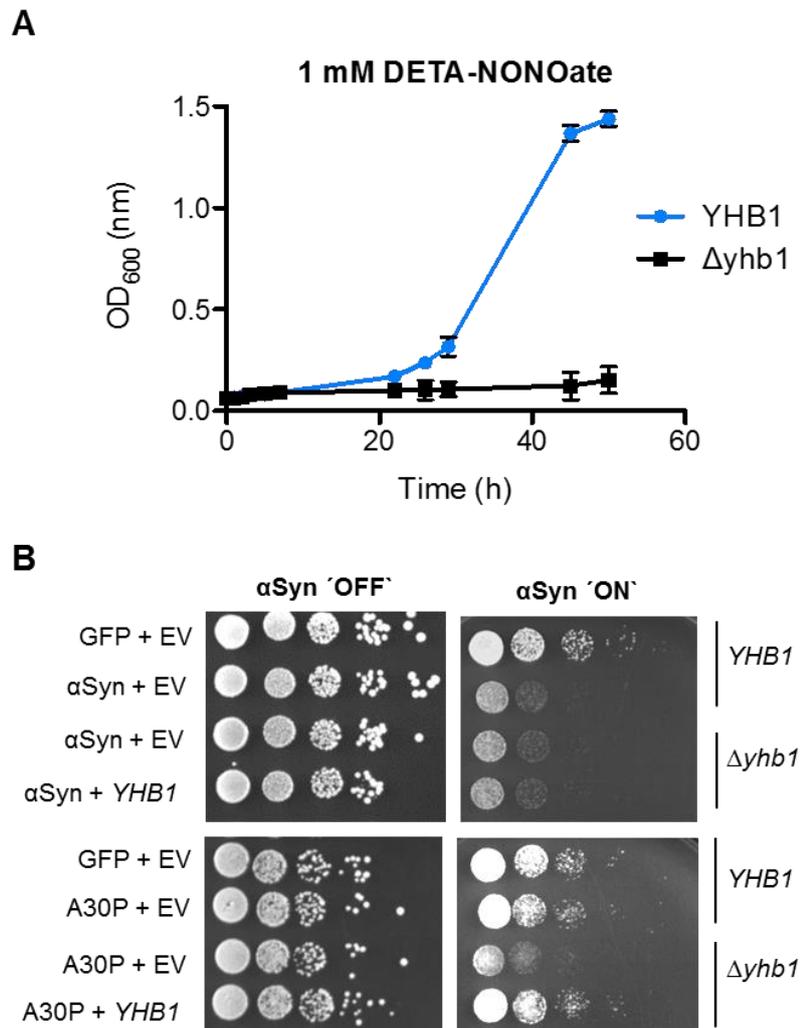

Figure 12. The nitric oxide oxidoreductase Yhb1 reduces A30P toxicity.

(A) Cell growth comparison of wild-type *YHB1* and mutant $\Delta yhb1$ yeast cells in the presence of the NO stress-mediating drug DETA-NONOate (1 mM) in liquid galactose-containing SC-Ura medium. Error bars indicate standard deviations of three independent experiments. (B) Spotting analysis of *YHB1* and $\Delta yhb1$ yeast cells expressing α Syn (upper boxes) or A30P (lower boxes) compared to GFP and empty vector (EV) as control on non-inducing and galactose-inducing SC-Ura medium after three days.

The correlation between growth inhibition and aggregate formation of α Syn variants was examined. Cells expressing α Syn or A30P were imaged by fluorescence microscopy and the cells displaying aggregates were counted. Deletion of *YHB1* resulted in an increased percentage of cells with A30P inclusions, whereas no significant difference was observed in cell expressing wild-type α Syn (Figure 13A). In agreement with the growth analyses, the complementation of the $\Delta yhb1$ deletion by *YHB1* rescued the lower aggregation potential of A30P (Figure 13A).

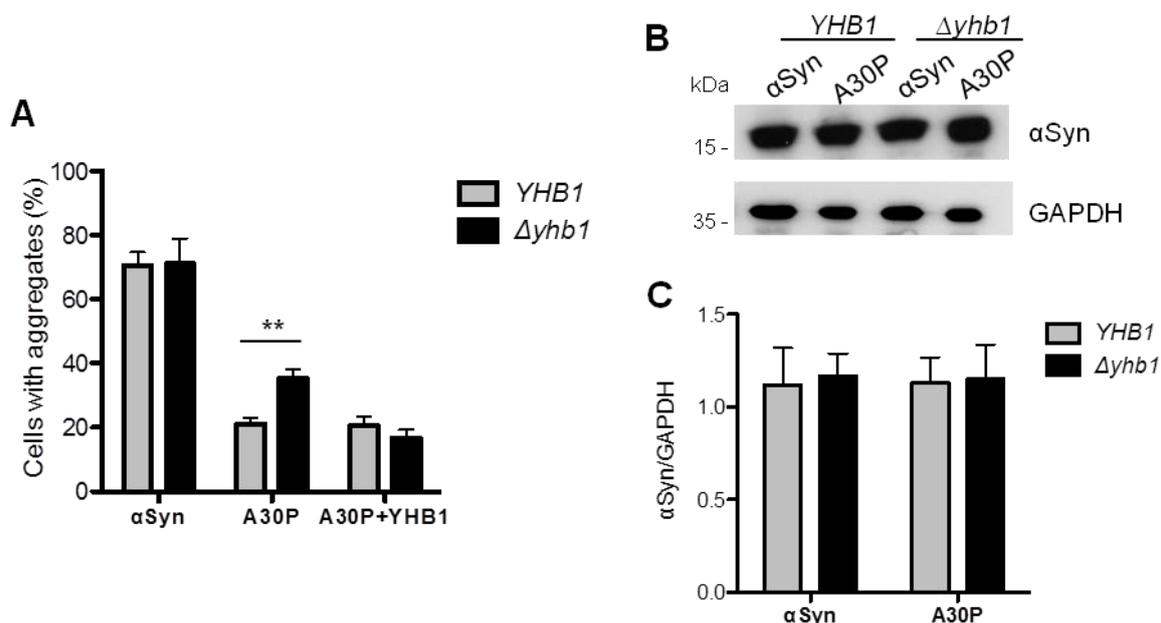

Figure 13. The nitric oxide oxidoreductase Yhb1 reduces A30P aggregation.

(A) Quantification of the percentage of cells displaying α Syn aggregates after six hours induction in galactose-containing medium. Significance of differences was calculated with t-test (**, $p < 0.01$, $n=6$). (B) Immunoblotting of protein crude extracts of α Syn and A30P expressed in *YHB1* and $\Delta yhb1$ yeast after six hours induction in galactose-containing medium. GAPDH antibody was used as loading control. (C) Quantification of α Syn and A30P levels in *YHB1* and $\Delta yhb1$ yeast cells. Densitometric analysis of the immunodetection of α Syn and A30P relative to the intensity obtained for GAPDH ($n=3$).

α Syn toxicity is dependent on the expression levels (Outeiro and Lindquist, 2003; Petroi et al., 2012). Thus, it was tested whether the A30P expression level is equal in $\Delta yhb1$ mutant compared to *YHB1* yeast. Immunoblot analysis revealed that the A30P variant is expressed at similar levels in both yeast backgrounds six hours after induction of gene expression (Figure 13B, C), excluding that differences in toxicity are due to different A30P expression levels.

3.5 Overexpression of *YHB1* impairs growth of *Saccharomyces cerevisiae*

As previous results of this study have shown, *YHB1* is a repressor of A30P aggregation and toxicity. To test whether this protein generally diminishes α Syn-induced toxicity and whether increasing the putative repressive function by overexpression leads to reduction of toxicity, *YHB1* was cloned into a high copy vector and overexpressed with wild-type α Syn and A30P in wild-type yeast. Growth analysis on solid medium shows that expression of *YHB1* with either empty vector or GFP inhibits growth of yeast cells (Figure 14A), indicating that overexpression of *YHB1* triggers cell processes that harm the cells. In yeast, Yhb1 detoxifies cell targets from nitric oxide (NO) (Liu et al., 2000). NO is a free radical that reacts with superoxide to form peroxynitrite. This oxidant harms the cell by damaging proteins, lipids and

DNA leading to dysfunction of important cell processes and cell death (Beckman, 1996). However, peroxynitrite was shown to have an important role for various cell signaling transduction pathways, due to its ability to nitrate tyrosine residues and thereby affecting phosphotyrosine-dependent signalling processes (Gow et al., 1996; Kong et al., 1996). Moreover, studies have found that peroxynitrite influences the activity of various kinases and phosphatases leading to up- or downregulation of signalling cascades (Kang et al., 2002; Klotz et al., 2000). Such examples of function variety demonstrate which dramatic influences the misbalance of peroxynitrite may induce in the cell. Overexpression of *YHB1* changes the peroxynitrite levels, which may lead to misregulation of signalling pathways causing growth inhibition or cell death.

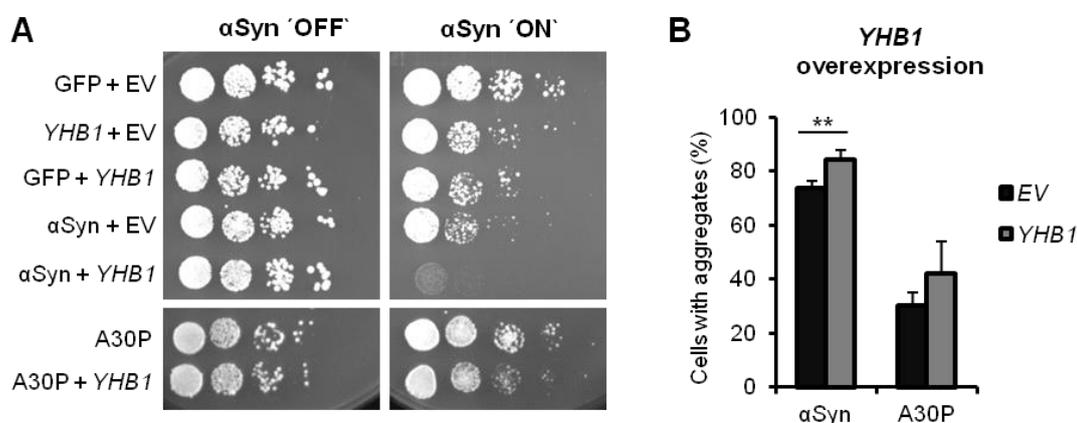

Figure 14. Overexpression of *YHB1* impairs growth of *Saccharomyces cerevisiae*.

(A) Spotting assay of wild-type yeast cells expressing α Syn, A30P and GFP (control) with either empty vector (pME2792) as control or high copy of *YHB1* on non-inducing and galactose-inducing SC-Ura medium after three days. (B) Quantification of the percentage of cells displaying α Syn and A30P aggregates after six hours induction in galactose-containing medium. Significance of differences was calculated with t-test (**, $p < 0.01$, $n=3$).

When overexpressing wild-type α Syn together with *YHB1*, growth inhibition of the cells is severely enhanced. In contrast, co-expressing A30P with *YHB1* only slightly inhibited growth similar to the control strains expressing the empty vector or GFP (Figure 14A). This suggests that the strong growth inhibition of wild-type α Syn and *YHB1* expressing cells is an additive impact of coincidentally overexpression of two genes causing cytotoxicity. Analysis of aggregation of wild-type α Syn and A30P co-expressing *YHB1* demonstrated that strong growth inhibition induced by wild-type α Syn is accompanied by increase of aggregate formation (Figure 14B). However, aggregation of A30P was not significantly changed by *YHB1* overexpression. The molecular target of Yhb1 is the small molecule nitric oxide. This free radical is the main source of nitrative stress but is also required as an endogenous signalling molecule involved in the regulation of different physiological processes. The observed growth inhibition of cells overexpressing *YHB1* may result from disturbance of NO-mediated cell processes.

3.6 Yhb1 decreases sensitivity of A30P expressing cells to nitritive stress

Deletion of *YHB1* constitutes an internal stress signal. The effect of nitritive stress on A30P was further investigated by adding external nitritive stress conditions. Growth tests in liquid culture were performed using DETA-NONOate, which reduces growth of the $\Delta yhb1$ mutant but not of the wild-type strain (Figure 15A).

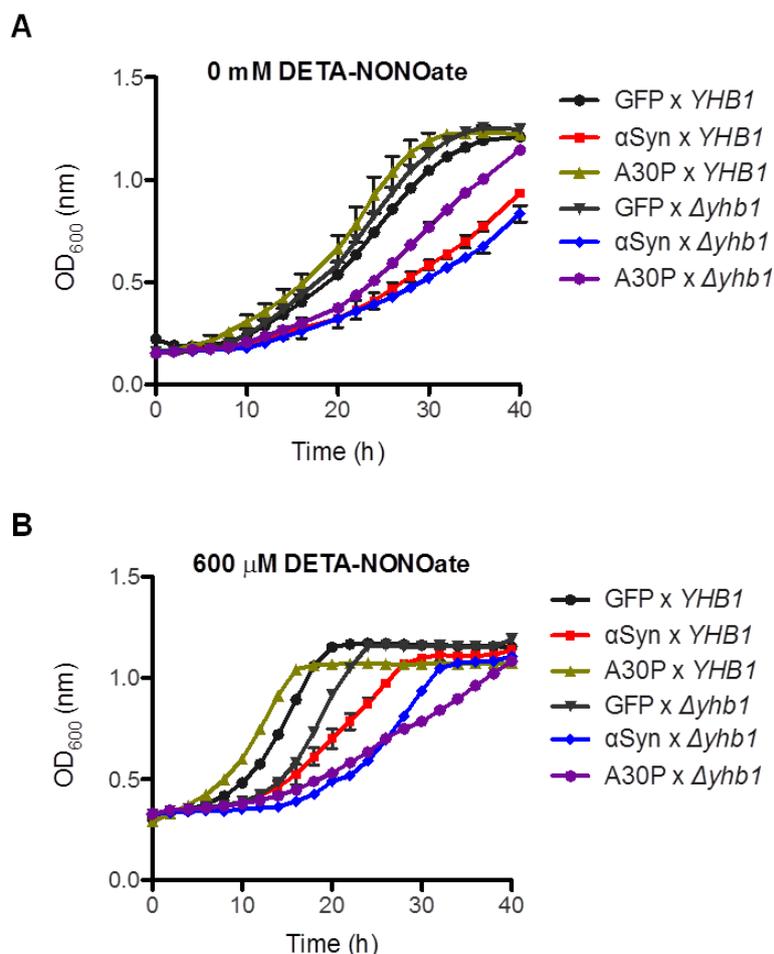

Figure 15. Yhb1 decreases sensitivity of A30P expressing cells to nitritive stress.

(A) Cell growth analysis of *YHB1* and $\Delta yhb1$ yeast cells expressing α Syn, A30P, 4(Y/F), A30P/4(Y/F) and GFP (control) after 40 hours induction in galactose-containing SC-Ura medium without DETA-NONOate. Error bars show standard deviations of three independent experiments. (B) Cell growth analysis of *YHB1* and $\Delta yhb1$ yeast cells expressing α Syn, A30P, 4(Y/F), A30P/4(Y/F) and GFP (control) with 600 μ M DETA-NONOate.

Cells expressing A30P α Syn grew uninhibited in the *YHB1* wild-type background, whereas $\Delta yhb1$ cells expressing A30P were less inhibited than α Syn, thus recapitulating the growth phenotype on solid medium (Figure 12B, 15A). In contrast, $\Delta yhb1$ cells expressing both α Syn variants were equally impaired in growth under nitritive stress conditions (Figure 15B). This indicates that increase in nitritive stress changes A30P to a toxic protein in yeast cells

comparable to wild-type α Syn. These results suggest a specific suppressive function of the nitric oxide oxidoreductase Yhb1 on A30P-induced aggregate formation and growth inhibition in yeast.

3.7 α -synuclein expression does not affect the sensitivity of yeast cells to H_2O_2

In addition to nitrate stress, oxidative stress was shown to be involved in the degeneration of dopaminergic neurons in PD. Increased levels of oxidized lipids, proteins and DNA was found in the *substantia nigra* of PD patients (Alam et al., 1997a; Alam et al., 1997b; Bosco et al., 2006). Moreover, *in vitro* studies showed that oxidative stress induces aggregation of α Syn when incubating with the reactive oxygen specie hydrogen peroxide (H_2O_2). Therefore, the sensitivity of α Syn expressing wild-type and $\Delta yhb1$ yeast cells to oxidative stress was analyzed by exposing the cells to H_2O_2 (Figure 16A). Sensitivity of yeast cells to H_2O_2 was concluded from the measured size of the growth inhibition area of cells grown on the surface of agar plates in the presence of a disc containing H_2O_2 (Figure 16B).

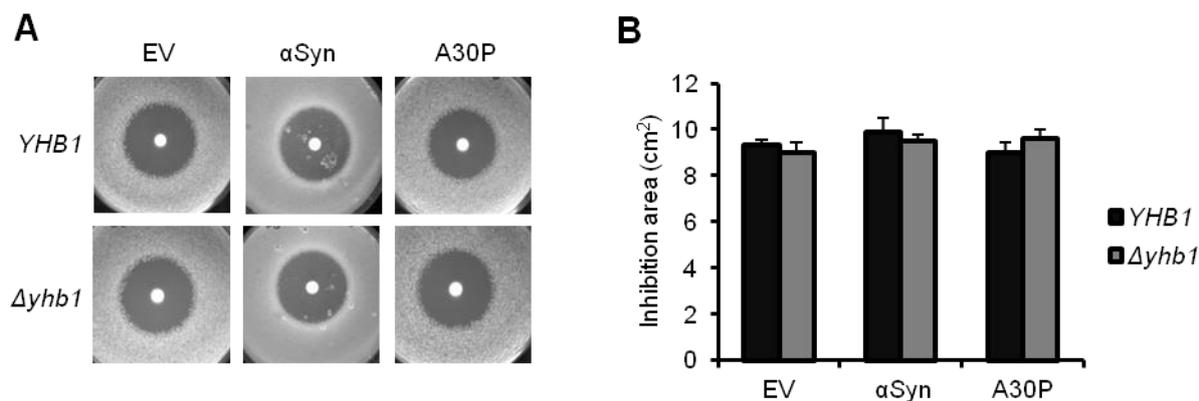

Figure 16. α Syn expression does not affect sensitivity of yeast cells to H_2O_2 .

(A) Halo assay of *YHB1* and $\Delta yhb1$ yeast cells expressing α Syn or A30P compared to empty vector (EV) as control on galactose-inducing SC-Ura medium in the presence of a Whatman paper disc containing 10 μ L 30 % H_2O_2 after three days. (B) Quantification of the inhibition area shown as cm^2 after three days induction on galactose-containing medium. Significance of differences was calculated with t-test ($n=2$).

α Syn and A30P expressing wild-type cells exhibit an equal inhibition area as the control cells expressing the empty vector (Figure 16) suggesting that expression of both α Syn variants does not change sensitivity of the yeast cells to H_2O_2 . Moreover, the inhibition area of $\Delta yhb1$ cells was similar to that of wild-type yeast cells, indicating that deletion of *YHB1* does not affect the susceptibility of yeast to oxidative stress. This result revealed that α Syn expressing cells exhibit low sensitivity to H_2O_2 under the used experimental conditions, which is not influenced by increased nitrate stress levels in *YHB1* deletion yeast.

3.8 Blockage of tyrosine nitration protects against A30P toxicity and aggregate formation under nitritative stress

The removal of the four tyrosines of α Syn as possible cellular nitration sites (4(Y/F)) might affect α Syn toxicity in yeast when the intracellular nitritative stress level is increased using the $\Delta yhb1$ strain defective in stress protection. This was examined by comparing α Syn, A30P and their tyrosine to phenylalanine replacement derivatives (4(Y/F)), which were expressed in yeast with wild-type *YHB1* or $\Delta yhb1$ deletion background. Growth was analyzed by spotting analysis and in liquid medium (Figure 17A, B).

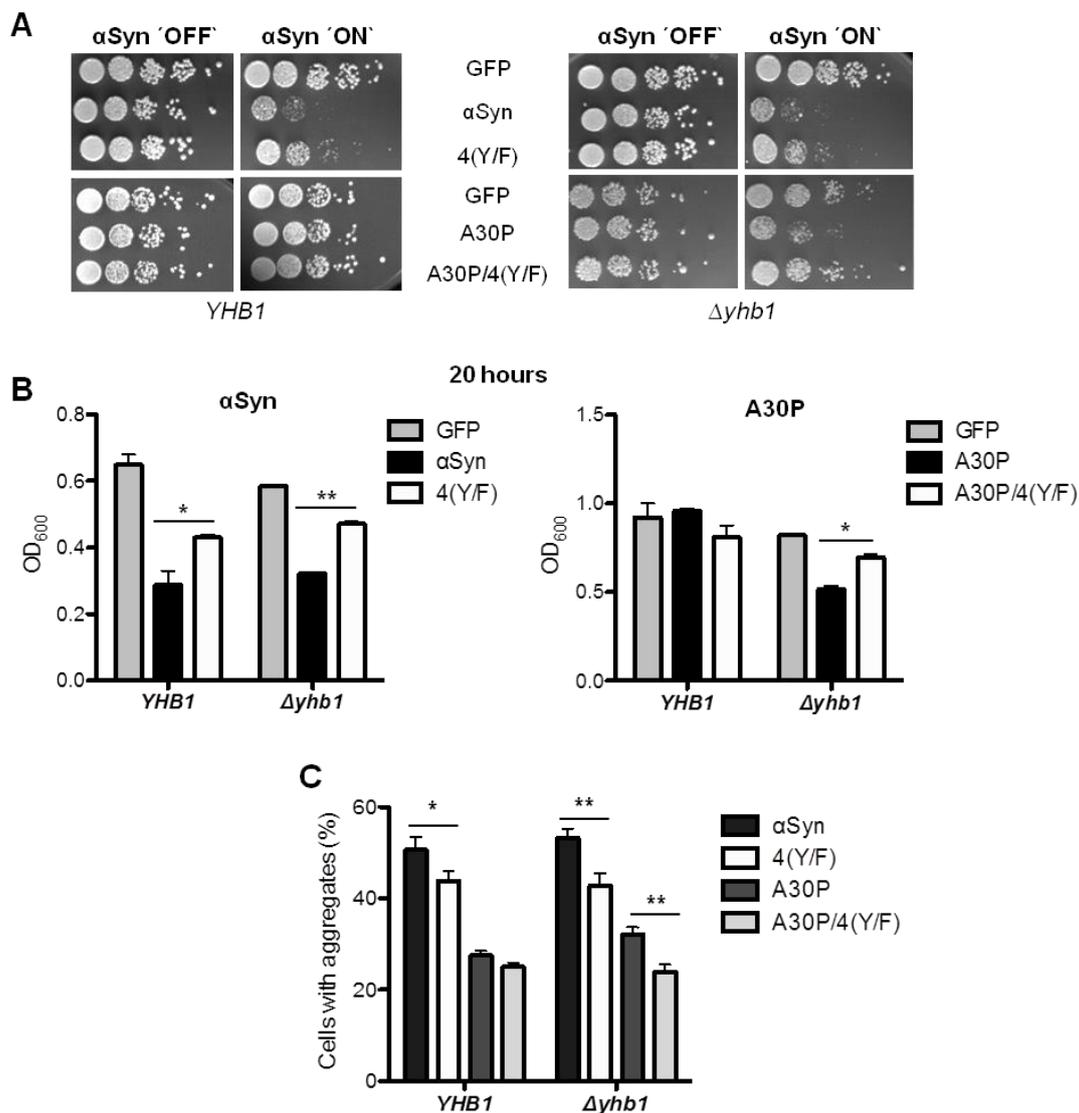

Figure 17. C-terminal tyrosine replacements of A30P decrease toxicity in $\Delta yhb1$.

(A) Spotting analysis of α Syn, A30P, 4(Y/F) α Syn, A30P/4(Y/F) and GFP (control) expressed in *YHB1* and $\Delta yhb1$ yeast on non-inducing and galactose-inducing SC-Ura plates after three days of growth. (B) Cell growth analysis of *YHB1* and $\Delta yhb1$ yeast expressing α Syn, A30P, 4(Y/F), A30P/4(Y/F) and GFP (control) at time point 20 hours. Significance of differences was calculated with t-test (*, $p < 0.05$; **, $p < 0.01$, $n=3$). (C) Quantification of the percentage of cells displaying α Syn aggregates after six hours induction in galactose-containing SC-Ura medium. Significance of differences was calculated with t-test (*, $p < 0.05$, **, $p < 0.01$, $n=6$).

Expression of 4(Y/F) α Syn with an intact *YHB1* gene resulted in improved growth, whereas A30P toxicity was not affected (Figure 10, 17A, B). In the absence of the *YHB1* gene, A30P delayed growth. However, 4(Y/F) A30P grew similar to the GFP control. A30P-mediated toxicity was related to the formation of inclusions (Figure 17C). These results corroborate that increased nitrate stress contributes to A30P toxicity by nitration of tyrosine residues. Nitration-deficient wild-type or A30P α Syn were less toxic and aggregated less, whereas an increase of intracellular nitrate stress resulted in growth retardation and increased aggregate formation of A30P variant only when tyrosine residues were present.

3.9 Yhb1 reduces the accumulation of reactive nitrogen species in A30P expressing cells

Oxidative and nitrate stresses are implicated in the pathogenesis of PD (Danielson and Andersen, 2008; Dias et al., 2013). These stresses emerge from the accumulation of reactive intermediates such as ROS and RNS. ROS and RNS production was visualized in yeast cells. α Syn and A30P expression was induced for six hours and ROS and RNS specific dyes were applied to compare the production of the reactive species in *YHB1* and $\Delta yhb1$ cells by fluorescence microscopy and flow cytometry. Dihydrorhodamine 123 (DHR123) was used for ROS detection. The dye accumulates in cells, where it is oxidized by free radicals to the bright red fluorescent product rhodamine 123 (Figure 18A, B). Expression of A30P and its derivative A30P/4(Y/F) did not significantly increase the number of cells accumulating ROS (Figure 18C). In contrast, expression of wild-type α Syn as well as its 4(Y/F) derivative strongly increased the number of cells that accumulate red fluorescence indicative for ROS. No difference in ROS accumulation was observed between the *YHB1* wild-type and the $\Delta yhb1$ mutant strain.

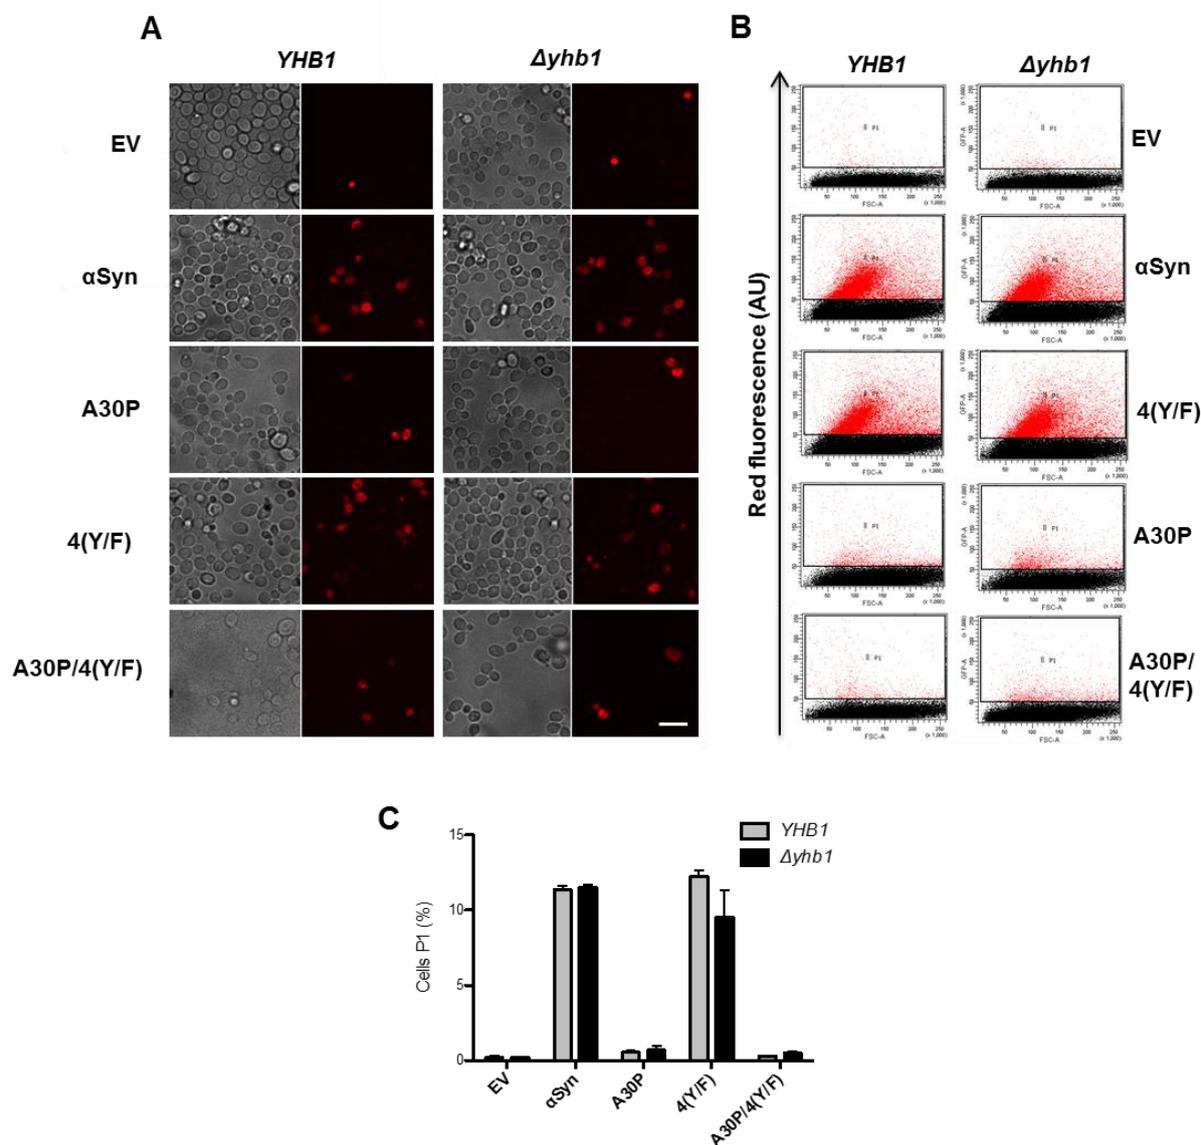

Figure 18. Expression of α Syn increases accumulation of ROS.

(A) α Syn and A30P were induced in galactose-containing medium for six hours in *YHB1* wild-type or $\Delta yhb1$ deletion yeast strains. Cells were incubated with 5 μ g/mL dihydrorhodamine 123 (DHR123) as an indicator of high intracellular ROS accumulation for 1.5 hours and analyzed by live-cell fluorescence microscopy. Scale bar = 5 μ m. (B) Fluorescent intensity of cells from (A), assessed with flow cytometry analysis. Forward scatter (FSC) and DHR123 fluorescence of cells after six hours induction of α Syn expression. (C) Quantification of α Syn and A30P expressing cells displaying ROS stained by DHR123 using flow cytometry. The percentage of the sub-population of yeast cells with higher fluorescent intensities (P1) than the background is presented.

DAF-2 DA (4,5-Diaminofluorescein diacetate) dye was used as a sensitive and highly specific fluorescent indicator for detection of NO (Figure 19A, B). Expression of both α Syn and A30P induced accumulation of reactive nitrogen species (Figure 19C). Interestingly, deletion of *YHB1* significantly increased the number of cells exhibiting RNS when A30P

variant was expressed. This effect was dependent on tyrosine residues since RNS accumulation in cells expressing A30P/4(Y/F) did not differ from empty vector control.

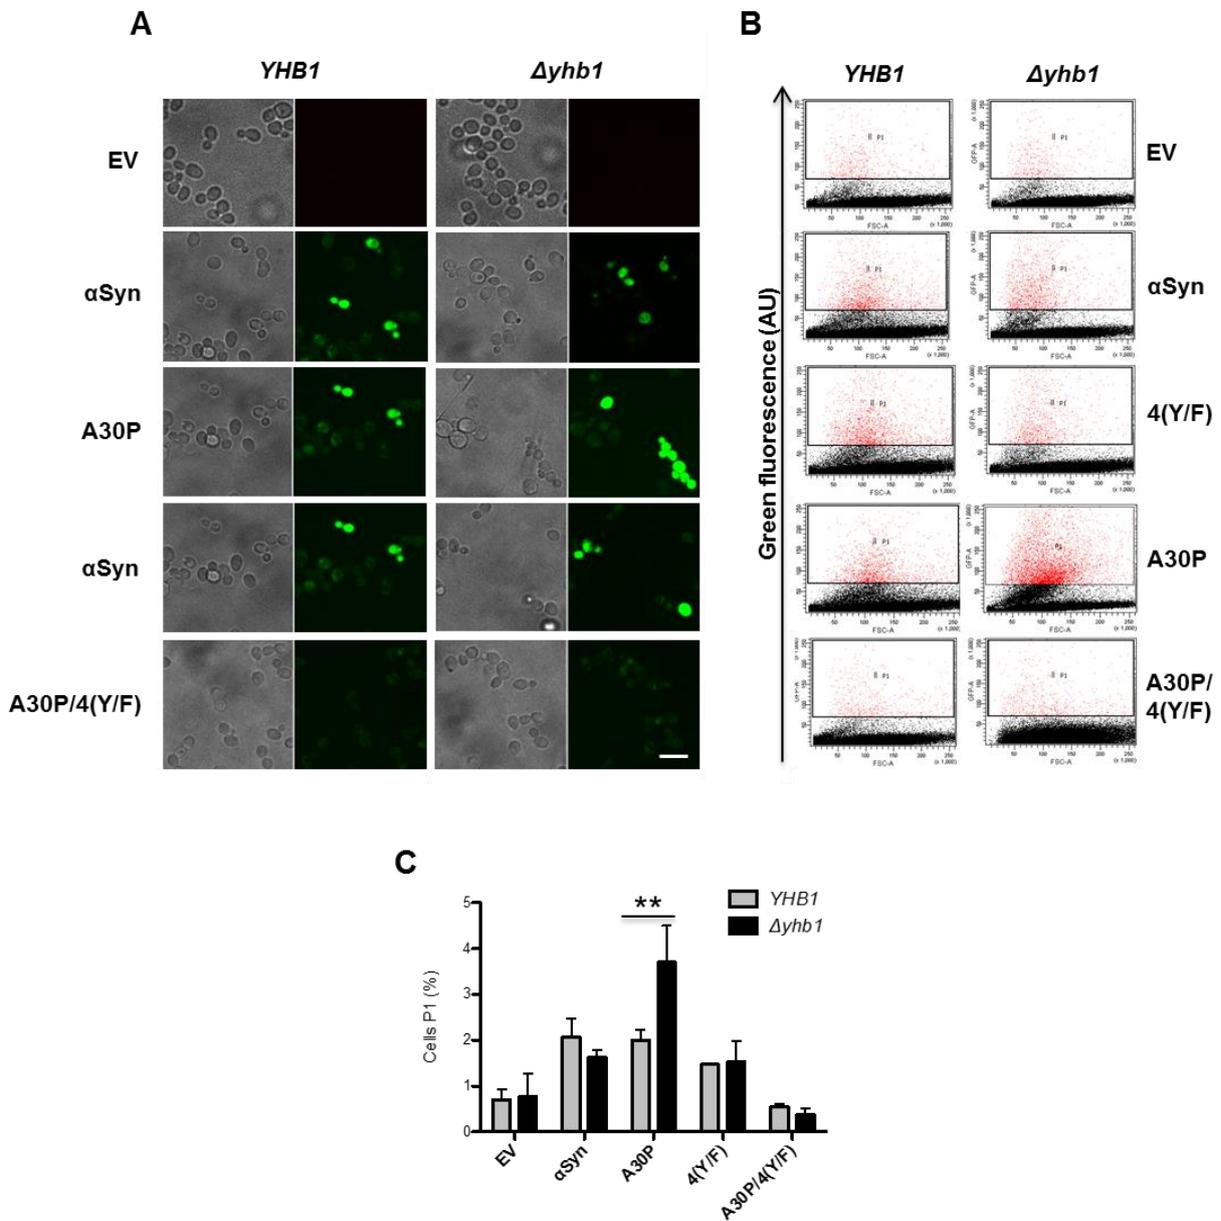

Figure 19. $\Delta yhb1$ increases accumulation of reactive nitrogen species (RNS) in A30P expressing cells.

(A) Microscopy analysis of RNS stained cells. α Syn and A30P were induced in galactose-containing SC-Ura medium for six hours in *YHB1* and $\Delta yhb1$ yeast strains. Cells were incubated with 25 μ g/mL DAF-2 DA for one hour at 30 °C for visualization of RNS and analyzed by live-cell fluorescence microscopy. Scale bar = 5 μ m. (B) Fluorescent intensity of cells from (A), assessed with flow cytometry analysis. Forward scatter (FSC) and DAF-2 DA fluorescence of cells after six hours induction of α Syn expression. (C) Quantification of α Syn and A30P expressing cells displaying RNS stained by DAF-2 DA using flow cytometry. The percentage of the sub-population of yeast cells with higher fluorescent intensities (P1) than the background is presented. Significance of differences was calculated with t-test (**, $p < 0.01$, $n=3$).

The results show that toxic wild-type α Syn expression induces significantly more ROS accumulation in yeast cells than non-toxic A30P. Accumulation of ROS species was not dependent on the presence of tyrosine residues or *YHB1* gene. In contrast, both α Syn as well as A30P induce the accumulation of RNS for oxidative stress in yeast cells. The levels of RNS in A30P but not wild-type α Syn expressing cells are dependent on the presence of tyrosine residues and *YHB1*. The results suggest that Yhb1 attenuates the accumulation of RNS of A30P expressing cells.

3.10 Yhb1 protects mitochondria from A30P toxicity

Overexpression of α Syn and A30P leads to increased levels of RNS and higher sensitivity to NO stress in $\Delta yhb1$ yeast. The Yhb1 protein is translocated into yeast mitochondria under hypoxic conditions where it detoxifies NO (Cassanova et al., 2005). Mitochondria are a major source of free radicals in the cells. Yhb1 is consuming NO, which inhibits mitochondrial respiration and thus increases the level of ROS. α Syn toxicity results in mitochondrial dysfunction and generation of ROS (Su et al., 2010). Overexpression of α Syn in mammalian cells results in mitochondrial fragmentation and involves a direct interaction of α Syn with mitochondrial membranes (Nakamura et al., 2011).

It was examined, whether deletion of *YHB1* influences the mitochondrial morphology in α Syn and A30P α Syn expressing yeast cells. α Syn expression in the wild-type and $\Delta yhb1$ background was induced for six hours in galactose medium and the mitochondria were visualized with a mitochondrial specific dye (MitoTracker Red). Yeast cells overexpressing GFP served as a control (Figure 20A). Co-localization of α Syn with mitochondria was not observed, which suggests that the described mitochondrial fraction of the protein might be small (Nakamura et al., 2011). The mitochondrial morphology was classified as tubular, partially fragmented or fully fragmented. In the control cells, the mitochondria revealed a ribbon-like tubular architecture, typical for healthy mitochondria. Cells expressing α Syn showed a dramatic increase in the percentage of cells with fully fragmented mitochondria (Figure 20A, B).

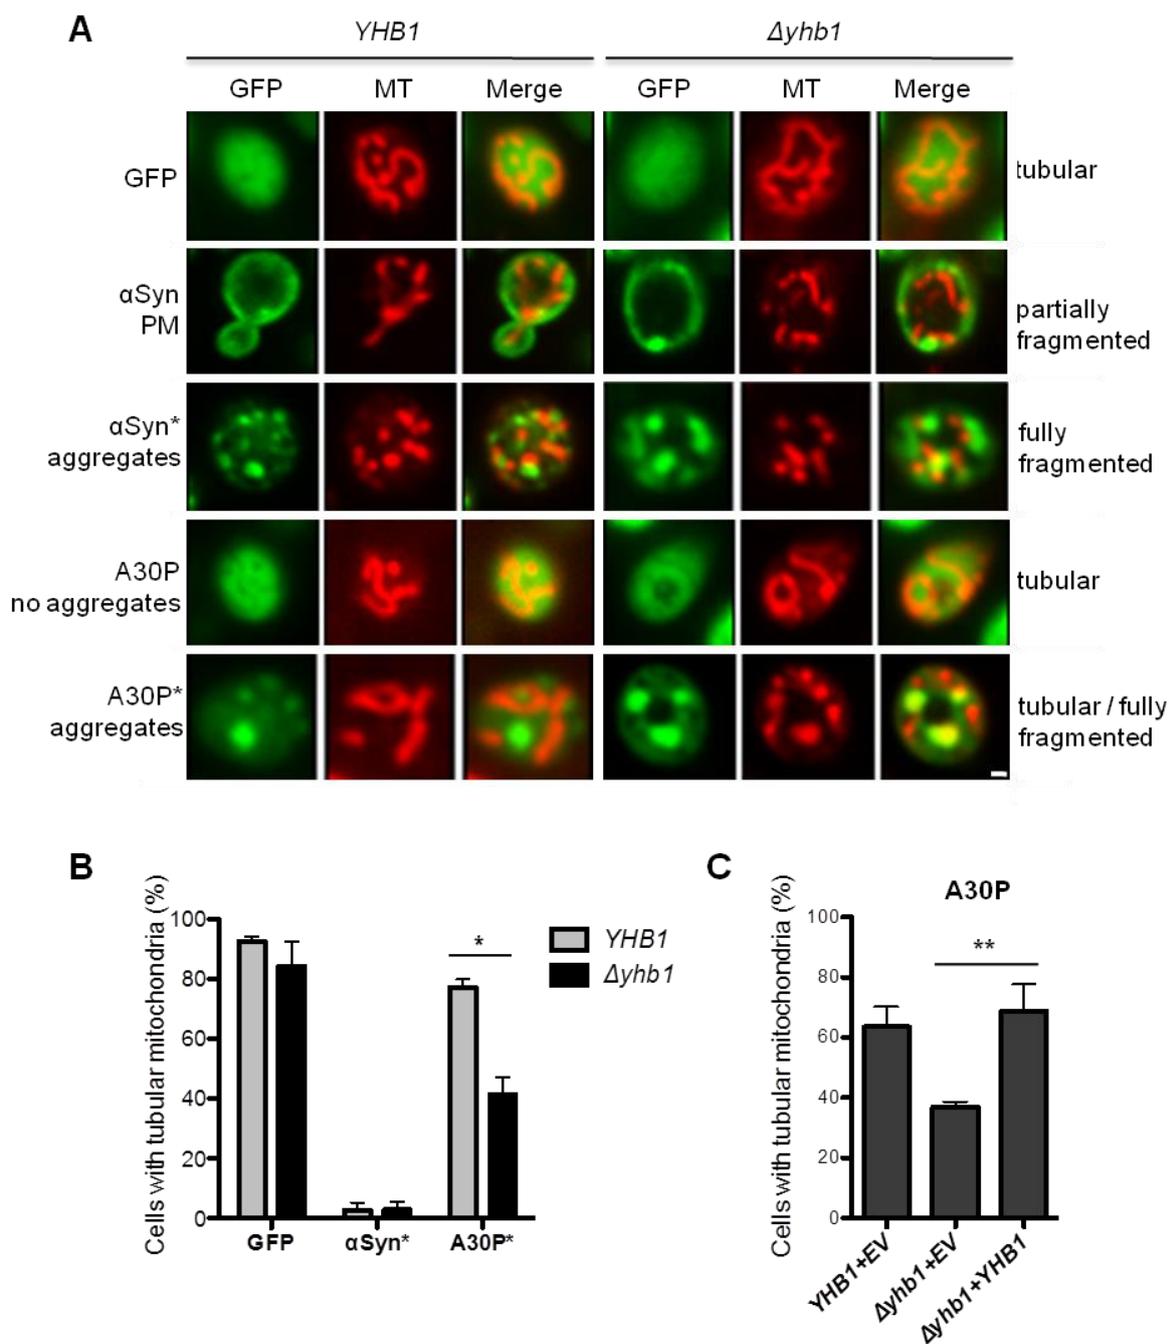

Figure 20. Yhb1 protects mitochondria from A30P toxicity.

(A) Live-cell fluorescence microscopy of *YHB1* compared to $\Delta yhb1$ yeast cells expressing GFP (control), α Syn or A30P after six hours induction in galactose-containing medium. MitoTracker Red was used to visualize mitochondria in the cells (MT panel). α Syn expressing cells with plasma membrane localization (PM) and with aggregates are visualized. Scale bar = 1 μ M. (B) Quantification of yeast cells with tubular mitochondrial network. GFP: percentage of all cells with tubular mitochondria; α Syn* and A30P*: percentage of cells with aggregates, showing tubular mitochondria. At least 50 cells were counted per cell type and experiment. Significance of differences was calculated with t-test (*, $p < 0.05$, $n=4$). (C) Quantification of yeast cells with tubular mitochondrial network for rescue of A30P phenotype. A30P with empty vector (EV) in *YHB1* and $\Delta yhb1$ strain and A30P co-transformed with *YHB1* on low-copy vector in $\Delta yhb1$ strain. A30P*: percentage of cells with aggregates, showing tubular mitochondria. Significance of differences was calculated with t-test (**, $p < 0.01$, $n=3$).

Cells with and without inclusions were considered separately for statistical evaluation. Cells with plasma-membrane localization of the GFP-signal, typical α Syn localization for early stages of expression or lower expression levels, revealed partially fragmented mitochondrial architecture. α Syn expressing cells with aggregates had fully fragmented mitochondria. In contrast to α Syn, A30P expressing cells with aggregates had mainly tubular mitochondria, similar to the control cells (Figure 20A). Deletion of *YHB1* increased the percentage of cells with fully fragmented mitochondria almost two-fold (Figure 20B). Thus, the disrupted mitochondrial morphology in $\Delta yhb1$ correlates with the increased levels of RNS (Figure 19) and diminished growth behavior of A30P expressing cells (Figure 12B). Complementation of the $\Delta yhb1$ phenotype in A30P expressing cells rescued the defect (Figure 20C), as mitochondrial morphology was recovered by expression of *YHB1* on a low-copy vector. The result suggests that Yhb1 protects against A30P-induced cytotoxicity by preventing the mitochondrial fragmentation.

3.11 Mitochondrial functionality is not affected by Yhb1 in A30P expressing yeast cells

Analysis of mitochondrial morphology revealed an *YHB1*-dependent mitochondrial fragmentation upon A30P expression. In the next step, it was investigated how mitochondrial functionality is affected by *YHB1* deletion. Mitochondrial respiration was assessed by measuring the oxygen consumption rate (OCR) under mitochondrial stress conditions by applying the mitochondrial inhibitors oligomycin A and antimycin A and the mitochondrial uncoupler fluoro-carbonyl cyanide phenylhydrazone (FCCP). After six hours induction of α Syn or A30P expression in *YHB1* yeast cells, no significant differences in the basal respiration could be detected (Figure 21A). However, expression of α Syn and A30P in $\Delta yhb1$ diminished basal respiration of the cells.

Interestingly, under stimulating conditions increased OCR was observed in $\Delta yhb1$ cells expressing A30P compared to *YHB1* yeast, suggesting that these cells have higher reserve capacity (Figure 21B). Addition of oligomycin A, which is an inhibitor of the mitochondrial ATP synthase, had only a moderate inhibitory effect on OCR. It is known that the yeast ATP synthase is less sensitive to oligomycin A than the animal mitochondrial ATP synthase. The gene *YOR1* (Yeast Oligomycin Resistance) is responsible for the tolerance to this drug (Katzmann et al., 1995). Addition of antimycin A strongly inhibited respiration in all strains. The reported severe effect of antimycin A on yeast mitochondrial respiration is in agreement with earlier investigations (Ocampo et al., 2012). The remaining oxygen consumption reveals the extent of non-mitochondrial sources of oxygen consumption in the cells (Figure 21C).

Non-mitochondrial respiration results from oxygen consumption of cytosolic oxidase enzymes. The formation of reactive oxygen and nitrogen species was shown to increase non-mitochondrial respiration (Chacko et al., 2014; Dranka et al., 2010; Hill et al., 2012).

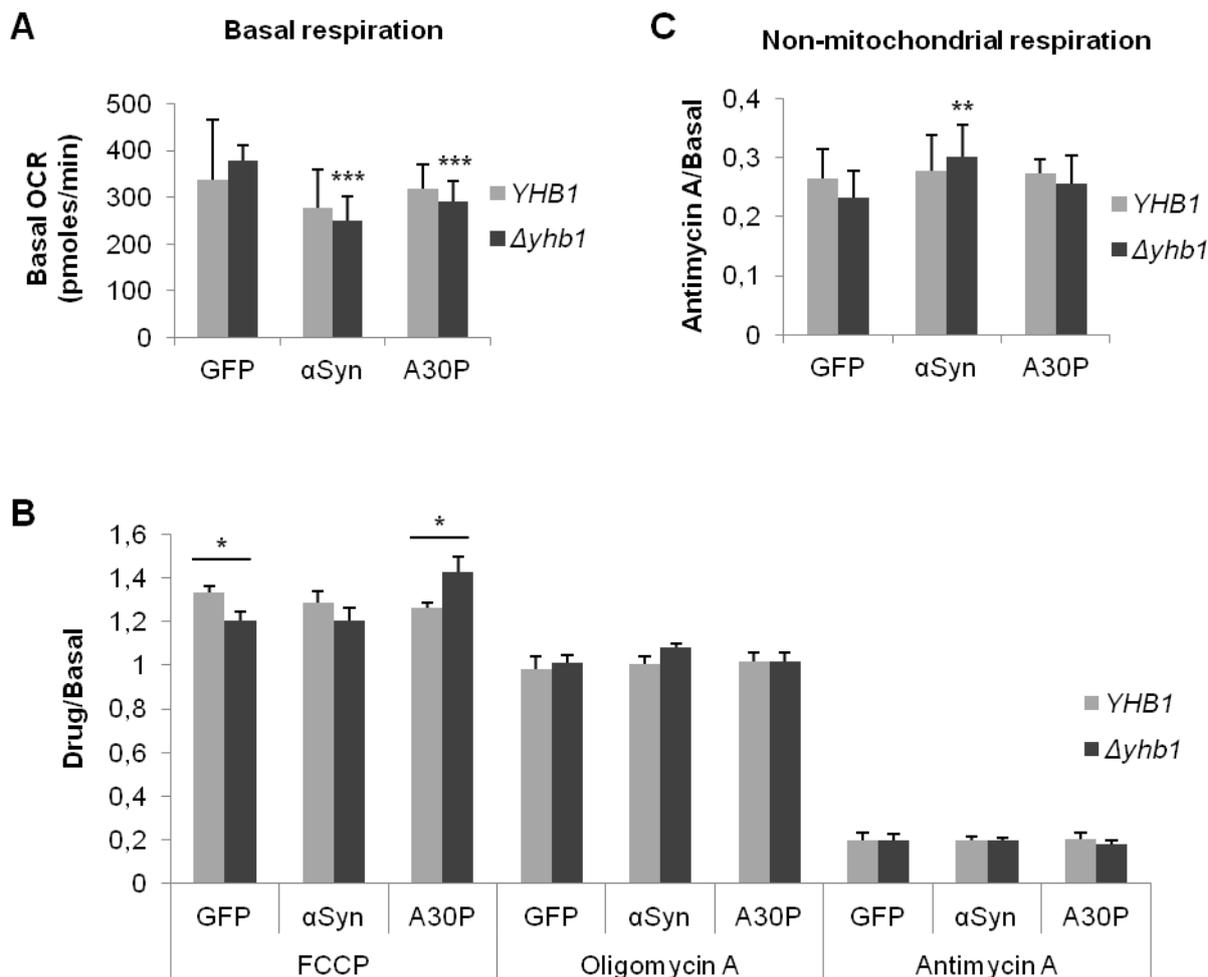

Figure 21. Mitochondrial functionality is not affected by Yhb1 in A30P expressing yeast cells.

(A) Measurement of basal oxygen consumption rate (OCR) of *YHB1* and $\Delta yhb1$ strains expressing α Syn, A30P and GFP (control) after six hours induction in galactose-containing SC-Ura medium. OCR is shown as absolute values in picomoles per minute after subtraction of non-mitochondrial respiration. Significance of differences was calculated with t-test (***, $p < 0.001$ versus GFP control; $n=9$). (B) Shown is OCR of *YHB1* and $\Delta yhb1$ strains expressing α Syn, A30P and GFP (control) after six hours induction in galactose-containing SC-Ura medium normalized to basal respiration. OCR was measured after consecutive application of 2 μ M fluoro-carbonyl cyanide phenylhydrazone (FCCP), 20 μ M oligomycin A and 50 μ M antimycin A. OCR is shown as ratio normalized to basal respiration. Significance of differences was calculated with t-test (*, $p < 0.05$, $n=9$). (C) Shown is the non-mitochondrial respiration of *YHB1* and $\Delta yhb1$ strains expressing α Syn, A30P and GFP (control) after six hours α Syn induction as ratio of OCR of antimycin A (50 μ M) treated cells to basal OCR. Significance of differences was calculated with t-test (**, $p < 0.01$ versus GFP control; $n=9$).

In wild-type yeast, no differences in non-mitochondrial respiration were observed between control cells expressing GFP and cells expressing the two α Syn variants (Figure 21C). However, $\Delta yhb1$ cells expressing wild-type α Syn revealed increased non-mitochondrial respiration, which might be due to enhanced oxygen consumption by cytosolic oxidases or increased formation of reactive oxygen and nitrogen species. These results indicate that α Syn-induced mitochondrial fragmentation does not compromise the bioenergetics of mitochondria when α Syn is overexpressed in yeast. However, non-mitochondrial oxygen consumption is varied in $\Delta yhb1$ cells expressing wild-type α Syn.

3.12 Human neuroglobin protects against α -synuclein aggregate formation in yeast and in mammalian cells

A BLAST search for human genes corresponding to yeast *YHB1* revealed 49 % similarities of the *YHB1* globin domain to the gene for human neuroglobin (*NGB*) as a putative homolog. It was analyzed whether the human counterpart of yeast *YHB1* can affect α Syn aggregation. Neuroglobins are oxygen-binding proteins that are highly conserved among vertebrates and are expressed in the central and peripheral nervous system. They provide protection against hypoxic induced cell injury in the brain, which is associated with ROS and RNS accumulation (Greenberg et al., 2008). Both Yhb1 and neuroglobin contain a globin domain and are members of the globin gene family. *NGB* was shown to diminish beta-amyloid-induced neurotoxicity *in vitro* and to attenuate the phenotypes in a transgenic mouse model of Alzheimer's disease (Khan et al., 2007). *NGB* acts as an oxidative stress-responsive sensor for neuroprotection (Watanabe et al., 2012).

It was examined, whether human *NGB* affects α Syn or A30P growth and aggregate formation in yeast. Growth and aggregation of α Syn was not changed by the expression of the human *NGB* (Figure 22A, B). However, *NGB* expression in $\Delta yhb1$ deletion strain rescued A30P yeast growth (Figure 22A) and reduced the number of cells with A30P aggregates (Figure 22C). The effect of *NGB* in yeast is similar to the impact of *YHB1* on α Syn and A30P growth and aggregate formation (Figure 12B, 13A).

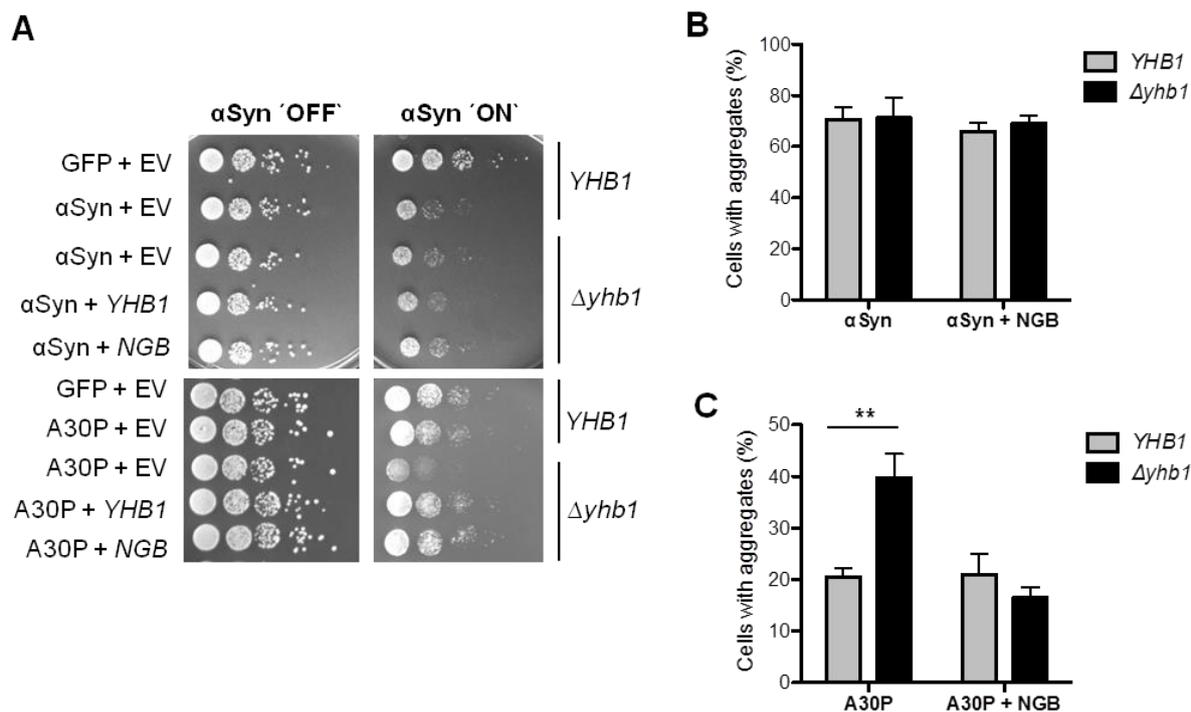

Figure 22. The human *NGB* gene for neuroglobin complements A30P growth in *YHB1* deletion yeast.

(A) Spotting analysis of *YHB1* and $\Delta yhb1$ yeast cells co-expressing α Syn and GFP (control) (upper panel) or A30P and GFP (lower panel) with either empty vector as control or *YHB1* and *NGB*, respectively on non-inducing and galactose-inducing SC-Ura medium after three days. (B) Quantification of the percentage of cells displaying α Syn aggregates after six hours induction in galactose-containing medium ($n=3$). (C) Quantification of the percentage of cells displaying A30P aggregates after six hours induction in galactose-containing medium. Significance of differences was calculated with t-test (**, $p < 0.01$, $n=3$).

It was examined, whether *NGB* has not only a protective role against α Syn aggregate formation in yeast but also in mammalian cells. Human Neuroglioma cells (H4) served as established α Syn aggregation model, where aggregation of α Syn is induced by co-expressing C-terminally modified α Syn (SynT) and synphilin-1, α Syn-interacting protein that was also found in LBs (Engelender et al., 1999; Lazaro et al., 2014). H4 cells were co-transfected with SynT, Synphilin-1 and *NGB* or empty vector and aggregate formation of SynT was monitored (Figure 23).

Expression of *NGB* reduced the number of cells with aggregates almost two-fold in comparison to the control and reduced the number of aggregates per cell (Figure 23A, B). These results support that similar to its yeast counterpart *YHB1*, the stress response gene *NGB* is a putative suppressor of α Syn aggregation in mammalian cells.

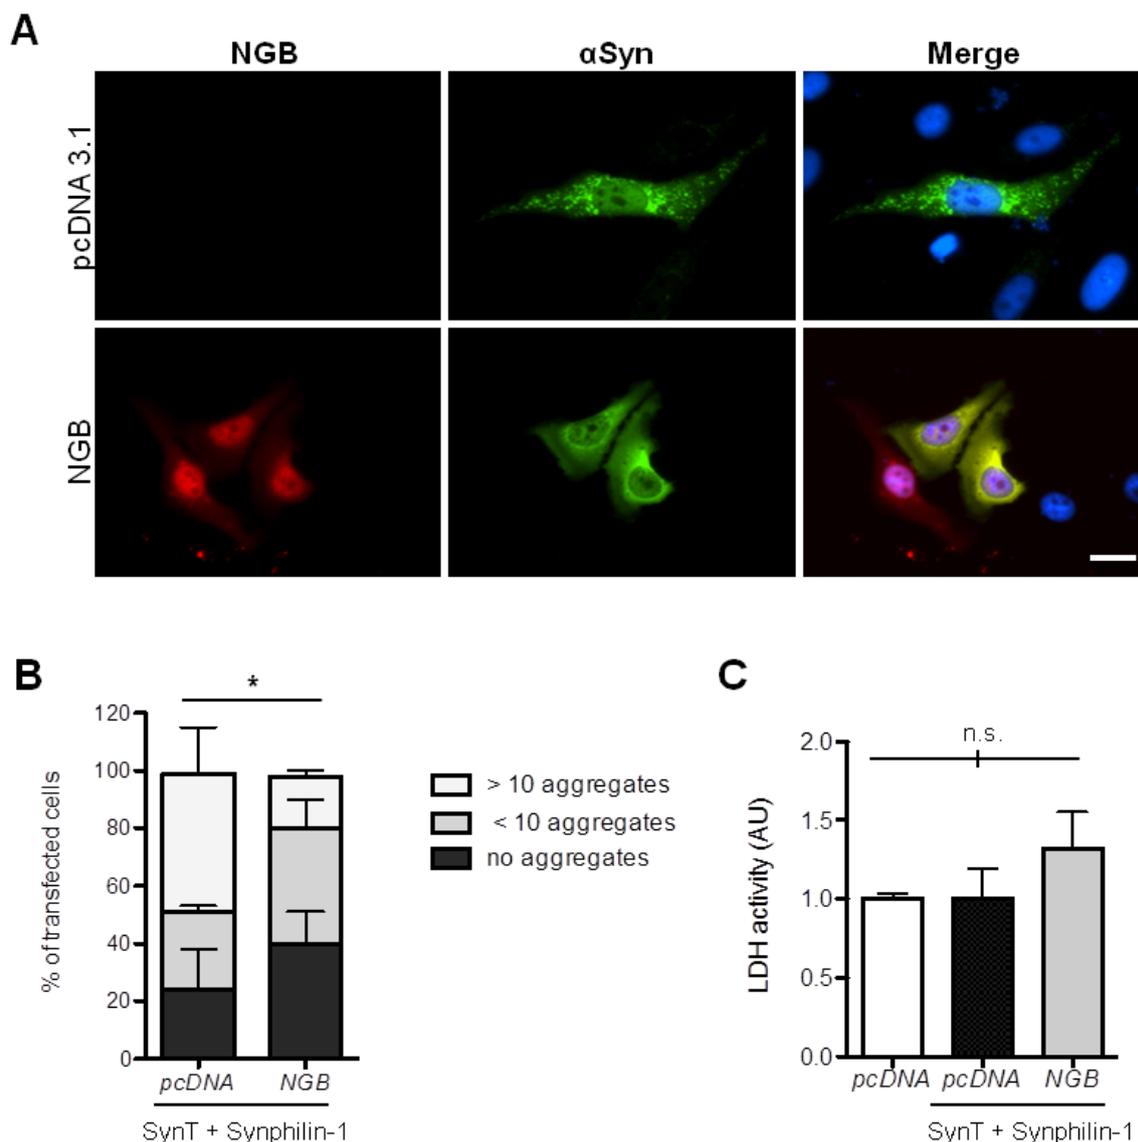

Figure 23. The human *NGB* gene for neuroglobin alters α Syn aggregation in mammalian cells.

(A) Fluorescence microscopy of H4 cells co-expressing SynT, Synphilin-1 and pcDNA (control) or *NGB*-mCherry. Nuclei are stained with Hoechst dye (blue). Scale bar = 30 μ m. (B) Quantification of the percentage of H4 cells displaying α Syn inclusions after 48 hours after transfection. Cells were classified into three groups according to the number of α Syn-immunoreactive inclusions observed: cells with 10 inclusions, cells with less than 10 inclusions and cells without inclusions. Significance of differences was calculated with one-way ANOVA (*, $p < 0.05$, $n=3$). (C) Lactate dehydrogenase (LDH) activity measurements support that *NGB* is non-toxic for H4 cells. H4 cells transfected with empty mammalian expression vector pcDNA3.1, with empty pcDNA3.1 or pcDNA3.1 encoding neuroglobin-mCherry (*NGB*) together with SynT and symphilin-1 (SynT+Synphilin-1) were analyzed. Media from indicated H4 cells were collected and the secretion of lactate LDH was determined as a measure of cytotoxicity. Significance of differences were calculated with t-test (not significant; $n=3$).

Lactate dehydrogenase (LDH) measurements were performed to determine, whether there is an effect of *NGB* on cell toxicity. LDH is released into the cell culture medium upon damage of the plasma membrane and is, therefore, a widely used marker in cytotoxicity studies. LDH measurements were similar for all tested H4 cells (Figure 23C). The results support that the stress response gene *NGB* does act as suppressor of α Syn aggregation without significantly affecting the cytotoxicity.

3.13 Yhb1 affects nitration but not dimerization level of A30P

It was assessed, whether the different cytotoxicity of α Syn and A30P in yeast correlates with different nitration levels of the two variants in wild-type yeast background and under increased nitrative stress in $\Delta yhb1$ strain. Immunoblotting performed with two specific antibodies against nitrotyrosine (3-nitrotyrosine and nitro-Y39 α Syn) showed that α Syn and A30P are nitrated in the *YHB1* as well as in $\Delta yhb1$ yeast (Figure 24A).

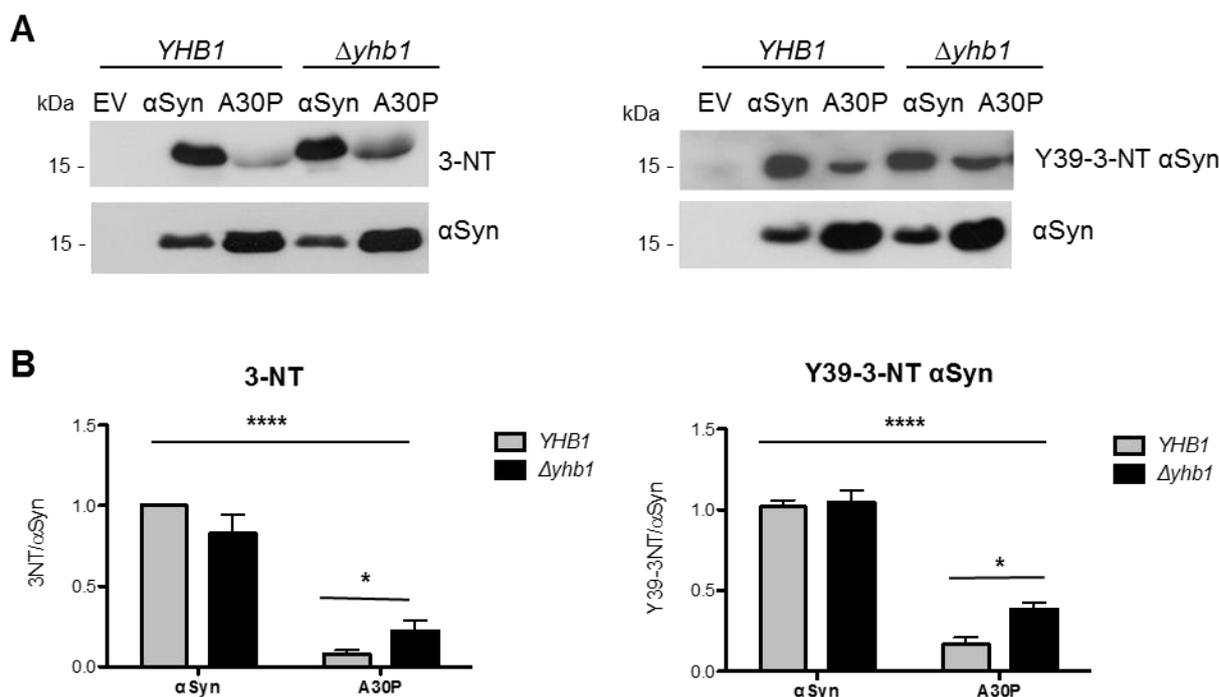

Figure 24. Yhb1 affects nitration of A30P.

(A) Immunoblotting of 3-nitrotyrosine using 3-nitrotyrosine antibody (3-NT, left) and nitro-Y39 α Syn antibody (Y39-3-NT α Syn, right). Protein expression was induced for 12 hours in galactose-containing SC-Ura medium. Concentrated protein extracts of Ni^{2+} pull down-enriched α Syn and A30P α Syn from *YHB1* and $\Delta yhb1$ yeast cells were applied. Cells expressing empty vector (EV) served as control. The same membranes were stripped and re-probed with α Syn antibody. (B) Quantification of α Syn and A30P nitration levels in *YHB1* and $\Delta yhb1$ yeast cells. Densitometric analysis of the immunodetection of nitrated α Syn and A30P relative to the intensity obtained for α Syn. Significance of differences was calculated with one-way ANOVA with Bonferroni's multiple comparison test (*, $p < 0.05$; ****, $p < 0.0001$; $n=3$).

Quantification of band intensities of both nitrated α Syn variants revealed significantly higher nitration level of α Syn in comparison to A30P. Deletion of *YHB1* resulted in increase of A30P nitration level, whereas α Syn nitration level was not affected (Figure 24B).

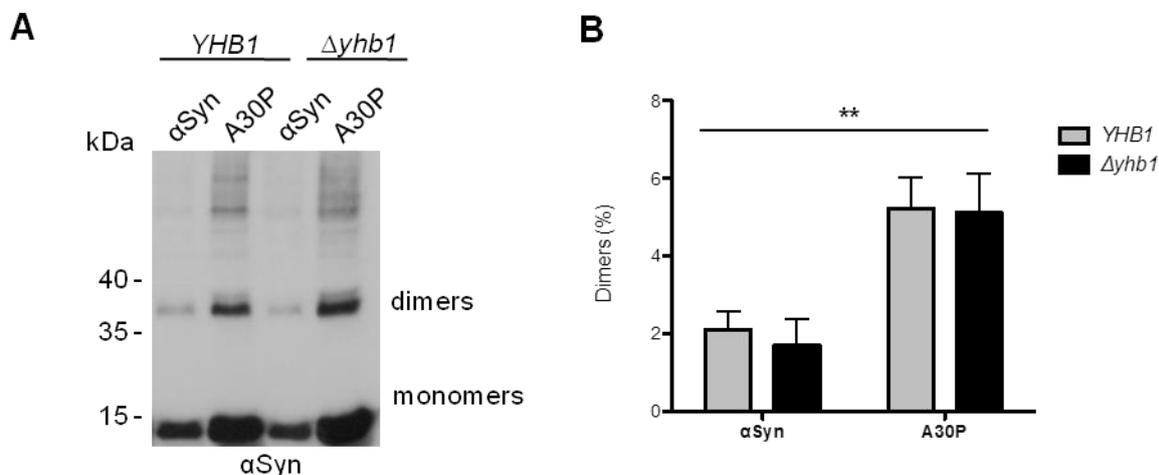

Figure 25. Yhb1 affects nitration but not dimerization of α Syn and A30P.

(A) Immunoblotting of α Syn enriched by Ni^{2+} pull-down with α Syn antibody. (B) Ratio of dimers relative to the sum of monomers and dimers. Densitometric analysis of the immunodetection of α Syn and A30P α Syn dimers, presented as percent of the total amount of α Syn detected per lane (monomer + dimer). Significance of differences was calculated with one-way ANOVA (**, $p < 0.01$; $n=4$).

The increased nitration level does not correlate with an increased dimerization level of both α Syn variants. The dimerization was not influenced by nitrative stress enhancement (Figure 25A, B). The results suggest that nitration of α Syn contributes to the cytotoxicity of the protein, whereas dimer formation is in reverse correlation to toxicity.

3.14 Tyrosine 133 is required for phosphorylation of α -synuclein at serine 129

Phosphorylation of Y125 is required *in vitro* as a priming event for efficient phosphorylation of S129 by casein kinase CK1 (Kosten et al., 2014). Phosphorylation of S129 is the major PTM of α Syn, found in 90 % of the aggregated protein in neuronal inclusions of PD patients (Anderson et al., 2006). α Syn and A30P are phosphorylated at S129 in yeast by endogenous kinases and phosphorylation has a protective role against α Syn-induced toxicity and aggregate formation (Shahpasandzadeh et al., 2014; Tenreiro et al., 2014b). Given the importance of these PTM and the close proximity of serine and tyrosine residues at the C-terminus, it was assessed whether there is a cross-talk between modifications of tyrosine residues and phosphorylation of α Syn at S129 *in vivo*. Immunoblotting with an antibody that

specifically recognizes α Syn phosphorylated at Y133 showed that both α Syn and A30P are phosphorylated at these residues, in accordance with our results from MS analysis (Figure 26A).

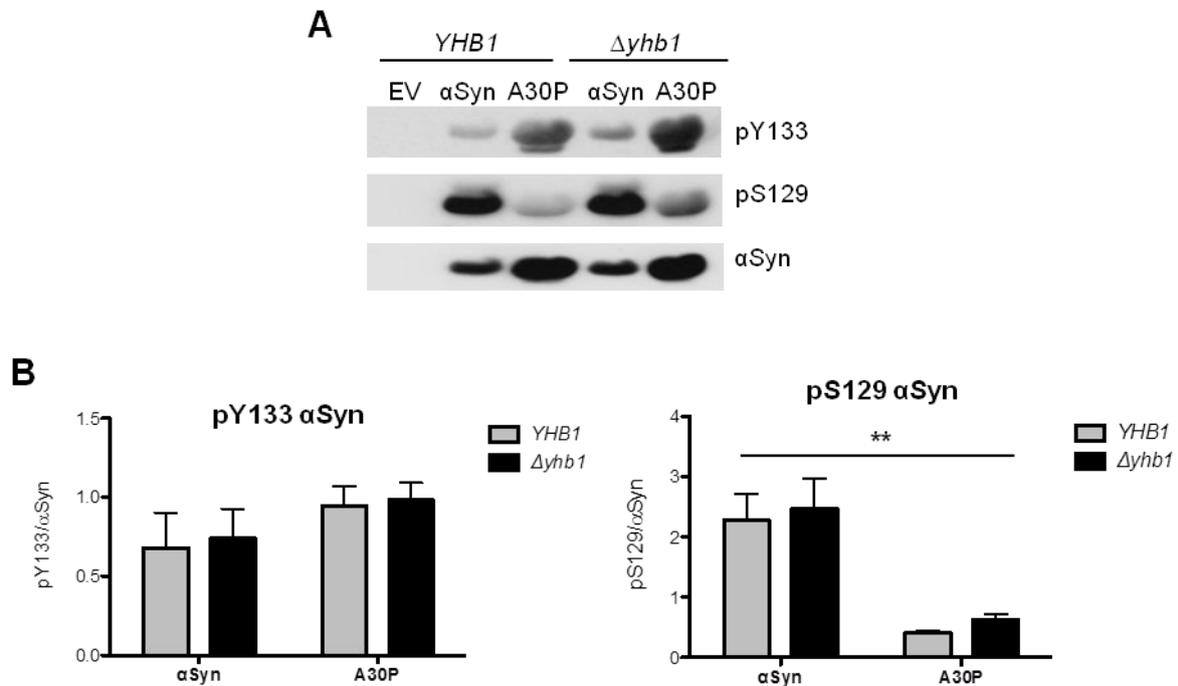

Figure 26. α Syn has a higher S129 phosphorylation level than A30P.

(A) Immunoblotting of α Syn and A30P expressed in *YHB1* and Δ *yhb1* yeast enriched by Ni^{2+} pull-down, using Y133 phosphorylation-specific α Syn antibody (pY133) and S129 phosphorylation-specific α Syn antibody (pS129). The same membrane was stripped and re-probed with α Syn antibody. (B) Quantification of α Syn and A30P Y133- and S129-phosphorylation levels in *YHB1* and Δ *yhb1* yeast cells. Densitometric analysis of the immunodetection of pY133, pS129 α Syn and A30P relative to the intensity obtained for α Syn. Significance of differences was calculated with one-way ANOVA test (**, $p < 0.01$; $n=4$).

Quantification of Y133 phosphorylation revealed similar phosphorylation level of α Syn and A30P variant both in presence and absence of Yhb1 (Figure 26A, B). Next, it was analyzed whether there is a difference between S129 phosphorylation level of α Syn and A30P. S129 phosphorylation level of α Syn was much higher than that of A30P (Figure 26A, B).

Tyrosine to phenylalanine (Y/F) substitutions were analyzed for their effects on the phosphorylation level at S129. Y/F mutation of the N-terminal tyrosine 39 as well as of the C-terminal Y125 and Y136 did not affect the phosphorylation status of S129 (Figure 27A). In contrast, mutation of Y133 had a drastic impact and resulted in complete loss of phosphorylation at S129. Yeast growth was compared in spotting assay as well as in liquid culture between yeast cells, expressing Y/F single mutants and S129A phosphorylation deficient mutant (Figure 27B, C). Yeast growth was measured after 20 hours induction of

protein expression. Expression of Y133F resulted in significant growth inhibition in comparison with α Syn and other tyrosine mutants. S129A showed slight growth inhibition (Figure 27B, C) and significant increase in the number of cells with aggregates (Figure 27D).

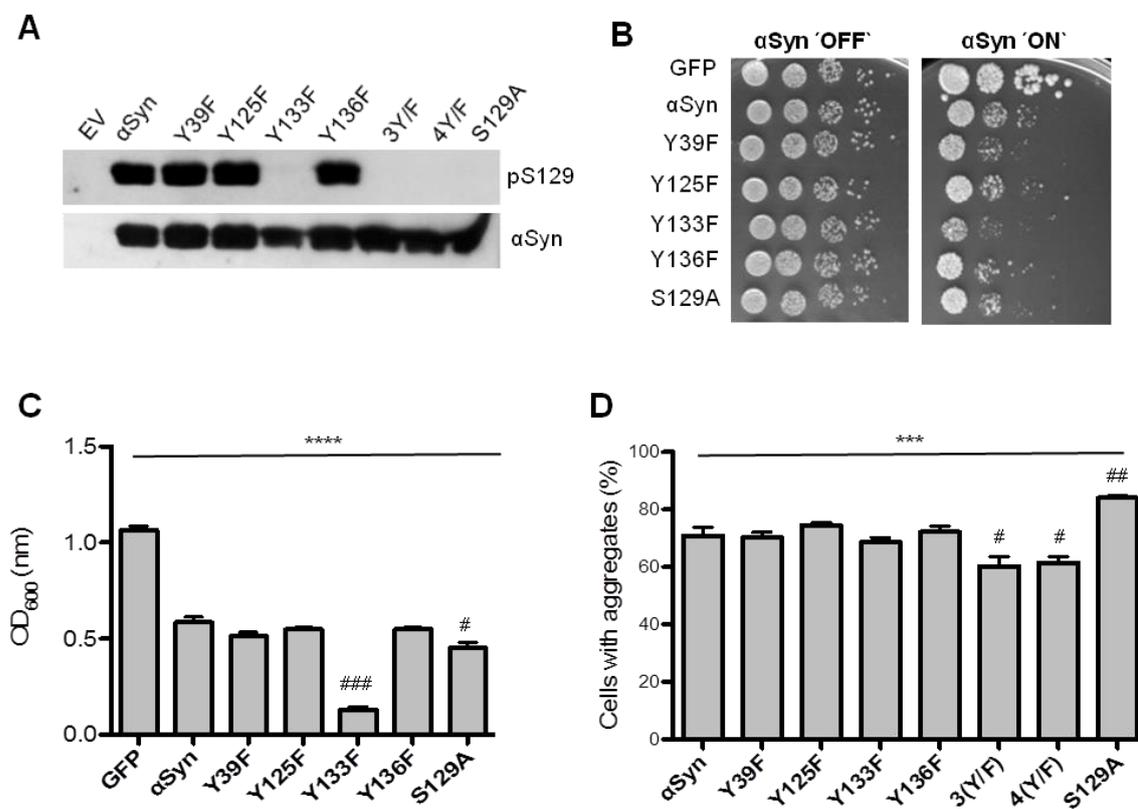

Figure 27. Tyrosine 133 is required for phosphorylation of α Syn at serine 129.

(A) Immunoblotting of crude extracts from yeast cells, expressing different α Syn variants after six hours induction of protein expression using S129 phosphorylation-specific α Syn antibody (pS129) and α Syn antibody. Cells expressing S129A mutant served as control. (B) Spotting analysis of α Syn and indicated mutant strains driven by the inducible *GAL1*-promoter on non-inducing ('OFF': glucose) and inducing ('ON': galactose) SC-Ura medium after three days. Yeast cells overexpressing GFP served as control. (C) Cell growth analysis of cells expressing different α Syn variants and GFP (control) after 20 hours induction of expression in galactose-containing SC-Ura medium. Significance of differences was calculated with one-way ANOVA (****, $p < 0.0001$) or Dunnett's multiple comparison test (#, $p < 0.05$; ###, $p < 0.001$, $n=4$). (D) Quantification of the percentage of cells displaying α Syn aggregates after six hours induction in galactose-containing SC-Ura medium. Significance of differences was calculated with one-way ANOVA (***, $p < 0.001$) or Dunnett's multiple comparison test (#, $p < 0.05$, ##, $p < 0.01$ versus α Syn; $n=6$).

In addition to growth analysis, membrane integrity of the Y/F single mutants and S129A phosphorylation deficient mutant was examined to assess the cell viability of the mutants (Figure 28). Propidium iodide (PI) staining was used after 20 hours of protein induction as a sensitive method to determine the fraction of cells with compromised membrane integrity.

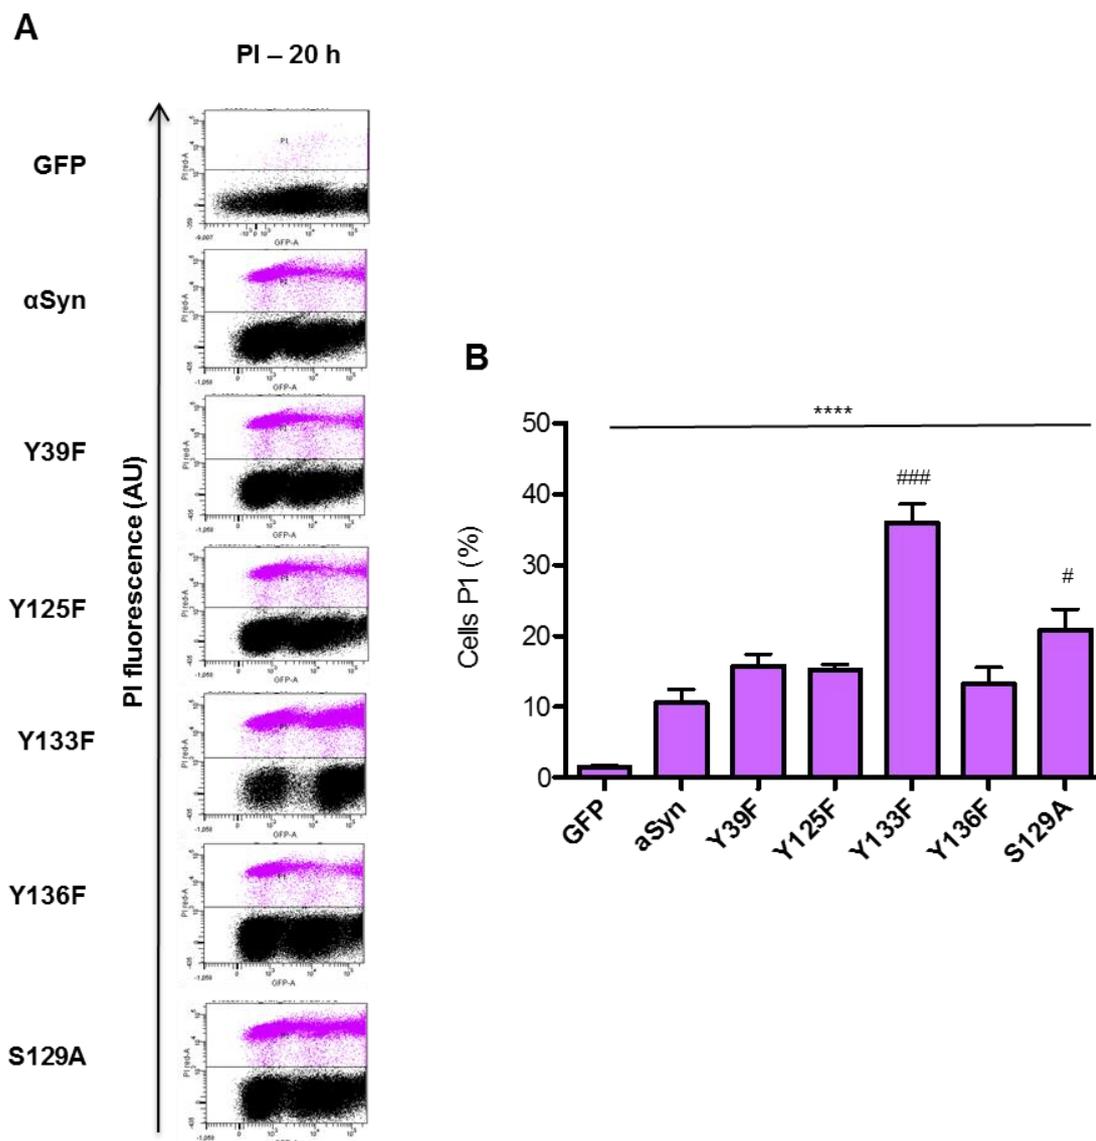

Figure 28. Y133F and S129A mutations increase α Syn-mediated cytotoxicity.

(A) Forward scatter (FSC) of cells assessed with flow cytometry analysis. Cells expressing different α Syn variants and GFP (control) after 20 hours induction of expression were stained with 12.5 μ M PI for 30 minutes. Shown is one representative result from at least four independent experiments. (B) Quantification of cells expressing different α Syn variants and GFP (control) displaying Propidium Iodide (PI) fluorescence after 20 hours induction of α Syn expression, assessed by flow cytometry. The percentage of PI-positive yeast cells with higher fluorescent intensities (P1) than the background is presented. Significance of differences was calculated with one-way ANOVA (****, $p < 0.0001$) or Dunnett's multiple comparison test (#, $p < 0.05$; ###, $p < 0.001$ versus α Syn; $n=4$).

Expression of Y133F and S129A significantly diminished membrane integrity, corroborating that expression of these mutants result in increased cytotoxicity. Flow cytometry measurements were performed to determine the accumulation of ROS and RNS in yeast cells, expressing the single mutants. DHR123 was used for detection of ROS (Figure 29A, C) and DAF-2 DA was used for detection of RNS (Figure 29B, D).

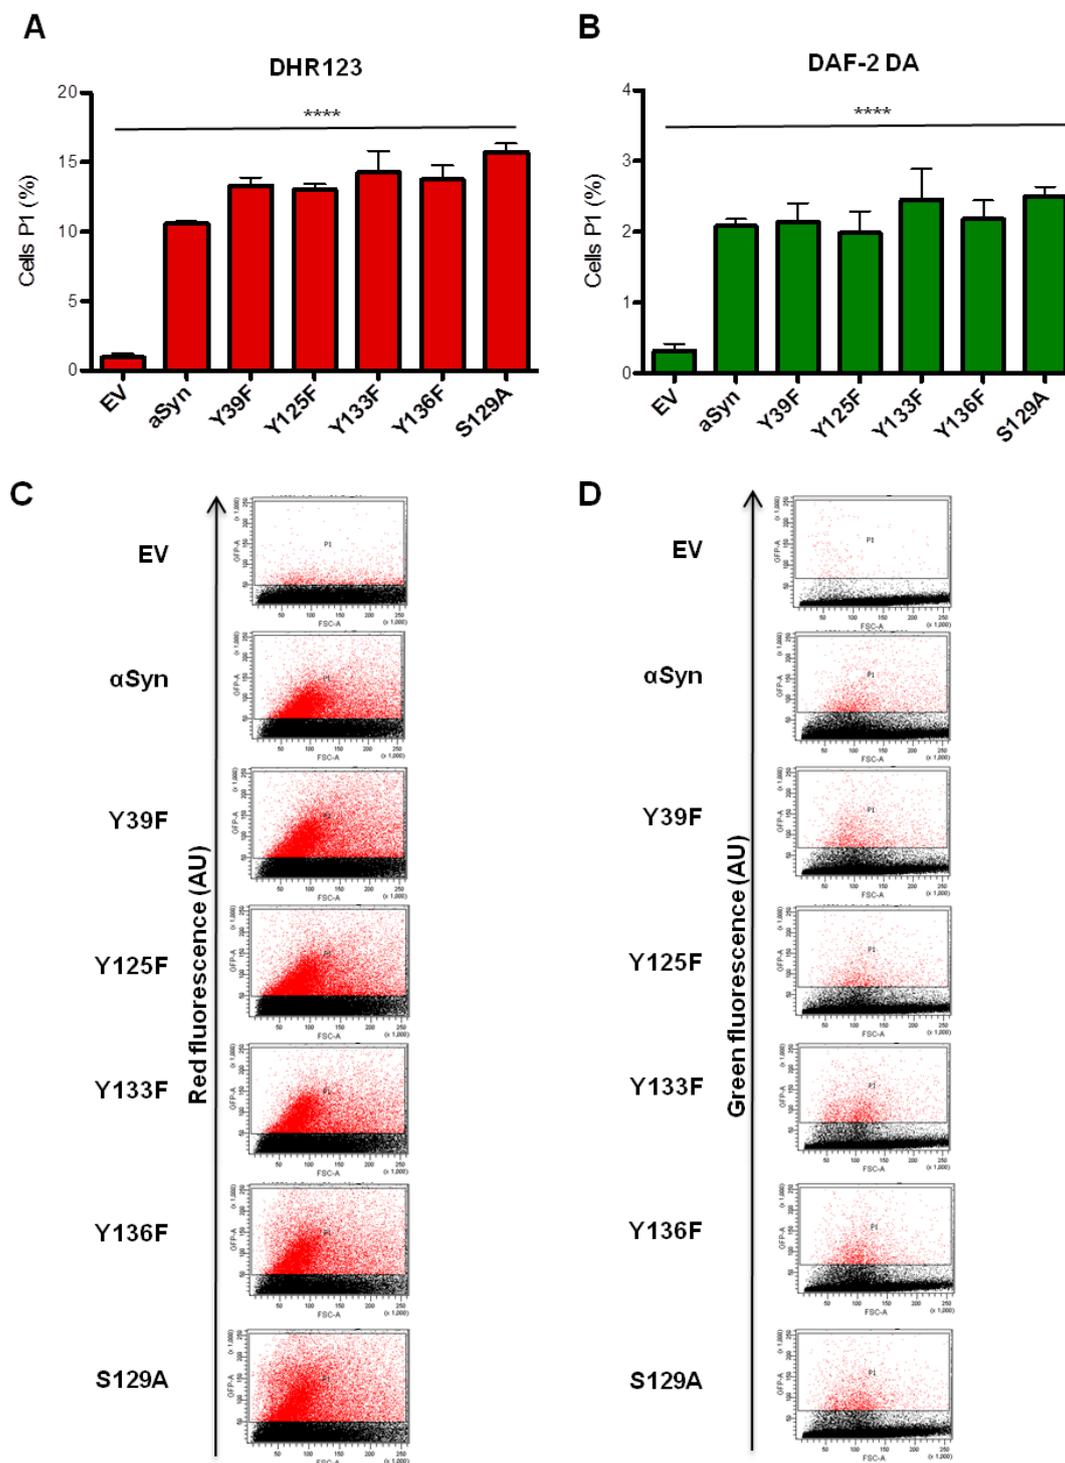

Figure 29. Tyrosine 133 mutation does not alter the accumulation of reactive oxygen and nitrogen species.

Quantification of cells expressing different α Syn variants displaying ROS (A) and RNS (B) assessed with flow cytometry analysis. α Syn expression was induced for six hours and the cells were stained for 1.5 hours with DHR123 to visualize ROS (A) and for 1.5 hours with DAF-2 DA to visualize RNS (B). Presented is the percentage of the sub-populations of yeast cells with higher fluorescent intensities (P1) than the background. Significance of differences was calculated with one-way ANOVA (****, $p < 0.0001$; $n=4$). (C, D) Forward scatter (FSC) of cells expressing different α Syn variants displaying DHR123 (C) and DAF-2 DA (D) fluorescence assessed with flow cytometry analysis. Shown is one representative result from at least four independent experiments.

Expression of all mutants revealed a significant increase in the levels of ROS and RNS in comparison with the control, however, no significant differences were observed between the single mutants revealing that the enhanced toxicity of Y133F and S129A mutant is not due to higher accumulation of ROS or RNS. These results indicate that Y133 is required for the protective effect of α Syn S129 phosphorylation *in vivo*. Expression of Y133F was more toxic than expression of the S129A phosphorylation deficient α Syn variant, suggesting additional protective contribution of Y133 modifications against α Syn cytotoxicity. The data support a complex cross-talk between nitration and phosphorylation of the C-terminal tyrosine residues and S129 phosphorylation of α Syn and A30P.

3.15 C-terminal α -synuclein modifications promote autophagy clearance of α -synuclein aggregates

GAL1-promoter shut-off experiments were performed to study the role of α Syn PTMs on autophagy/vacuole and proteasome-mediated aggregate clearance of α Syn. The impact of blocking these systems by drug treatments was examined. Expression of α Syn was induced for four hours in galactose-containing medium and the cells were then shifted to glucose-containing medium in order to repress the promoter. Cells were imaged four hours after promoter shut-off and the percentage of cells with inclusions was determined. Shut-off studies were performed with wild-type α Syn and the mutants 4(Y/F), S129A and Y133F. PMSF was used as an inhibitor of autophagy/vacuole to study the contribution of this pathway for aggregate clearance (Petroi et al., 2012). PMSF impairs the activity of many vacuolar serine proteases without interfering with proteasome function (Dubiel et al., 1992; Jones, 2002). Inhibition of autophagy resulted in inefficient aggregate clearance of α Syn, as shown previously (Petroi et al., 2012; Shahpasandzadeh et al., 2014). Mutations of the codons for the four tyrosines as well as the S129 and Y133 single exchanges resulted in similar aggregate clearance by inhibition of the autophagic proteases as in the control cells without drug (ethanol) (Figure 30A). This suggests that autophagy is less involved in aggregate clearance of these mutants and shows that autophagy-mediated aggregate clearance requires modifications of the tyrosines and S129.

The contribution of the proteasome on 4(Y/F), S129A and Y133F α Syn aggregate clearance was analyzed by applying the proteasome inhibitor MG132 (Lee and Goldberg, 1998). In contrast to autophagy impairment, cells expressing 4(Y/F) and S129A α Syn cleared inclusions equally as the wild-type α Syn (Figure 30B) when the proteasome system was impaired.

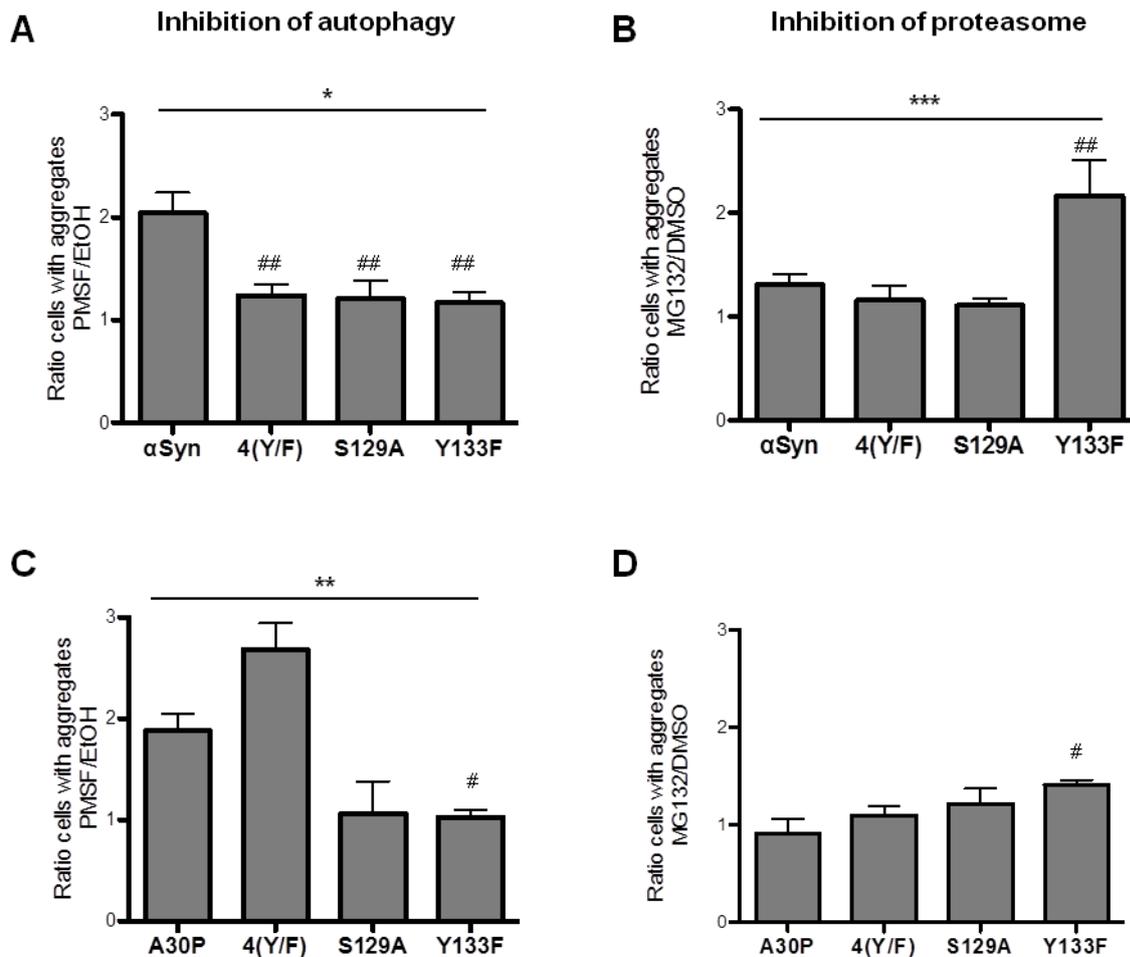

Figure 30. αSyn aggregate clearance after promoter shut-off.

(A, C) Quantification of cells displaying aggregates of αSyn (A) and A30P (C) upon inhibition of autophagy by PMSF. Cells expressing αSyn (A) or A30P (C) and its 4(Y/F), S129A and Y133F variants were incubated in 2 % galactose-containing media for four hours and shifted to 2 % glucose-containing media supplemented with 1 mM PMSF dissolved in EtOH and only EtOH as a control. Cells with aggregates were counted after four hours *GAL1*-promoter shut-off and presented as ratio to the control (EtOH). Significance of differences was calculated with one-way ANOVA (*, $p < 0.05$; **, $p < 0.01$) or Dunnett's multiple comparison test (#, $p < 0.05$; ##, $p < 0.01$ versus αSyn; $n=4$). (B, D) Quantification of cells displaying aggregates of αSyn (B) and A30P (D) upon inhibition of the proteasome by MG132. Cells expressing αSyn (B) or A30P (D) and the indicated 4(Y/F), S129A and Y133F variants were incubated in 2 % galactose-containing media for four hours and shifted to glucose medium, supplemented with 75 μM MG132 dissolved in DMSO or only DMSO as a control. Cells with aggregates were counted after four hours *GAL1*-promoter shut-off and presented as ratio to the control (DMSO). Significance of differences was calculated with one-way ANOVA (***, $p < 0.001$) or Dunnett's multiple comparison test (#, $p < 0.05$; ##, $p < 0.01$ versus αSyn; $n=4$).

These results corroborate previous findings showing a minor contribution of proteasome-dependent clearance of αSyn aggregates (Petroi et al., 2012). However, cells expressing the Y133F mutant were unable to clear inclusions in a same manner as the wild-type, 4(Y/F) and S129A αSyn. This indicates that αSyn, which is not modified at Y133, is degraded by the proteasomal pathway. The results suggest that PTMs of tyrosine residues and S129 promote

the autophagy mediated aggregate clearance, whereas non-modified Y133 residue is a key determinant for the targeting of the protein to the proteasome. Inhibition of autophagy of A30P expressing cells revealed diminished clearance of aggregates of A30P as well as the A30P/4(Y/F) mutant indicating that degradation of the A30P/4(Y/F) aggregates depends on the autophagy/vacuole system similarly to wild-type α Syn and A30P (Figure 30C). A30P/S129A and A30P/Y133F mutants were able to degrade aggregates efficiently upon autophagy inhibition, similar to S129A and Y133F. Proteasome impairment resulted in inefficient clearance of the A30P/Y133F mutant (Figure 30D). However, this impact was not as strong as in the α Syn Y133F mutant, confirming that the wild-type α Syn is strongly dependent on Y133 modification as a determinant for aggregate clearance.

4 Discussion

In industrialized countries, better nutrition, growing health awareness and less heavy physical work result in improved quality of life. In addition, medical advances such as novel drugs, novel ways of diagnostic, preventive medicine and technological progress lead to increased life expectancy. However, extended life span correlates with an elevated risk for neurodegenerative disorders resulting in physical or mental impairments and a long period of suffering. Up to now, no curative therapies are available because most of the pathogenic causes are unknown. Therefore, study of human neurodegenerative diseases such as Parkinson's disease (PD) is becoming increasingly important.

The small neuronal protein α Syn is thought to be one of the most crucial factors in the pathogenesis of PD. α Syn is an intrinsically unfolded brain protein of 140 amino acids which is present in high concentration at presynaptic terminals as soluble or membrane-associated fractions. It is the major component of the fibrillary intracellular protein inclusions termed Lewy bodies that are associated with selective loss of dopamine-producing neurons in the *substantia nigra* in PD. Among other factors, posttranslational modifications were observed to alter the aggregation propensities of α Syn.

In this study, *Saccharomyces cerevisiae* was used as reference cell to study the function of posttranslational modifications such as nitration or phosphorylation on the toxicity of α Syn. Apart from understanding the behavior of α Syn in PD, this model system is also used for identification of new therapeutic strategies. When expressed in yeast, α Syn associates with the plasma membrane in a highly selective manner, before forming cytoplasmic inclusions through a concentration-dependent process (Outeiro and Lindquist, 2003; Petroi et al., 2012). α Syn accumulations, further referred to as aggregates, cause vesicle traffic defects, proteasome dysfunction, mitochondrial activity impairment and damage to cellular membranes. These cellular disorders in yeast are reminiscent to α Syn-related effects of PD (Chen et al., 2005; Outeiro and Lindquist, 2003).

Chemical reactive molecules such as reactive oxygen species (ROS) and reactive nitrogen species (RNS) are formed that damage the cell by causing oxidative and nitrative stress. Both cellular stresses are implicated in the pathogenesis of PD. Previous studies indicated that oxidative injury of α Syn, specifically nitration of tyrosine residues, contributes directly to the pathology of PD. However, the toxic mechanism involved in nitrative stress-induced damage or even the precise nitration sites leading to toxicity are not sufficiently examined.

4.1 Role of tyrosine nitration on α -synuclein cytotoxicity

In α Syn four tyrosines sites were discovered that serve as targets of nitration (Sevcsik et al., 2011). One is located in the membrane binding N-terminus at residue 39, and three near the C-terminus at residues 125, 133 and 136. All four tyrosines can be nitrated in the presence of oxidizing agents such as peroxynitrite (PON). These modifications lead to the accumulation of stable oligomers originating from covalent crosslinking through the formation of di-tyrosine species (Souza et al., 2000a).

Several examples in the literature indicate a contribution of α Syn nitration in aggregation and α Syn-related neuronal vulnerability and suggest an implication of nitrative stress in the pathogenic mechanism of PD (Giasson et al., 2000; Jenner and Olanow, 1996; McCormack et al., 2012; Olanow, 1990; Souza et al., 2000a; Yao et al., 2004). Nitrated α Syn was detected in LBs from *post mortem* brain tissue using 3-nitrotyrosine antibodies (Giasson et al., 2000). It has been observed that nitrated α Syn can be toxic to dopaminergic neurons *in vitro* as well as *in vivo* (Yu et al., 2010). Neuroinflammation followed by nitration of α Syn causes accumulation of α Syn aggregates and neurodegeneration in mice (Gao et al., 2008). Nitrated α Syn was observed to induce adaptive immune responses that exacerbate PD pathology in the MPTP mouse model (Benner et al., 2008). Increased nitrated α Syn levels were detected in peripheral blood mononuclear cells of idiopathic PD patients compared to healthy individuals (Prigione et al., 2010). There might be a direct link between nitrative damage and the onset and progression of neurodegenerative synucleinopathies, but the precise molecular mechanism that leads to the formation of pathological inclusions is still elusive. Concluding these evidences, oxidative and nitrative stress plays an important role in α Syn induced cytotoxicity and consequently in the pathogenesis of PD.

Phosphorylation at serine residue S129 represents the major protective phosphorylation site of α Syn, which is conserved from man to the baker's yeast as a eukaryotic Morbus Parkinson cell model. The effect of nitrative modifications of α Syn and their contribution towards α Syn-induced cytotoxicity was investigated. A complex interplay was discovered between modifications of the C-terminal tyrosine residues and S129 phosphorylation (Figure 31). These tyrosine residues of α Syn can be phosphorylated or nitrated with drastic consequences for cellular growth. There is a strong preference of the C-terminus of α Syn for nitration or di-tyrosine formation. Nitration interferes with protective phosphorylation of S129, whereas di-tyrosine formation protects yeast cells.

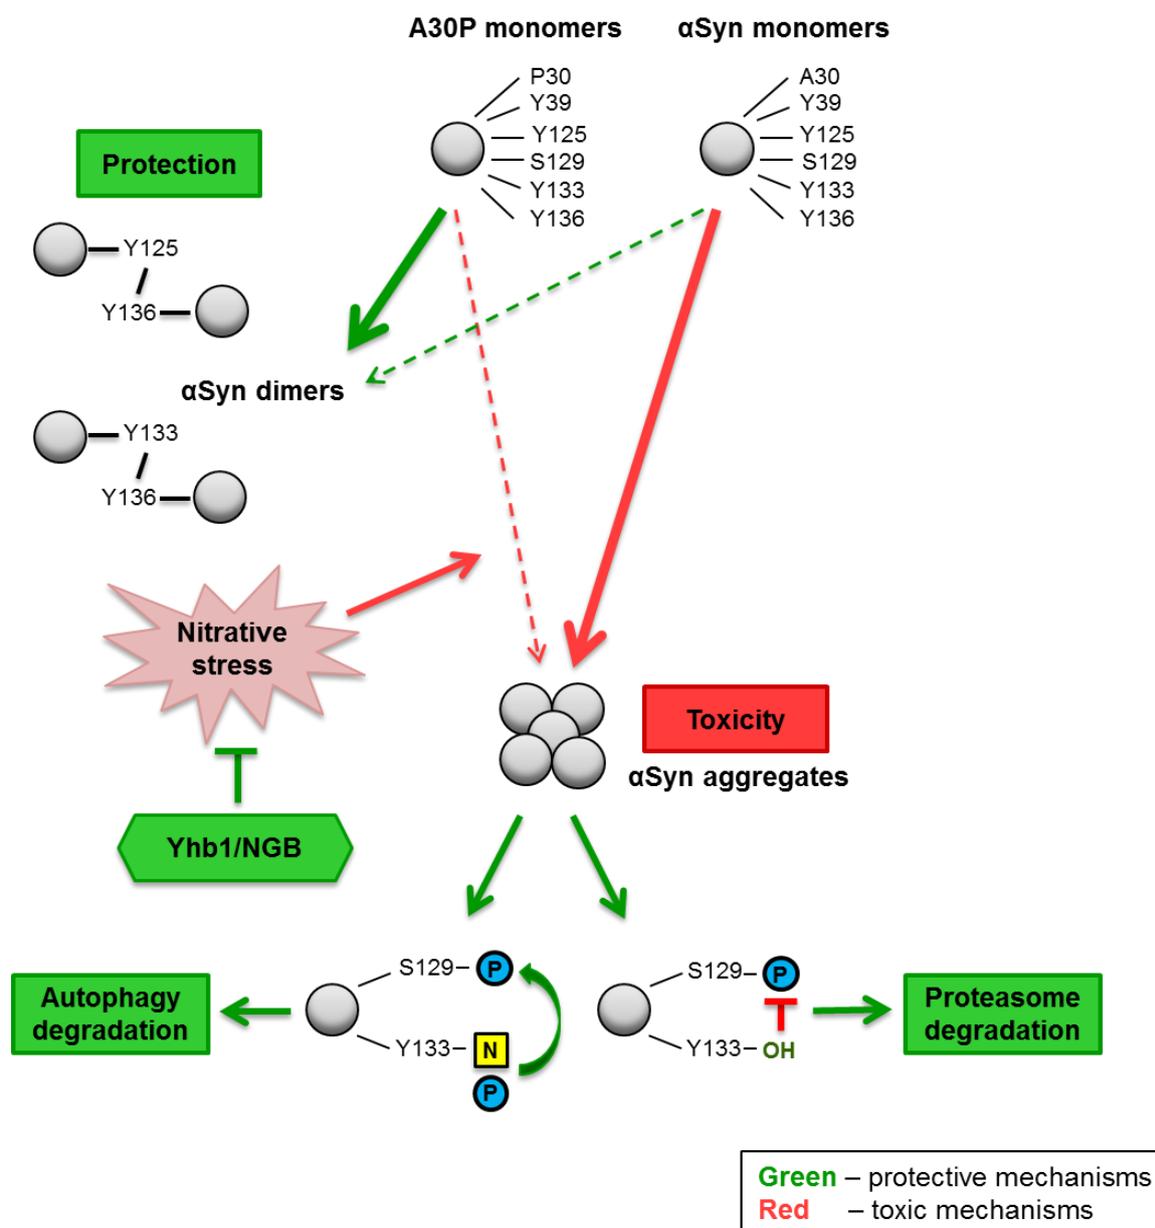

Figure 31. αSyn posttranslational modifications and nitrative stress in yeast.

Enhanced intracellular nitrative stress increases the protein nitration level and influences yeast growth and aggregation. The nitration of tyrosine residues acts as trigger for αSyn and A30P toxicity. Wild-type αSyn, which is highly nitrated, inhibits growth and shows a high aggregation rate. A30P is weakly nitrated and therefore, does not inhibit yeast growth and has a low aggregation propensity. Yhb1 and its human homolog NGB protect the cells against accumulation of nitrative species and diminish the aggregate formation. Increased aggregation contributes to ROS/RNS accumulation and mitochondrial fragmentation. Di-tyrosine crosslinked dimers are formed in reverse correlation to cytotoxicity and do not depend on Yhb1. A30P forms twice as many dimers as the toxic αSyn variant, suggesting that the di-tyrosine crosslinked dimers are not toxic species and are presumably part of a cellular detoxification pathway, sequestering the protein off-pathway of αSyn nucleation. The C-terminal tyrosine modifications have dual effect on the toxicity of the protein. Y133, which is nitrated and phosphorylated, is required for the protective phosphorylation at S129 and for the autophagy degradation of αSyn aggregates. Non-modified Y133 promotes the proteasomal degradation of αSyn aggregates. N: nitration; P: phosphorylation.

Expression of α Syn in yeast induces a number of cellular defects and efficiently mimics the α Syn-related effects of PD (Chen et al., 2005; Outeiro and Lindquist, 2003; Zabrocki et al., 2005). Among others, chemically reactive molecules such as ROS and RNS are formed that damage the cell by causing oxidative and nitrative stress which in turn contributes to cell death (Flower et al., 2005). Nitration reduces the binding affinity of α Syn to lipid vesicles and therefore disrupts α Syn-membrane interaction (Sevcsik et al., 2011). Hodora and colleagues concluded that nitration hinders α Syn to bind membrane lipids leading to increased unbound α Syn, which results in enhance of intracellular aggregates (Hodara et al., 2004).

Oxidative injury of α Syn, specifically nitration of tyrosine residues, has been widely discussed to contribute directly to the pathology of PD. Nitrative stress was proposed to induce α Syn aggregation as well as α Syn-induced pathology (Benner et al., 2008; Giasson et al., 2000; Liu et al., 2011; Paxinou et al., 2001; Ulrih et al., 2008; Yu et al., 2010). However, also opposing influence of nitrated α Syn has been shown (Uversky et al., 2005; Yamin et al., 2003b). Thus, the effect of nitrative α Syn modifications and their influence on the toxicity and aggregation of α Syn is still controversial. In this study, it was shown that PTMs on α Syn tyrosine residues have a dual impact on α Syn mediated growth inhibition of yeast cells (Figure 31). Previous studies suggested that nitration of α Syn might be responsible for the formation of the proteinaceous inclusions observed in PD brains and for the neuronal loss in the *substantia nigra* (Giasson et al., 2000; Yu et al., 2010). Here, it was shown that nitration increases the growth defect induced by α Syn in yeast cells. Tyrosine nitration increases aggregation, mitochondrial fragmentation and growth inhibition. A correlation between the growth impairment, mediated by α Syn and A30P and their nitration level was demonstrated. α Syn, which inhibits yeast growth and has a high aggregation level, is strongly nitrated. In contrast, A30P, which is not toxic to yeast and aggregates to a lesser extent, is weakly nitrated. Increased nitration of A30P as a consequence of *YHB1* deletion leads to A30P-induced toxicity in yeast cells, which indicates that nitration is able to convert a non-toxic to toxic specie.

4.2 Role of Yhb1 and neuroglobin on α -synuclein cytotoxicity

Expression of A30P in yeast has different toxicity properties from wild-type α Syn (Outeiro and Lindquist, 2003; Petroi et al., 2012). A30P is located in the cytoplasm, whereas α Syn is delivered to the plasma membrane. Overexpression from a high-copy number plasmid results in formation of A30P fluorescent foci, however, the aggregation is transient and yeast cell growth is not affected. In *Saccharomyces cerevisiae*, the gene *YHB1* (yeast flavohemoglobin) was identified to be implicated in oxidative and nitrative stress response (Cassanova et al., 2005). This gene encodes a nitric oxide oxidoreductase that belongs to

the globin family. Yhb1 protects against nitration of cellular targets by NO detoxification (Liu et al., 2000) and was also shown to be involved in the control of ferric reductase activity and modulation of NO signaling pathways (Lewinska and Bartosz, 2006; Martinez-Ruiz and Lamas, 2009; Schildknecht and Ullrich, 2009). Using the $\Delta yhb1$ mutant lacking the flavohemoglobin Yhb1, this study could demonstrate that nitration plays also a role for A30P and confirmed that nitration increases aggregation and growth inhibition (Figure 31). Yhb1 decreases the nitration level of the A30P variant of α Syn by reducing the accumulation of reactive nitrogen species, with the result that yeast cells can tolerate increased levels of this α Syn variant without significant growth inhibition. Deletion of the *YHB1* yeast gene results in deficient cellular detoxification machinery towards NO and makes A30P as toxic as wild-type α Syn. This shows that the A30P nitration level is a crucial factor for gaining toxicity. Consequently, elimination of its putative NO-detoxifier Yhb1 results in stronger formation of toxic α Syn aggregates. Yhb1 reduced the level of nitrate stress in A30P expressing cells. Moreover, Yhb1 protected the A30P-expressing cells from mitochondrial fragmentation. α Syn-induced fragmentation of mitochondrial structure caused by direct interaction of α Syn with the mitochondrial membranes was already demonstrated (Nakamura et al., 2011). It was proposed that ROS accumulation induced by α Syn expression is an indirect effect due to mitochondrial dysfunction (Su et al., 2010). A connection between increased nitrate stress and mitochondrial fragmentation was found. This suggests a mechanistic model based on the specific ability of α Syn and A30P to form aggregates and damage mitochondria induced by nitrate stress.

A protein BLAST search for human homologues of yeast *YHB1* identified similarity of Yhb1 to human neuroglobin (Figure 32).

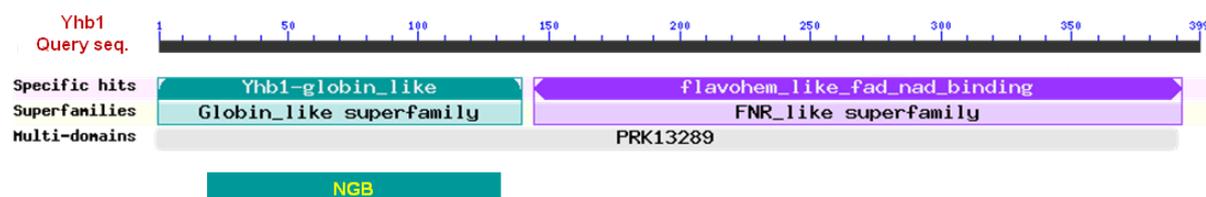

Figure 32. Putative conserved domain of Yhb1 and NGB.

Yhb1 amino acid sequence was used as query sequence (seq.) and analyzed by the blastp tool using UniProtKB/Swiss-Prot as database. The human neuroglobin (NGB) was identified as a hit with a score of 60.1 bits and an E value of $5e-11$, 28% identity and 49 % similarities in the globin domain of Yhb1.

Analysis of neuroglobin (NGB), the human homologue of *YHB1*, in human cell lines (H4 cells) confirmed that this protein modulates α Syn aggregation. Expression of neuroglobin in mammalian cells reduced the number inclusions per cell. The yeast nitric oxidoreductase

Yhb1 as well as its related human protein neuroglobin play protective roles against α Syn aggregation. Similar as Yhb1, NGB is a member of the globin family. In general, neuroglobins play a role as regulators of ROS, reservoir for oxygen, facilitator for oxygen transport and also acts as scavenger of nitric oxide. In human, neuroglobin is expressed primarily in neurons and protects against hypoxic neuronal death and ischemic brain injury (Wang et al., 2008). Furthermore, expression of neuroglobin protects against beta-amyloid-induced neurotoxicity in transgenic mice *in vivo* (Khan et al., 2007). Increased neuroglobin levels were observed in brain tissue of patients with early and moderately advanced Alzheimer's disease (AD) (Sun et al., 2013). Recent reports revealed that overexpression of neuroglobin prevents tau hyperphosphorylation at multiple AD-related sites (Chen et al., 2012). These data support our findings and imply NGB as a new therapeutic target in PD and other neurodegenerative diseases.

4.3 Dimerization of α -synuclein by covalent di-tyrosine crosslinking

Beside nitration, the reaction between tyrosine and RNS can result in the formation of di-tyrosine bonds, leading to the formation of stable α Syn oligomers, including dimers and higher oligomeric structures. At low peroxynitrite level, di-tyrosine formation outcompetes the reaction of tyrosine nitration (Pfeiffer et al., 2000; Schildknecht et al., 2013) indicating a forced reaction to tyrosine nitration under nitrative stress. This study observed formation of dimers and oligomers *in vivo* without exposure of yeast cells to nitrating agents; therefore, they represent the consequence of endogenous nitrative stress. Previous studies already demonstrated nitration-induced oligomerization of α Syn (Norris et al., 2003; Souza et al., 2000a). There, treatment with nitrating agent resulted in the formation of α Syn dimers and oligomers crosslinked by di-tyrosine bonds. Using MS, this study characterized the tyrosine residues involved in covalent dimer formation and nitration and identified to what extent the different tyrosine residues are involved in the di-tyrosine formation and what are the precise positions of the respective tyrosines. This data is the first characterization of α Syn dimer species, formed *in vivo* and without additional exposure to nitrative agents.

The LC-MS results reveal strong preference of the C-terminal tyrosine residues for dimer formation with predominant forms including Y136 interacting either with Y125 (Y125-Y136) or with Y133 (Y133-136). Y39 was hardly involved in dimer formation under physiological conditions in yeast or *in vitro* after PON treatment. Recently, *in vitro* studies on α Syn oligomerization and di-tyrosine formation upon treatment with tetranitromethane (TMN) demonstrate a predominant formation of di-tyrosine dimers when Y39 is not available for nitration (Y39F) and suggest that the N-terminal region of α Syn plays a role in TMN-induced di-tyrosine formation of higher order oligomers (Burai et al., 2015). Previous studies

described an increase of nitration at Y39 of α Syn in an oxidative cellular model of PD (Danielson et al., 2009), whereas data of this study reveal resistance of Y39 to 3-NT modification in comparison to the C-terminal tyrosine residues which are nitrated *in vitro* as well as *in vivo*. These results are corroborated by previous findings, where treatment of purified α Syn with PON did not result in nitration of Y39; however, all C-terminal residues were nitrated (Schildknecht et al., 2011).

Higher nitration levels of α Syn compared to A30P were also detected by LC-MS data confirming the results from immunoblot analyses. There, only one tyrosine residue is nitrated in A30P, whereas three α Syn residues are nitrated. These data reveal that α Syn dimers originating from di-tyrosine crosslinking are non-toxic species in contrast to nitrated α Syn (Figure 31). Covalent bonding of the di-tyrosines stabilizes the dimeric structures and consequently removes α Syn molecules from aggregation to toxic aggregates. α Syn protein lacking all four tyrosine residues forms less aggregates, however, the aggregate formation is not prevented. This indicates that tyrosine residues are not crucial for *in vivo* assembly of the protein to aggregates and suggests an independent pathogenic mechanism of α Syn aggregation. Similarly, nitration of α Syn was shown to promote formation of stable off-pathway oligomeric species that inhibit α Syn fibrillation (Uversky et al., 2005; Yamin et al., 2003b). Thus, the formation of stable oligomers under oxidative stress conditions redirects the monomers to oligomers that do not contribute to fibril formation.

4.4 Interplay between tyrosine nitration and serine 129 phosphorylation of α -synuclein in yeast

This study revealed that C-terminal tyrosine 133 is required for the protective phosphorylation of α Syn at S129. α Syn C-terminal tyrosines Y125, Y133 and Y136 are in close proximity to S129, which raises the question whether there is an interplay between different PTMs at these residues. S129-phosphorylated α Syn is abundantly found in LBs (Anderson et al., 2006; Fujiwara et al., 2002). This phosphorylation site is conserved in yeast and can be used by several endogenous kinases (Wang et al., 2012). The effects of S129 phosphorylation are complex and the role of this modification on α Syn-induced toxicity and aggregation is still controversial (Tenreiro et al., 2014a). Phosphorylation of S129 was shown to play a role in the regulation of α Syn localization, aggregation and toxicity. Several mammalian models of PD have demonstrated a protective role of S129 phosphorylation on neuronal dysfunction (Gorbatyuk et al., 2008; Kuwahara et al., 2012). Contrary, neurotoxicity tests in rats revealed no protective role of S129 phosphorylation on α Syn toxicity (McFarland et al., 2009). Even a pathogenic effect of α Syn S129 phosphorylation was observed (Chen and Feany, 2005).

In yeast, S129 phosphorylation has a protective role against growth impairment and aggregate formation (Popova et al., 2015; Shahpasandzadeh et al., 2014; Tenreiro et al., 2014b). Moreover, increased phosphorylation of α Syn mediated by PLK2 leads to aggregate clearance by the autophagy-vacuole system and suppresses cytotoxicity (Oueslati et al., 2013). Further yeast studies revealed that autophagy-dependent clearance of α Syn aggregates is stimulated by sumoylation of α Syn (Shahpasandzadeh et al., 2014). Inhibition of sumoylation results in increased toxicity, impaired autophagic clearance as well as in redirection of the α Syn aggregates to the proteasome. Expression of the human kinase GRK5 in yeast results in increased phosphorylation and ubiquitination of non-sumoylated α Syn, which promotes the autophagy- and proteasome-mediated clearance of α Syn aggregates. Further studies in yeast showed downregulation of α Syn aggregate clearance and increased toxicity by inhibition of S129 phosphorylation using the S129A mutant of α Syn (Tenreiro et al., 2014b).

Phosphorylation of the tyrosine residues of α Syn is less explored and the effects of this modification are still unclear, varying from protective to no impact on neurotoxicity and oligomerization (Chen et al., 2009; Ellis et al., 2001; Kosten et al., 2014; Nakamura et al., 2002; Nakamura et al., 2001; Negro et al., 2002; Papay et al., 2002). This study shows for the first time that tyrosine 133 is strictly required for phosphorylation at S129 in yeast. Tyrosine 133 can be nitrated or phosphorylated, as demonstrated by immunoblot analysis and MS analysis. These two PTMs might have opposing roles on the cellular toxicity of the protein. Phosphorylation might prevent tyrosine residues from nitration and *vice versa*. In this study, tyrosine to phenylalanine exchanges that abolishes both phosphorylation and nitration were used. There are no protective mechanisms exist in the cell, which do not depend on aggregate formation but support cellular survival. This suggests an even more complicated interplay between different α Syn modifications.

Recently, the role of site-specific nitration of α Syn was investigated using site-specifically nitrated synthetic proteins at Y39 and Y125 (Burai et al., 2015). The authors assessed the influence of nitration at Y125 and Y39 on PLK3-mediated *in vitro* phosphorylation at S129 and showed that tyrosine nitration does not prevent recognition of the protein by PLK3 and the subsequent phosphorylation at S129. These results strengthen the link between the C-terminal tyrosine and serine modifications, revealing a complex cross-talk between PTMs with different contributions to the cytotoxicity of α Syn (Figure 31).

Previously, it was shown that autophagy is the major pathway for aggregate clearance in yeast (Petroi et al., 2012). The phosphorylation state of α Syn influences the clearance mechanism of the protein. Blocking of S129 phosphorylation in yeast leads to impaired aggregate clearance by autophagy (Tenreiro et al., 2014b). Increased levels of S129 phosphorylation can suppress the defect of impaired α Syn sumoylation by rescuing the

autophagic aggregate clearance and promoting the proteasomal clearance of α Syn (Shahpasandzadeh et al., 2014).

In this study, it was shown that posttranslational modifications of the four tyrosine residues, similar to S129 phosphorylation, promote the autophagic clearance of α Syn aggregates. Inhibition of autophagy rendered yeast cells unable to clear α Syn aggregates, however had no effect on the clearance of S129A, 4(Y/F) and Y133F mutants. Interestingly, Y133F mutant could not be degraded upon inhibition of the proteasome. Therefore, Y133 represents a key determinant for the degradation fate of α Syn. Phospho- and nitro-modifications at Y133 promote the autophagic clearance of the aggregates, whereas the non-modified Y133 protein is directed to the proteasome. Natural amino acids that mimic the phosphorylation or nitration state of the tyrosine residue, thus restricting the investigation of the contribution of a single posttranslational modification at one and the same tyrosine residue *in vivo*. These results reveal Y133 as major tyrosine phosphorylation site in yeast, and only insignificant phosphorylation at Y125 was observed. This study reveals a correlation between tyrosine nitration and the cellular S129 phosphorylation level (Figure 31).

The wild-type α Syn has significantly higher nitration levels as well as increased protein populations with S129 phosphorylation but similar levels of Y133 phosphorylation when compared to its A30P variant. These results suggest that rather nitration than phosphorylation at Y133 promotes S129 phosphorylation in yeast. Alternatively, nitration at Y133 might change the protein conformation and make S129 more accessible for protein kinases. The protective effect of Y133 was not accompanied with changes in the potential to form aggregates. The discrepancy between the clear protective effect of Y133 on yeast growth without significant effect on inclusion formation suggests that additional yet elusive protective mechanisms exist in the cell, which do not depend on aggregate formation but support cellular survival. This suggests an even more complicated interplay between different α Syn modifications.

4.5 C-terminal tyrosine residue modifications modulate α -synuclein toxicity in yeast as unicellular model for Parkinson's disease

The main goal in today's PD research is the discovery of the pathogenic mechanism causing PD which may help to find a cure for the disease. α Syn aggregation and formation of α Syn oligomeric species have been proposed as one of the pathophysiological mechanisms that participates in neurodegeneration. Therefore, studies uncovering the conditions leading to α Syn aggregation and toxicity are urgently required. In this study, nitration and phosphorylation of α Syn were analyzed. It was demonstrated that tyrosine nitration is not required for aggregate formation but is necessary for covalently crosslinking of dimers and

oligomers. The data reveal that nitration rather than dimer formation correlates with increased toxicity leading to mitochondrial fragmentation. Moreover, this study discloses a complex interplay between nitration and phosphorylation of α Syn C-terminal residues, deeply interconnected with nitrative stress, which determines the aggregate clearance by autophagy or ubiquitin-dependent 26S proteasome pathways. The proposed model derived from yeast as unicellular eukaryotic cell provides interesting hints and insights for the study of α Syn posttranslational modifications as it happens in the human brain and its connection to oligomer or aggregate formation and clearance (Figure 31). Furthermore, this study suggests the human NGB as a modulator of α Syn aggregation, which can be used to gain a deeper understanding into the cellular processes that trigger α Syn aggregation in human cells.

Abbreviations

%	percent
2 μ (2 μ m)	2 micrometer high-copy yeast expression vector
μ g	microgram
μ L	microliter
μ m	micrometer
μ M	micromolar
3-NT	3-nitrotyrosine
Å	Ångström
AA	amino acids
Ade (A)	adenine
Ala (A)	alanine
Amp ^R	ampicillin resistance
ANOVA	analysis of variance
approx.	approximately
APS	ammonium persulfate
Arg (R)	arginine
AS	ammonium sulfate
Asn (N)	asparagine
Asp (D)	aspartic acid
α Syn	α -synuclein
ATG	autophagy-related gene
ATP	adenosine triphosphate
ATP13A2	ATPase type 13A2
BLAST	basic local alignment search tool
bp	base pair(s)
BSA	bovine serum albumin
°C	degree Celsius
cDNA	complementary DNA
<i>CEN/ARS</i>	centromere/autonomously replicating sequence
CKs	casein kinases
cm	centimeter
CMV	cytomegalovirus
C-terminus	carboxy terminus
ctrl	control
<i>CYC1</i>	cytochrome C-1

Cys (C)	cysteine
Da	Dalton
DAF-2 DA	4,5-diaminofluorescein diacetate
DETA-NONOate	diethylenetriamine NONOate
dH ₂ O	distilled water
DHR123	dihydrorhodamine 123
DJ-1	human protein deglycase
DMSO	dimethyl sulfoxide
DNA	deoxyribonucleic acid
dNTPs	deoxyribonucleoside triphosphates
DTT	dithiothreitol
ECL	enhanced chemiluminescence
<i>E. coli</i>	<i>Escherichia coli</i>
EDTA	ethylenediaminetetraacetic acid
e.g.	<i>exempli gratia</i>
EtOH	ethanol
EUROSCARF	European <i>Saccharomyces cerevisiae</i> archive for functional analysis
EV	empty vector
FCCP	carbonyl cyanide-4-(trifluoromethoxy)phenylhydrazone
FSC	forward scatter
g	gram
G418	geneticin
GABA	γ-aminobutyric acid
Gal	galactose
GAPDH	glyceraldehyde 3-phosphate dehydrogenase
GFP	green fluorescent protein
Glc	glucose
Gln (Q)	glutamine
Glu (E)	glutamic acid
Gly (G)	glycine
GRKs	G protein-coupled receptor kinases
h	hour(s)
His (H)	histidine
H+L	heavy + light chains
HPLC	high-performance liquid chromatography
HRP	horseradish peroxidase
IgG	immunoglobulin G

Ile (I)	isoleucine
kanMX4	kanamycin resistance
kb	kilobase pair(s)
kDa	kilodalton
kV	kilovolt
L	liter
LB	lysogeny broth
LBs	Lewy bodies
LC-MS	liquid chromatography–mass spectrometry
LDH	lactate dehydrogenase
Leu (L)	leucine
LiOAc	lithium acetate
log	decadic logarithm
LRRK2s	leucine-rich repeat kinases
Lys (K)	lysine
M	molar
MATa	mating type a
Met (M)	methionine
mg	milligram
MG132	N-benzyloxycarbonyl-L-leucyl-L-leucyl-L-leucinal
min	minute(s)
mL	milliliter
mm	millimeter
mM	millimolar
MM	minimal medium
MPTP	1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine
mRNA	messenger ribonucleic acid
MS	mass spectrometry
MT	mitochondria
MV	minimal medium plus vitamins
n	number
NAC	non-amyloid- β component
ng	nanogram
NGB	neuroglobin
nm	nanometer
nM	nanomolar
n.s.	not significant

NTA	nitrilotriacetic acid
N-terminus	amino terminus
OCR	oxygen consumption rate
OD ₆₀₀	optical density measured at a wavelength of 600 nanometer
ori	origin of replication
PA	polyacrylamide
PABA	para-aminobenzoic acid
PAGE	polyacrylamide gel electrophoresis
PBS	phosphate buffered saline
PCR	polymerase chain reaction
PD	Parkinson´s disease
PEG	polyethylene glycol
<i>Pfu</i>	<i>Pyrococcus furiosus</i>
P1	population of cells
pH	<i>potentia hydrogenii</i>
Phe (F)	phenylalanine
PI	propidium iodide
PIM	protease inhibitor mix
PINK1	PTEN-induced putative kinase 1
PLKs	polo-like kinases
pmol	picomol
PMSF	phenylmethanesulfonyl fluoride
PON	peroxynitrite
ppm	parts per million
Pro (P)	proline
PTM	posttranslational modification
PVDF	polyvinylidene fluoride
Raff	raffinose
RFP	red fluorescent protein
RNA	ribonucleic acid
RNS	reactive nitrogen species
ROS	reactive oxygen species
rpm	rounds per minute
RT	room temperature
SC	synthetic complete
<i>S. cerevisiae</i>	<i>Saccharomyces cerevisiae</i>
SDS	sodium dodecyl sulfate

sec	second(s)
SEM	standard error of the mean
Ser (S)	serine
SN	substantia nigra
SNARE	soluble N-ethylmaleimide-sensitive-factor attachment receptor
SNCA	synuclein alpha
SS	single stranded salmon sperm DNA
SUMO	small ubiquitin-like modifier
TAE	Tris-acetate-EDTA
<i>Taq</i>	<i>Thermus aquaticus</i>
TBST	Tris-buffered saline with Tween
TCA	trichloroacetic acid
TE	Tris-HCl, EDTA
TEMED	tetramethylethylenediamine
Thr (T)	threonine
Tm	melting temperature
TMN	tetranitromethane
Tris	tris-(hydroxymethyl)-aminomethane
tRNA	transfer ribonucleic acid
Trp (W)	tryptophan
Tween	polyoxyethylen(20)-sorbitan-monolaurat
Tyr (Y)	tyrosine
U	enzyme unit(s)
UPS	ubiquitin-proteasome system
Ura (U)	uracil
UTR	untranslated region
UV	ultraviolet
UV/VIS	ultraviolet and visible spectroscopy
V	volt
Val (V)	valine
v/v	volume per volume
w/v	weight per volume
WT	wild-type
YEPD	yeast extract peptone dextrose
Yhb1	yeast flavohemoglobin
YNB	yeast nitrogen base

Acknowledgements

Finally, it is my pleasure to express my appreciation to all, who supported me during the time of my PhD work!

I would like to express my sincere gratitude to Prof. Gerhard Braus for providing me the great chance to join his research group and carry out my PhD thesis under his supervision. I am very grateful for his excellent mentoring, advisement and patience.

My very special appreciation goes to Dr. Blagovesta Popova for her great help and encouragements in this project. I am very grateful for her endless patience and kindness.

I would like to thank my thesis committee members Prof. Tiago Outeiro for the cooperation and inspiring discussions and Prof. Blanche Schwappach for her feedback on my projects during the years.

I would like to extend my thanks to Maria Meyer for her endless kindness, excellent technical assistance and great patience in everyday laboratory practice. I would also like to thank Dr. Oliver Valerius and Dr. Kerstin Schmitt for handling all my LC-MS samples and sharing their expertise in *in vitro* nitration. I am very grateful for all their helpful support and instructions in the evaluation of LC-MS data.

I am very grateful to Diana Lázaro for performing the aggregation study in mammalian cells (Figure 23) and fruitful discussions. Moreover, my gratefulness goes to Raquel Pinho for invaluable insights into the Seahorse analysis.

I also want to thank all members of the Department of Molecular Microbiology and Genetics. During my PhD work I enjoyed a very pleasant working atmosphere in a very helpful research team. Thanks for scientific support, useful suggestions and friendly words. In particular, my very special thank goes to all my colleagues from Lab 1.110 for their friendship and support.

Moreover, I would like to thank the bachelor students Lara Schmitz, Maria Kuzyakova, Alexander Hempelmann and the Master student Sina Kristin Stumpf, who contributed to my thesis with their experiments. I would like to thank my colleagues Dr. Blagovesta Popova and Sabine Thieme for proof-reading my thesis.

I deeply appreciate to carry out my PhD study as a member of the doctoral program “Molecular Physiology of the Brain” of the Göttingen Graduate School for Neurosciences, Biophysics, and Molecular Biosciences (GGNB). The CMPB seminars and retreats gave me

the opportunity for scientific learning and exchanging experiences in PD-related research. Especially, I would like to thank Prof. Michael Hörner for coordinating the program. I am grateful to GGNB for supporting me with “Travel Grants” to present my results in various international conferences that gave me impulses and new ideas and inspired me for further work steps.

My dearest appreciation goes to my husband Alexander for his patience, love and moral support. Last, I would like to thank my parents and all my dear friends, who always believed in me and encouraged me also in hard times.

Curriculum Vitae

Personal details

Alexandra Kleinknecht (née Juckert)

Born 22nd of August, 1986

in Jawlenka / Kazakhstan

Education and Academic Qualification

08/2004 - 06/2007 **Gymnasium Johanneum, Lingen (Ems), Germany**

Abitur: university entrance qualification (June 2007)

10/2007 - 09/2010 **Georg-August-Universität Göttingen, Germany**

Bachelor of Science in Molecular Biology

Bachelor thesis at the German Primate Center, Department of Primate Genetics (Prof. Dr. Lutz Walter / Dr. Jens Gruber) – subject: “Zelltypabhängigkeit der regulatorischen Funktion der snoRNA HBI-43 und U60“

10/2010 - 09/2012 **Georg-August-Universität Göttingen, Germany**

Master of Science in Microbiology and Biochemistry

Master thesis at the Institute for Microbiology and Genetics, Department of Molecular Microbiology and Genetics (Prof. Dr. Gerhard Braus / Dr. Blagovesta Popova) – subject: “Modulators of α -synuclein toxicity in yeast model of Parkinson´s disease”

12/2012 - 07/2016 **Georg-August-Universität Göttingen, Germany**

PhD student in the doctoral program “Molecular Physiology of the Brain” (CMPB) of the Göttingen Graduate School for Neurosciences and Molecular Biosciences (GGNB)

PhD thesis at the Institute for Microbiology and Genetics, Department of Molecular Microbiology and Genetics (Prof. Dr. Gerhard Braus) – subject: “C-terminal tyrosine residue modifications modulate α -synuclein toxicity in yeast as unicellular model for Parkinson´s disease”
